The July monarchy. The renovated regime (often called the July monarchy or the bourgeois monarchy) rested on an altered political theory and a broadened social base. Divine right gave way to popular sovereignty; the social centre of gravity shifted from the landowning aristocracy to the wealthy bourgeoisie. The Charter of 1814 was retained but no longer as a royal gift to the nation; it was revised by the Chamber of Deputies and in its new form imposed on the king. Censorship was abolished; the tricolour was restored as the national flag, and the National Guard was resuscitated. Roman Catholicism was declared to be simply the religion "of the majority of Frenchmen," the voting age was lowered to 25, and the property qualification reduced to include all who paid a direct tax of 200 (formerly 300) francs. The suffrage was thus doubled, from about 90,000 to almost 200,000.

The new king seemed admirably suited to this new constitutional system. The "Citizen King" was reputed to be a liberal whose tastes and sympathies coincided with those of the upper bourgeoisie. He had spent the Revolutionary years in exile but was out of sympathy with the irreconcilable émigrés; and since his return, his house in Paris had been a gathering place for the opposition. Yet, in spite of appearances, Louis-Philippe was not prepared to accept the strictly symbolic role of a monarch who (in Thiers's phrase) "reigns but does not govern." His authority, he believed, rested on heredity and not merely on the will of the Chamber; his proper function was to participate actively in decision making and not merely to appoint ministers who would govern in his name. As time went by, he was increasingly inclined to choose ministers who shared his view of the royal power. The Orleanist system thus rested on a basic ambiguity about the real locus of authority.

The leadership of Guizot

In the Chamber two major factions emerged, known by the rather imprecise labels right-centre and left-centre. The former group, led by the historian François Guizot, shared the king's political doctrines; it saw the revised Charter of 1814 as an adequate instrument of government that needed no further change. The left-centre, whose ablest spokesman was the kingmaker Adolphe Thiers, saw 1830 as the beginning rather than the culmination of a process of change. It favoured restricting the king's active role and broadening the suffrage to include the middle strata of the bourgeoisie. These differences of viewpoint, combined with the king's tendency to intrigue, contributed to chronic political instability during the 1830s.

The decade of the 1830s was marked also by repeated challenges to the regime by its enemies on the right and the left and by a series of attempts to assassinate the king. Both the ultras (who now came to be called legitimists) and the republicans refused to forgive "the usurper" of 1830. In 1832 the Duchess de Berry, mother of "the miracle child," landed clandestinely in southern France in an effort to spark a general uprising; but the scheme collapsed, and most legitimists withdrew into sullen opposition. More serious was the agitation of the republicans, fed by rising labour discontent. In the most serious of these outbreaks (Lyon, 1831), 15,000 workers confronted the National Guard in the streets and suffered some 600 casualties before capitulating. Again in 1834 there were serious disturbances in Lyon and Paris. In 1836 it was the turn of the Bonapartist pretender to challenge the regime. Since Napoleon's death in 1821, a legend had rapidly taken shape around his name. No longer detested as a ruthless autocrat who had sacrificed a generation of young Frenchmen on the battlefield, he became transmuted into the Little Corporal who had risen to the heights by his own talents and had died a victim of British jealousy. The emperor's nephew Louis-Napoleon Bonaparte presented himself as the true heir; he crossed the frontier in 1836 and called on French troops in Strasbourg to join his cause. The venture failed ignominiously, as did also a second attempt on the Channel coast in 1840. Louis-Napoleon was condemned to prison for life but managed in 1846 to escape to England. Interspersed with these attempts at political risings were individual attacks on the king's person; the most elaborate of these plots was the one organized by a Corsican named Giuseppe Fieschi in 1835.

By 1840, however, the enemies of the regime had evidently become discouraged, and a period of remarkable stability followed. François Guizot emerged as the key figure in the ministry; he retained that role from 1840 to 1848. One of the first Protestants to attain high office in France, Guizot possessed many of the moral and intellectual qualities that marked this small but influential minority. Hard-working and intelligent, Guizot was devoted to the service of the king and to the defense of the status quo. He was convinced that the wealthy governing class was an ideal natural elite to which any Frenchman might have access through talent and effort. To those who complained at being excluded by the property qualification for voting and seeking office, Guizot's simple reply was "Enrichissez-vous!" ("Get rich!"). His government encouraged the process by granting railway and mining concessions to its bourgeois supporters and by contributing part of the development costs. High protective tariffs continued to shelter French entrepreneurs against foreign competition. The result was a modest economic boom during the 1840s, beginning the transformation of France from a largely rural into an industrial society.

Guizot's foreign policy

Guizot shared with Louis-Philippe a strong preference for a safe and sane foreign policy. The king, from the beginning of his reign, had cautiously avoided risks and confrontations and had especially sought friendly relations with Britain. In 1830, when the revolution in Paris inspired the Belgians to break away from Dutch rule, Louis-Philippe avoided the temptation of seeking to annex Belgium or of placing one of his sons on the Belgian throne. Again in 1840, when a crisis flared up in the Middle East and Thiers (then head of the government) took an aggressive stance that threatened to coalesce all of Europe against France, the king had found an excuse to replace his firebrand minister. Guizot continued this cautious line through the 1840s, with the single exception of an episode in Spain. A long contest involving rival suitors for the Spanish queen's hand finally tempted Guizot, in 1846, to try for a cheap diplomatic victory; it infuriated the British and helped to destroy the Anglo-French entente. One problem Guizot inherited from his predecessors was that of Algeria. Since 1830 the French had maintained an uneasy presence there, wavering between total withdrawal and expanded conquest. The decision to remain had been made in the mid-1830s; during the Guizot era, General Thomas-Robert Bugeaud de La Piconnerie's forces broke the back of Algerian resistance, pushed the native population back into the mountains, and began the process of colonizing the rich coastal plain.

THE SECOND REPUBLIC AND SECOND EMPIRE

The Revolution of 1848. The overthrow of the constitutional monarchy in February 1848 still seems, in retrospect, a puzzling event. The revolution has been called a result without a cause; more properly, it might be called a result out of proportion to its cause. Since 1840 the regime had settled into a kind of torpid stability; but it had provided the nation with peace abroad and relative prosperity at home. Louis-Philippe and his ministers had prided themselves on their moderation, their respect for the ideal of cautious balance embodied in the concept of *juste-milieu.* France seemed to be arriving at last at a working compromise that blended traditional ways with the reforms of the Revolutionary era.

The mood of restlessness

There were, nevertheless, persistent signs of discontent. The republicans had never forgiven Louis-Philippe for "confiscating" their revolution in 1830. The urban workers, moved by their misery and by the powerful social myths engendered by the Great Revolution, remained unreconciled. For a decade or more they had been increasingly drawn toward socialism in its various utopian forms. An unprecedented flowering of socialist thought marked the years 1840–48 in France: this was the generation of Barthélemy-Prosper Enfantin, Charles Fourier, Auguste Blanqui, Louis Blanc, Pierre-Joseph Proudhon, Étienne Cabet, and many others. Most of these system builders preached persuasion rather than violence, but they stimulated the hopes of the common man for an imminent transformation of society. Within the bourgeoisie as well, there was strong and vocal pressure for change in the form of a broadening of the political elite. Bills to extend the suffrage (and the right to hold office) to the middle bourgeoisie were repeatedly introduced in parliament but were stubbornly opposed by Guizot. Even the National Guard, that honour society of the lesser bourgeoisie, became infected with this mood of dissatisfaction.

Other factors, too, contributed to this mood. In 1846 a crop failure quickly developed into a full-scale economic crisis: food became scarce and expensive; many businesses went bankrupt; unemployment rose. Within the governing elite itself there were signs of a moral crisis: scandals that implicated some high officials of the regime and growing dissension among the Notables. Along with this went a serious alienation of many intellectuals. Novelists such as Victor Hugo, George Sand, and Eugène Sue glorified the common man; the caricaturist Honoré Daumier exposed the foibles of the nation's leaders; and historians such as Jules Michelet and Alphonse de Lamartine wrote with romantic passion about the heroic episodes of the Great Revolution.

Beginning in 1847, the leaders of the opposition set out to take advantage of this restless mood and to force the regime to grant liberal reforms. Since public political meetings were illegal, they undertook a series of political "banquets" to mobilize the forces of discontent. This campaign was to be climaxed by a mammoth banquet in Paris on Feb. 22, 1848. But the government, fearing violence, ordered the affair canceled. On the 22nd, crowds of protesting students and workers gathered in the streets and began to clash with the police. The king and Guizot expected no serious trouble: the weather was bad, and a large army garrison was available in case of need. But the disorders continued to spread, and the loyalty of the National Guard began to seem dubious. Toward the end of two days of rioting, Louis-Philippe faced a painful choice: to unleash the army (which would mean a bloodbath) or to appease the demonstrators. Reluctantly, he chose the second course and announced that he would replace the hated Guizot as his chief minister. But the concession came too late. That evening, an army unit guarding Guizot's official residence clashed with a mob of demonstrators, some 40 of whom died in the fusillade. By the morning of February 24, the angry crowd was threatening the royal palace. Louis-Philippe, confronted by the prospect of civil war, hesitated and then retreated once more; he announced his abdication in favour of his nine-year-old grandson and fled to England.

Abdication of Louis-Philippe

The Second Republic, 1848–52. The succession to the throne was not to be decided so easily, however. The Chamber of Deputies, invaded by a mob that demanded a republic, set up a provisional government whose members ranged from constitutional monarchists to one radical deputy, Alexandre-Auguste Ledru-Rollin. Led by the poet-deputy Alphonse de Lamartine, the members of the government proceeded to the Hôtel de Ville, where the radical republican leaders had begun to organize their own regime. After considerable palaver, the provisional government co-opted four of the radical leaders, including the socialist theoretician Louis Blanc and a workingman who called himself Albert. Under heavy pressure from the crowd surrounding the Hôtel de Ville, the government proclaimed the republic. During the next few days, continuing pressure from the social reformers pushed the government farther than its bourgeois members really wanted to go. The government issued a right-to-work declaration, obligating the state to provide jobs for all citizens. To meet the immediate need, an emergency-relief agency called the *ateliers nationaux* (national workshops) was established. A kind of economic and social council called the Luxembourg Commission was created to study programs of social reform; Louis Blanc was named its president. The principle of universal manhood suffrage was proclaimed—an almost unprecedented experiment in that day and one that increased the electorate at a stroke from 200,000 to 9,000,000. In matters of foreign policy, on the other hand, Foreign Minister Lamartine resisted radical demands. The radicals were eager for an ideological crusade on behalf of all peoples who were thirsting for freedom: Poles, Italians, Hungarians, and Germans had launched their own revolutions and needed help. Lamartine preferred to confine himself to lip-service support, since he was aware that an armed crusade would quickly inspire an anti-French coalition of the major powers.

The election of April 23, 1848

By April 23, when Frenchmen went to the polls to elect their constituent assembly, the initial mood of brotherhood and goodwill had been largely dissipated. Paris had become a caldron of political activism; dozens of clubs and scores of newspapers had sprung up after the revolution. Severe tension developed between moderates and radicals both within and outside the government and led to a number of violent street demonstrations that were controlled with difficulty. The *ateliers nationaux* satisfied no one: for the radicals they were a mere caricature of social reform, whereas for the moderates they were a wasteful and dangerous experiment that attracted thousands of unemployed to Paris from every corner of France. Financial problems plagued the government, which sought a solution by imposing a special 45-centime surtax on each franc of direct property taxes; this burden weighed most heavily on the peasantry and was bitterly resented in the countryside. The radicals, fearing that universal suffrage under these conditions might produce unpleasant results, vainly urged postponement of the elections until the new voters could be "educated" as to the virtues of a social republic.

The election returns confirmed the radicals' fears: the country voted massively for moderate or conservative candidates. Radicals or socialists won only about 80 of the 880 seats; the rest were bourgeois republicans (500) or constitutional monarchists (300). Lamartine led the popularity parade, being elected in 10 districts. When the assembly convened in May, the new majority showed little patience or caution; it was determined to cut costs and end risky experiments. In spite of Lamartine's efforts to maintain broad republican unity and avert a sharp turn to the right, the assembly abolished the Luxembourg Commission and the *ateliers nationaux* and refused to substitute a more useful program of public works to provide for the unemployed.

The June Days

The immediate consequence was a brief and bloody civil war in Paris—the so-called June Days (June 23–26, 1848). Thousands of workers suddenly cut off the state payroll were joined by sympathizers—students, artisans, employed workers—in a spontaneous protest movement. Barricades went up in many working-class sections. The assembly turned to General Louis Eugène Cavaignac as a saviour. Cavaignac had made his mark in repressing Algerian rebel tribes and was entrusted with full powers to do the same in Paris. He gave the workers time to dig themselves in, then brought up artillery against their barricades. At least 1,500 rebels were killed; 12,000 were arrested, and many were subsequently exiled to Algeria. The radical movement was decapitated; the workers withdrew into silent and bitter opposition.

Social conflict now gave way to political maneuvering and constitution making. Cavaignac was retained in office as temporary executive, while the assembly turned to its central task. After six months of discussion, it produced a constitution that appeared to be the most democratic in Europe. The president of the republic would be chosen for a four-year term by universal male suffrage; a one-house legislative assembly would be elected for three years by the same suffrage. What remained unclear was the relationship between president and assembly and the way out of a potential deadlock between them.

This problem might not have been fatal if the right kind of president had been available in 1848. Instead, the voters chose Louis-Napoleon Bonaparte, who had returned from British exile in September, after having successfully stood for the constituent assembly in a by-election. He had made a poor initial impression; indeed, some politicians, such as Thiers, backed him for the presidency because they thought him too stupid to rule and thus soon to be shunted aside for an Orleanist monarch. What he possessed, however, was a name—a name that Frenchmen knew and that conveyed an aura of glory, power, and public order. In December Louis-Napoleon won by a landslide, polling 5.5 million votes as against 2 million for all other candidates combined. In May 1849 the election of the legislative assembly produced an equal surprise. The two extremes—the radical left and the monarchist right—made impressive gains, whereas the moderate republicans, who had shaped the new system, were almost wiped out. The moderates emerged with only 80 seats, the radicals with 200, the monarchists with almost 500. But the monarchist majority lacked coherence, being split into legitimist and Orleanist factions that distrusted each other and differed on political principles.

During the next two years, President Bonaparte played his cards carefully, avoiding conflict with the monarchist assembly. He pleased Roman Catholics by restoring the pope to his temporal throne in Rome, from which he had been driven by Roman republicans. At home, he accepted without protest a series of conservative measures adopted by the assembly: these laws deprived one-third of all Frenchmen of the right to vote, restricted the press and public assemblage, and gave the church a firm grip on public as well as private education. Yet there was some reason to doubt that Louis-Napoleon really welcomed this trend toward conservatism. His writings of the 1840s had been marked by a kind of technocratic outlook, in the tradition of Saint-Simonian socialism. His effort to please the assembly probably derived from his hope that the assembly would reciprocate: he wanted funds from the treasury to pay his personal debts and run his household, along with a constitutional amendment that would allow him to run for a second term.

Louis-Napoleon's coup d'état

By 1851 it was clear that the majority was not ready to give the president what he wanted. His alternatives were to step down in 1852, bereft of income and power, or to prepare a coup d'état. Some members of his entourage had long urged the latter course; Louis-Napoleon now concurred, with some reluctance.

On the early morning of Dec. 2, 1851, some 70 leading politicians were arrested, and the outlines of a new constitution were proclaimed to the nation. It restored manhood suffrage, sharply reduced the assembly's powers, and extended the president's term to 10 years. Although the coup went off smoothly, it was followed by several days of agitation. Barricades went up in the streets, crowds clashed with troops and police in Paris and in the provinces, several hundred demonstrators were killed, and 27,000 were arrested. Once the resistance was broken, Louis-Napoleon proceeded with his announced plebiscite on the new constitution and was gratified to receive the approval of 92 percent of those who voted. But the authoritarian republic was only a stopgap. Officially inspired petitions for a restoration of the empire began to flow to Paris; the Senate responded to what it described as the nation's desires, and on Dec. 2, 1852, Napoleon III was proclaimed emperor of the French. This time there was no open protest; and the voters, in a new plebiscite, accorded Napoleon a handsome majority of 97 percent.

The Second Empire, 1852–70. Posterity's image of Napoleon III and his regime has not been uniform. Some historians have seen him as a shallow opportunist whose only asset was a glorious name. Others have described him as a visionary reformer and patron of progress, a man who successfully attempted to reconcile liberty and authority, national prestige and European cooperation. The emperor's enigmatic character and the contradictions built into his regime make it possible to argue either case.

The authoritarian years. From 1852 to 1859 the empire was authoritarian in tone. Civil liberties were narrowly circumscribed; vocal opponents of the regime remained in exile or were constrained to silence; parliament's wings were clipped; elections to the Legislative Corps (Corps Législatif; the lower house of the Parliament) were spaced at six-year intervals and were "managed" by Napoleon's prefects, who sponsored official candidates. An illusion of popular control was created by the use of the plebiscite to ratify decisions already made. The emperor and his ministers (members of his personal entourage or former Orleanist politicians) rested their authority on the peasant masses, the business class, the church, and those local notables who were willing to cooperate. Little attempt was made to install a new power elite or to create an organized Bonapartist party. Policy during the 1850s was consistently conservative; defense of the social order took precedence over reform.

Economic growth during the Second Empire

The most striking achievements of these authoritarian years were in economic growth and foreign policy. France had never before experienced such vigorous economic expansion. During the Second Empire industrial production doubled, foreign trade tripled, the use of steam power increased fivefold, railway mileage sixfold. The first great investment banks were founded (*e.g.*, the Péreire brothers' Crédit Mobilier) and the first department store (the Bon Marché in Paris). The surge of French enterprise transcended frontiers: French capital and engineers built bridges, railways, docks, and sewerage systems throughout much of continental Europe.

In part, this burst of energy had its source in favourable world conditions: the availability of more rapid steam transportation, an influx of new gold from overseas, general recovery from the slump of 1846–51. But to some degree Napoleon's government could claim credit, too—not so much by direct intervention in economic life as by creating a favourable climate for private enterprise. Many Frenchmen took advantage of the opportunities offered; they accumulated sizable fortunes and founded enterprises that still exist today. Among these entrepreneurs, however, there was a disproportionate number of "outsiders"—notably men of Protestant or Jewish origin, or former disciples of Henri de Saint-Simon. Alongside these dynamic newcomers, the older business and banking leaders continued to operate on more cautious traditional lines. From the Second Empire onward, the French economy would combine these two contrasting sectors: a dynamic modernized element superimposed upon a largely static traditional kind of enterprise.

Napoleon's foreign policy at the outset was cautious; "the empire means peace," he assured his countrymen and the nervous powers of Europe. Yet for a ruler who bore the name Napoleon the prudent and colourless policy of a Louis-Philippe seemed hardly appropriate. Besides, the emperor was eager to achieve recognition from the other European monarchs, who regarded him as an upstart. It was for these reasons rather than because of urgent national interest that he becamc involvcd in the Crimean War in 1854. Britain and Russia were engaged in a contest for influence in the crumbling Turkish empire. A dispute over the holy places in Palestine gavc Napoleon an excuse to offer the British his support and thus to restore the Franco-British ententc. Although the Crimean campaign was on the whole a fiasco for all of thc participating armies, the French forces came off less ingloriously than the others and could with some justicc pose as victors. Napoleon served as host for thc Paris peace conference that ended the war in 1856. Midway through thc conference, the birth of a male heir to the emperor and his empress, Eugćnie, seemed to assure the pcrmanence of the dynasty.

The liberal years. The empire thus appeared to have compiled a record of unbroken succcsses and to be beyond challenge by its domestic critics. Perhaps it was this stability and self-confidence that led Napoleon, beginning in 1859, to turn in the dirction of libcralizing the empire. The immediate impulse for this dramatic reversal was the attempted assassination of the emperor in January 1858 by an Italian patriot, Felice Orsini, who sought thus to draw public attention to the frustrated hopes of Italian nationalists. Napoleon, shaken by the cpisode and by the reminder that in his youth he, too, had fought for Italian independence, met secretly in July 1858 with Count Cavour, premier of Piedmont; thc two mcn laid plans designed to evict Austria from northern Italy and to convert Italy into a confederation of states headed by the pope. In return, France was promised Nicc and Savoy (Savoie). The new allies provoked the Austrians into a declaration of war in April 1859, and Napoleon led his armies across the Alps. French victories at Magenta and Solferino were followed by a somewhat premature scttlement in which the Austrians turned over the province of Lombardy to the Piedmontese. The campaign had aroused the passions of Italian nationalists all up and down the peninsula; revolutions broke out in some of the smaller Italian states, and in 1860 the colourful freebooter Giuseppe Garibaldi set forth from Piedmont to conquer Sicily and Naples.

Intervention in Italy

These repercussions of Napoleon's new foreign policy stirred up bitter controversy in France. Conservatives were outraged and feared that the pope would be deposed as temporal ruler of Rome by the Italian nationalists. On the other hand, the long-silent liberal and radical opposition voiced reluctant approval. It is likely that Napoleon, whose bent toward Saint-Simonian reform ideas was strong, had never been very comfortable in his alliance with the conservatives and welcomed a chance to indulge his deeper instincts. At any rate, late in 1859 he announced the first hesitant steps toward a liberal empire. Political exiles were amnestied, press controls were relaxed, and the Legislative Corps was given slightly increased authority. An even more dramatic turn toward economic liberalism soon followed; in January 1860 Napoleon negotiated a low-tariff treaty with Britain, ending the long tradition of protectionism that had insulated French producers. By this move, however, the emperor alienated the businessmen, who until now had been his strong supporters.

Some of the emperor's advisers had sharply opposed the turn toward liberalism. Events during the next decade seemed to confirm their warnings; for the empire now ran into increasingly stormy weather. The political opposition, stifled since 1851, showed little gratitude to its benefactor and took every opportunity to harass the government. In the 1863 elections, opposition candidates polled two million votes, and 35 of them were elected to the Legislative Corps—including such effective spokesmen as the Orleanist Thiers and the republican Jules Favre. A downward turn in the economy played into the hands of the opposition. Foreign policy errors added to the regime's embarrassment: Napoleon's ill-conceived intervention in Mexico, where he hoped to establish a client empire under Maximilian of Austria, proved costly and futile and seemed to threaten a conflict with the United States. And from the mid-1860s a new threat began to loom up across the Rhine: the burgeoning power of Prussia, under the guidance of Otto von Bismarck.

Further liberal reforms

Despite these evil portents, Napoleon clung doggedly to his liberalization venture; additional reforms were granted throughout the decade. He expressed sympathy with the workers, granted them a kind of extralegal right to form trade unions and to strike, and helped them organize mutual-aid societies. His minister of education, Victor Duruy, carried out an enlightened program of broadened public education, including the establishment of the first secondary education for girls. In 1867 the emperor restored quite considerable freedom of the press and of public assembly and further broadened the powers of the Legislative Corps. Yet the response of the voters to these concessions caused some dismay; in the elections of 1869 the opposition vote rose to 3.3 million, and the number of seats held by oppositionists more than doubled.

The emperor now faced a momentous choice: a still further dose of liberalism or a brusque return to the authoritarian empire. He chose the former alternative; in January 1870 he asked the leader of the liberal opposition, Émile Ollivier, to form a government. Ollivier supervised the drafting of a new constitution, which, though hybrid in nature, converted the empire into a quasi-parliamentary regime. The ministers were declared to be "responsible," and their powers (as well as those of the Legislative Corps) were increased. At the same time the emperor retained most of his existing prerogatives, so that the real locus of power in case of a conflict was unclear. Nevertheless, the voters, when consulted by referendum (May 8, 1870), gave the new system a massive vote of confidence: 7 million in favour to only 1.5 million against. Outwardly, at least, it appeared that the emperor had found a widely accepted solution. But war and defeat only four months later were to prevent a fair test of the liberal empire in its final form.

The Franco-German War. Napoleon, meanwhile, had become uncomfortably involved in a diplomatic poker game with Bismarck. Prussian victories over Denmark (1864) and Austria (1866) indicated a serious shift in the European balance of power. Napoleon, aware that he faced a severe challenge, set out to strengthen his armed forces; he proposed a tighter conscription law that would increase the size of the standing army but had to retreat in the face of public and parliamentary hostility. The crisis that finally erupted in July 1870 over the succession to the Spanish throne was clumsily handled by French officials. The French successfully blocked the accession of a Hohenzollern prince in Spain, then demanded further guarantees for the future; they thus provided Bismarck with an easy opportunity to arouse German opinion and to goad France into declaring war on July 19.

Few French or foreign observers anticipated the military disaster that followed. The French armies, sunk in routine and slow to mobilize, were not yet ready to fight when the Prussian forces under Helmuth von Moltke crossed into France. One French army, under Achille-François Bazaine, was bottled up in Metz; another, under Patrice Mac-Mahon, was cornered at Sedan. There, on September 1, the Prussians won a clear-cut victory; Napoleon himself was taken prisoner. The regime could not survive such a humiliation. When the news reached Paris on September 4, crowds filled the streets and converged on the Legislative Corps, demanding the proclamation of a republic. The imperial officials put up no serious resistance; the Revolution of September 4 was the most bloodless in French history.

The Revolution of September 4

THE THIRD REPUBLIC

A provisional government of national defense was set up and took as its first task the continuation of the war against the invaders. Composed of the deputies representing Paris and formally headed by General Louis-Jules Trochu, the new government's most forceful member was Léon Gambetta, hero of the radical republicans. Gambetta, a young Parisian lawyer of provincial origin, had been elected to the Legislative Corps in 1869 and had already made his mark through his energy and eloquence. As minister of the interior and, some weeks later, minister of war as well, he threw himself into the task of improvising military resistance. His task was complicated by the advance of the Prussian forces, which, by September 23, surrounded and besieged Paris. Gambetta shortly left the city by balloon to join several members of the government at Tours. During the next four months, Gambetta's makeshift armies fought a series of indecisive battles with the Prussians in the Loire valley and eastern France. But his attempt to send a force northward to relieve Paris from siege was frustrated by Moltke. Adolphe Thiers had been sent meanwhile to tour the capitals of Europe in search of support from the powers; but he returned empty-handed. By January 1871 it was clear that further armed resistance would be futile. Over Gambetta's angry protests, an armistice was signed with the Prussians on January 28.

One provision of the armistice called for the prompt election of a national assembly with authority to negotiate a definitive treaty of peace. That election, held on February 8, produced an assembly dominated by monarchists—more than 400 of them, compared to only 200 republicans and a few Bonapartists. The decisive issue for the voters, however, had not been the nature of the future regime but simply war or peace. Most of the monarchists had campaigned for peace; the republicans had insisted on a last-ditch fight. Most Frenchmen opted for peace, though Paris and certain provinces, such as Alsace, voted heavily for republicans. When the National Assembly convened in Bordeaux on February 13, it chose the aging Orleanist Adolphe Thiers as "chief of the executive power of the French republic." Thiers had been the most outspoken critic of Napoleon's foreign policy and had repeatedly warned the country of the Prussian danger. He set out at once to negotiate a settlement with Bismarck; on March 1 the Treaty of Frankfurt was ratified by a large majority of the assembly. The terms were severe: France was charged a war indemnity of five billion francs plus the cost of maintaining a German occupation army in eastern France until the indemnity was paid. Alsace and half of Lorraine were annexed to the new German Empire. The German army was authorized to stage a victory march through the Arc de Triomphe de l'Étoile in Paris. After the assembly ratified the treaty, the deputies of the lost provinces (including Léon Gambetta) resigned their seats in protest.

The Treaty of Frankfurt

The Paris Commune. A few days later, the assembly transferred the seat of government from Bordeaux to Versailles. It had scarcely arrived when it was confronted by a major civil war—the rebellion of the Paris Commune. This event, complex in itself, has been made even more difficult to understand by the mythology that later grew up around it. Karl Marx, who promptly hailed the Commune as the first great uprising of the proletariat against its bourgeois oppressors, was partly responsible for creating this mythology. There was undoubtedly a class-struggle element in the episode, but this was not the central thread. Parisians, tense and irritable after the long strain of the siege, were outraged by the action of rural France in electing a monarchist assembly committed to what they regarded as a dishonourable peace. They were further angered by the assembly's subsequent acts, notably those that ended the wartime moratorium on debts and rents, cut off further wage payments to the National Guard (which had been resuscitated in Paris after the empire fell), and transferred the capital to Versailles rather than to Paris.

Thiers, aware that Paris was in an ugly mood, thought it prudent to disarm the National Guard, which heavily outnumbered the regular army units at the government's disposition. Before dawn on March 18 he sent troops to confiscate the National Guard cannon on the butte of Montmartre. A crowd gathered; a bloody encounter ensued; two generals were caught and lynched by the mob. As violence spread through the city, Thiers hastily withdrew all troops and government offices from Paris and went to Versailles to plan his strategy. He appealed successfully to Bismarck to release French prisoners of war in order to form a siege army that could eventually force Paris to capitulate. During the next two months, this governmental force was slowly assembled. Within Paris, meanwhile, initial chaos gradually gave way to an improvised experiment in municipal self-government. On March 26, Parisians elected a council that promptly adopted the traditional label Commune of Paris. Its membership ranged from radical republicans of the Jacobin and Blanquist variety to socialists of several different sorts—notably disciples of Proudhon, who favoured a decentralized federation of self-governing communes throughout France. These internal divisions prevented any vigorous or coherent experiments in social reform and also interfered with the Commune's efforts to organize an effective armed force. Communes on the Paris model were set up briefly in several other cities (Lyon, Marseille, Toulouse) but were quickly suppressed.

"Bloody Week"

By May 21 Thiers's forces were ready to strike. In the course of "Bloody Week" (May 21–28) the Communards resisted, street by street, but were pushed back steadily to the heart of Paris. In their desperation, they executed a number of hostages (including the archbishop of Paris) and in the last days set fire to many public buildings, including the Tuileries Palace and the Hôtel de Ville. A final stand was made in Père-Lachaise Cemetery, where the last resisters were shot down against the Mur des Fédérés—ever since, a place of pilgrimage for the French left. Thiers's government took a terrible vengeance. Twenty thousand Communards were killed in the fighting or executed on the spot; thousands of survivors were deported to the penal islands, while others escaped into exile.

The formative years (1871–1905). The repression of the Paris Commune left its mark on the emerging republic. The various socialist factions and the newly organized labour movement were left leaderless; the resultant vacuum eventually opened the way to Marxist activists in the 1880s. Much of the working class became more deeply alienated than before, but, to the moderate and conservative elements, Thiers gained added stature as the preserver of law and order against "the reds." His ruthless action probably hastened the conversion of many rural and small-town Frenchmen to the idea of a republic because the regime had proved its toughness in handling subversion. A large number of by-elections to the assembly in July 1871 brought startling gains to the republicans: they won 99 of 114 vacancies. The voters were clearly willing to accept a republic so long as it was run by a man like Thiers.

Republican gains

Attempts at a restoration. The monarchists, however, still held a comfortable majority in the assembly and continued to hope and plan for a restoration. Legitimists and Orleanists remained at odds, but a compromise seemed possible. The Bourbon pretender, the Count de Chambord ("the miracle child" of 1820), was old and childless; the Orleanist pretender, Philippe, Count de Paris, was young and prolific. The natural solution was to restore Chambord, with the Count de Paris as his successor. Chambord, however, refused to accept the throne except on his own terms, which implied a return to the principle of absolute royal authority, unchecked by constitutional limitations. The Orleanists and even some legitimists found this too much to swallow. For the time being, they, too, settled for Thiers's presidential rule.

During the next two years, Thiers's position was beyond challenge, and he gave the republic vigorous and efficient leadership. He reorganized the army and worked to restore national morale; he successfully floated two bond issues that permitted the war indemnity to be paid off in 1873, thus ending the German occupation ahead of schedule. Late in 1872, however, Thiers abjured his long-held Orleanist faith and publicly announced his conversion to republicanism. The monarchists, outraged and seeing their majority in the assembly dwindling because of by-elections, found an excuse to force Thiers's resignation as provisional president (May 1873) and hastily substituted the commander of the army, Marshal Patrice de Mac-Mahon. Behind the scenes, monarchist politicians again set out to arrange an agreement between the two pretenders. Their hopes were once more sabotaged by Chambord, who again announced that he would return only on his own terms and under the fleur-de-lis flag of the old regime. The disheartened monarchists fell back on waiting for the Bourbon line to die out. But when Chambord passed from the scene in 1883, it was too late for a restoration.

The constitution of the Third Republic. Meanwhile, the task of writing a constitution for the republic could no longer be postponed. The assembly began its deliberations in 1873; in 1875 it adopted a series of fundamental laws, which, taken collectively, came to be known as the constitution of the Third Republic. A patchwork compromise, it established a two-house legislature (with an indirectly elected Senate as a conservative check on the Chamber of Deputies); a Council of Ministers (Cabinet), responsible to the Chamber; and a president, elected for seven years by the two houses, with powers resembling those of a constitutional monarch. The label republic was approved by a single-vote margin. Monarchists believed that this system could be easily converted to their purposes once the right monarch was available. The constitution left untouched many aspects of the French governmental structure, notably the centralized administrative system inherited from Napoleon I, the hierarchy of courts and judges, and the Concordat of 1801, governing church-state relations. At the end of 1875 the National Assembly at last dissolved itself, and the provisional phase of the Third Republic came to an end.

End of the provisional phase

The new Senate, which heavily overrepresented rural France, was safely monarchist from the outset; and the term of President Mac-Mahon, a loyal monarchist, ran until 1880. But when the first Chamber of Deputies was elected in 1876, the republicans won more than two-thirds of the seats. A period of severe friction between Mac-Mahon and the Chamber followed, and a crisis in May 1877 produced a total deadlock. Mac-Mahon dissolved the Chamber and called on the voters' support, but again they opted for the republic, by a narrower but clear-cut margin. Léon Gambetta, who had returned to political life and had led the republicans during the campaign, called on Mac-Mahon to "give in or get out." The president gave in, naming a premier acceptable to the republican majority. Two years later partial elections gave the republicans control of the Senate, and Mac-Mahon shortly found an excuse to resign. He was replaced by a colourless republican, Jules Grévy, who was believed to favour a reduced role for the president.

Republican factions. With the republican regime apparently safe from outside attack, rival factions developed among the republicans. During the 1880s the labels Radical and Opportunist began to be attached to the two wings of the republican movement. On the left, the Radicals saw themselves as heirs to the Jacobin tradition: they stood for a strong centralized regime, intransigent anticlericalism, an assertive nationalism in foreign policy, a revision of the constitution to prune out its monarchical aspects, and such social reforms as labour laws and a graduated income tax; their most colourful spokesman was Georges Clemenceau, a ferocious debater and duelist who specialized in overthrowing Cabinets. The Opportunists (so named by a satirical journalist because of their penchant for compromises and postponements) occupied the centre seats in the Chamber: their stance was more cautious and their techniques gradualist; they were content to work within the system, and they aimed to restrict governmental interference in the affairs of private citizens. Only on the issue of the church's role in politics and education were the two factions in general agreement.

Opportunist control. Between 1879 and 1899 the Opportunists, with only brief interruptions, controlled the machinery of government. Gambetta, their most dynamic leader, had begun his career as an outspoken Radical, but in time his political instincts had prevailed. The other Opportunist leaders—men such as President Grévy and Jules Ferry—disliked Gambetta's flamboyance, however, and feared his alleged dictatorial ambitions; they kept him out of the premiership save for a brief interlude in 1881–82, shortly before his death. Ferry served as premier or in other key Cabinet posts during most of the period from 1880 to 1885 and left his mark on two institutions: the public school system and the colonial empire. His school laws made primary education free, compulsory, and secular, with religious teaching in the public schools replaced by "civic education"; a strong anticlerical bias thenceforth marked French public education. Ferry's support of various colonial expeditions—sometimes behind the back of the Chamber—gave France protectorates over Tunisia and Annam and Tongking (Tonkin), a large new colony in the Congo basin, and an initial foothold in Madagascar. This expansionist policy, unpopular at the time, led later generations to call Ferry the founder of the French empire.

Educational reforms and colonial expansion

In the 1885 elections the monarchists, Bonapartists, and Radicals all made significant gains, partly because of boredom with the Opportunists, Catholic resentment over the school laws, and revived agitation by socialist organizers. The Opportunists, lacking a clear majority in the Chamber, sought Radical support to form a Cabinet; the Radicals insisted on the inclusion of General Georges Boulanger as minister of war. Within a few weeks Boulanger was the most talked-about man in France. He restored the tradition of military parades and rode at their head; he instituted popular reforms in the army; and he spoke out in chauvinistic fashion against the Germans, thus reviving the memory of 1871 and the lost provinces. The unnerved Opportunist leadership dropped him from the Cabinet and sent him in 1887 to an obscure provincial command. But Boulanger's backers urged him to plunge into politics and began to enter his name in by-elections. Privately, monarchist and Bonapartist agents also made contact with Boulanger, promising financial support and hoping to use him for their cause.

By 1889 the Boulanger movement had become a major threat to the regime. The government had placed him on the retired list, but this merely freed him to run openly for office on a vague program of constitutional revision. He triumphed in a series of by-elections, but his goal was the parliamentary election of 1889, which he hoped to turn into a kind of national plebiscite. Just prior to the election, however, believing that he was about to be arrested for subversive activities, Boulanger took flight to Brussels. His movement gradually disintegrated; word leaked out of his dealings with the monarchists, and his supporters fell away. The Opportunists' hold on the republic was strengthened by the discomfiture of those on both right and left who had been taken in by this adventurer.

The Panama Scandal

A new crisis soon arose for the regime: the Panama Scandal. Ferdinand de Lesseps, the noted French engineer who had built the Suez Canal, had organized a joint-stock company to cut a canal across the Isthmus of Panama. The venture proved difficult and costly; in 1889 the company collapsed, and large numbers of shareholders were stripped of their savings. Demands for a parliamentary investigation proved ineffective until 1892, when a muckraking journalist named Édouard Drumont obtained evidence that agents of the company had bribed a large number of politicians and journalists in a desperate effort to get funds to keep the company afloat. The directors of the company and several deputies and senators were brought to trial in 1893, but the outcome was on the whole a whitewash. The regime survived the scandal, but the effects were more serious than appeared to be the case. Cynicism about the honesty of the republic's political leadership gave added strength to the rising socialist movement; in 1893 almost 50 socialists won seats in the Chamber. Georges Clemenceau, unjustly accused of involvement in the scandal, was defeated; and many prominent Opportunists, tainted by the affair, withdrew and were replaced by such younger men as Raymond Poincaré and Louis Barthou, who thenceforth preferred to call themselves Progressists or Moderates.

The dramatic socialist gains in 1893 resulted only partly from the Panama Scandal. For more than a decade socialism had been gaining strength among the increasingly class-conscious urban workers. The movement was weakened, however, by multiple splits into antagonistic factions. The Marxist party created by Jules Guesde in 1880 broke up two years later into Guesdists and followers of Paul Brousse—the latter group popularly called possibilists because of their gradualist temper. In 1890 a third faction broke away, headed by Jean Allemane and limited to simon-pure proletarian members. Alongside these Marxist sects there were the Blanquistes (disciples of Auguste Blanqui), the anarchists (whose terrorist campaign in the early 1890s earned them wide notoriety), and a considerable scattering of independent socialists (mainly intellectuals, notably Jean Jaurès). By 1900 the parties had been reduced to the two led by Guesde and Jaurès, which merged in 1905 to form the French Section of the Workers' International (Section Française de l'Internationale Ouvrière [SFIO]), known as the Socialist Party.

The trade union movement, however, refused to join forces with the socialists. Trade unions were finally legalized in 1884 and joined together to form a national General Labour Confederation (Confédération Générale du Travail [CGT]) in 1895. CGT leaders rejected political action in favour of direct action—sabotage, boycotts, strikes, and especially the general strike, which they saw as the ultimate weapon that would transform France into a workers' state. This doctrine, known as revolutionary syndicalism, made the French trade union movement appear to be one of the most radical in Europe. In practice, however, the trade union rank and file was less revolutionary than its leadership.

Revolutionary syndicalism

The Dreyfus affair. The 1890s also saw the Third Republic's greatest political and moral crisis—the Dreyfus affair. In 1894 Captain Alfred Dreyfus, a career army officer of Jewish origin, was charged with selling military secrets to the Germans. He was tried and convicted by a court-martial and sentenced to life imprisonment on Devil's Island off the South American coast. Efforts by the Dreyfus family to reopen the case were frustrated by the general belief that justice had been done. But secrets continued to leak to the German embassy in Paris, and a second officer, Major Marie-Charles-Ferdinand Esterhazy, became suspect. The chief of army counterintelligence, Colonel Georges Picquart, eventually concluded that Esterhazy and not Dreyfus had been guilty of the original offense, but his superior officers refused to reopen the case. Rumours and scraps of evidence soon began to appear in the press; and a few politicians, notably Georges Clemenceau, took up Dreyfus' cause. But the army high command refused to discuss the affair, although army officers leaked documents to the press in an effort to discredit the critics. Each leak aroused new controversy, and by 1898 the case had become a violently divisive issue. Intellectuals of the left led the fight for Dreyfus, while right-wing politicians and many Roman Catholic periodicals defended the honour of the army. The socialists were split: Jaurès insisted that no socialist could remain aloof on such a moral issue, while Guesde called the conflict a bourgeois squabble.

In 1898 some of the army's most persuasive documents against Dreyfus were discovered to be forgeries. Esterhazy promptly fled to England. In a second court-martial, late in 1899, Dreyfus was again found guilty but with extenuating circumstances; he received a presidential pardon and was later (1906) vindicated by a civilian court. For a generation the affair left deep scars on French political and intellectual life. The Moderates, who had tried to avoid involvement in the affair and in the end had split into two warring factions, lost control to the Radicals.

Radical control

A coalition Cabinet headed by René Waldeck-Rousseau, a pro-Dreyfus Moderate, took office in June 1899; the Radicals dominated the coalition, and even the socialists supported it. From then until the end of the Third Republic the Radical Party (thenceforth called Radical-Socialist) remained the fulcrum of French political life. Both the army and the church were seriously hurt by their role in the affair; republicans of the left were more convinced than ever that both institutions were antirepublican and hostile to the rights of man enunciated during the Revolution. The new left majority retaliated by bringing the army under more rigorous civilian control and by embarking on a new wave of anticlerical legislation. Most religious orders were dissolved and exiled, and in 1905 a new law separated church and state, thus liquidating the Concordat of 1801.

Foreign policy. Meanwhile, some important successes were being scored in the field of foreign policy. For two decades after 1871 France had remained diplomatically isolated in Europe. Bismarck, to ward off potential ideas of revenge in France, had shrewdly encouraged French governments to embark on colonial conquest overseas and had negotiated alliances with all those European powers the French might otherwise have courted. He thus kept Austria-Hungary, Russia, and Italy in tow, while Britain chose to remain aloof in "splendid isolation." Upon Bismarck's fall in 1890, the German emperor William II terminated the secret treaty between Germany and Russia. The Russians began to cast about for friends and looked with some distaste toward Paris. French policymakers encouraged French bankers to make loans to the Russian government and opened negotiations for an entente. In 1891 a loose agreement provided for mutual consultation in crisis; in 1894 this was broadened into a military alliance by whose terms each partner promised to aid the other in case of attack by Germany or Germany's allies.

Franco-Russian Alliance

For a decade the Franco-Russian Alliance had little practical effect (though French loans did continue to flow to Russia). French diplomats turned to winning the Italians away from the Triple Alliance, and a Franco-Italian secret agreement in 1902 substantially weakened that Italian commitment. Of more central importance throughout the 1890s was recurrent tension between France and Britain, who had been at odds in various parts of the world and whose colonial competition at times seemed to threaten war. Britain's Boer War in South Africa added further ill feeling, and some British leaders began to urge an end to "splendid isolation" in favour of an entente with a continental power—most probably Germany, which was seen as part of an Anglo-Saxon racial bloc. But the German government responded coolly to overtures in this direction, thus feeding the fears of British leaders who saw Germany as a threat to British interests. The British turned to France instead and found a willing partner in the foreign minister Théophile Delcassé. A visit to Paris by King Edward VII in 1903 helped pave the way to the Anglo-French Entente Cordiale of 1904, which resolved all outstanding colonial conflicts between the two powers but stopped short of military alliance. The new entente was consolidated a year later, when French moves to take over Morocco as a protectorate were resented by the Germans, who thought they saw an opportunity to break up the new entente. Emperor William II offered Germany's support to the sultan of Morocco; this action irritated the British and led them to promise France strong support. In the conference of powers that followed at Algeciras (1906) France had to be content with special privileges rather than a protectorate in Morocco; but the Entente Cordiale was solidified, and it was Germany that thenceforth began to complain of isolation.

Stable government of the Bloc Républicain

The prewar years. From 1899 to 1905 a fairly coherent coalition of left-wing and centre parties (the so-called Bloc Républicain) provided France with stable government. The Cabinets headed by Waldeck-Rousseau in 1899–1902 and Émile Combes in 1902–1905 managed to liquidate the Dreyfus affair and to carry through the anticlerical reforms that culminated in the separation of church and state. The Entente Cordiale and the Russian alliance ensured France a more influential voice in European affairs. France possessed a colonial empire second only to Britain's in size. A new period of economic growth set in after the mid-1890s. Not surprisingly, later generations were to look back on the pre-1914 decade as *la belle époque* ("the good old days").

Still, some sources of sharp dissatisfaction and conflict remained. Many Roman Catholics were outraged by the triumph of the anticlericals, and they responded to the Vatican's urging to sabotage the new system. They resisted (sometimes violently) the transfer of church property to state ownership and refused to establish lay associations to govern the church. By 1907, however, resistance was clearly futile, and they began to accept the separation law as an accomplished fact. A difficult period followed for the church. The recruitment of priests fell off sharply, and many Catholic schools were closed for lack of funds. In the long run, however, the separation law reduced the intensity of conflict between Catholics and anticlericals. There was less reason for republicans to suspect and denounce a disestablished church.

A vocal minority on the right remained unreconciled to the radical republic and rallied round the banner of the Action Française, headed by Charles Maurras. This organization had developed at the height of the Dreyfus affair as a focal point for intellectuals who opposed a new trial for Dreyfus. Maurras, an aspiring young writer from the south, quickly emerged as its theorist and leader. In his view, France had gone astray in 1789 and had since been dominated by the "four alien nations"—Jews, Freemasons, Protestants, and *métèques* ("aliens"). He preached a return to stable institutions and an organic society, in which the monarchy and the church would be essential pillars. Maurras appealed to many traditionalists, professional men, churchmen, and army officers. Action Française readily resorted to both verbal and physical violence, and its organized bands, the Camelots du Roi, anticipated the tactics of later Fascist movements. By 1914 Maurras' movement, though still relatively small, was the most coherent and influential enemy of the republic.

Alienation of the working class

Equally serious was the alienation of much of the working class. The CGT remained officially committed to revolutionary syndicalism; it rejected political action as a useless diversion of the proletariat's energies and exalted the idea of the general strike as the proper weapon to destroy bourgeois society. Although the CGT attracted only about 10 percent of French workers (most workers stubbornly refused to join any union), it was aggressive enough to cause sporadic turmoil during the period 1906–10. Several major strikes were broken by forcible repression; the government either called out troops or mobilized the strikers (who were also reservists) into the army. Proposals for labour-reform legislation drew little support in a parliament dominated by representatives of the bourgeoisie and the peasantry.

Despite the CGT, most workers by now were voting for the new unified Socialist Party. But the SFIO refused to permit its deputies to participate in or support bourgeois Cabinets (a policy dictated to the French party in 1904 by the Second International, dominated by the German socialists) and thus condemned itself to an oppositionist stance in parliament. This destroyed the left-wing coalition that had given France stable Cabinets from 1899 to 1905. Socialist strength continued to rise, and by 1914, the party was second only to the Radicals in the Chamber of Deputies. Although its doctrine remained rigorously Marxist, in deference to the instructions of the International, the party's conduct was much more flexible. Jaurès, whose "humanitarian" socialism was in large part derived from an older French heritage of left-wing thought, guided the socialists in parliament toward informal cooperation with the bourgeois left in an effort to achieve domestic social reforms and an internationalist, antimilitarist foreign policy. Jaurès' central concern during the pre-1914 decade was to avert the general war that he saw looming ahead in Europe.

The socialist withdrawal from the Bloc Républicain in 1905 forced the Radicals to look to the other centre parties

Centre coalition governments

as coalition partners. Until 1914—and, indeed, most of the time until 1940—France was governed by heterogeneous centre coalitions in which the Radicals most often held the key posts. In 1906 the Radical Georges Clemenceau began a three-year premiership. He proposed a long list of social reforms, including the eight-hour day and an income tax, but parliament blocked virtually all of them. More surprising was Clemenceau's ruthless suppression of strikes and his vigorous, nationalistic foreign policy. In 1907 his government sponsored a rapprochement between Britain and Russia that completed the triangle of understandings thenceforth called the Triple Entente. But Clemenceau refused to risk war through all-out support of his Russian ally during the Bosnian crisis of 1908. When his Cabinet fell in 1909, Clemenceau had effectively alienated his own Radical Party and seemed unlikely ever to return to high office.

Clemenceau's successors, Aristide Briand and Joseph Caillaux, undertook a policy of détente in European affairs. Briand, like Clemenceau, belied his left-wing origins by forcibly repressing a major strike in 1910; in foreign affairs, however, he preferred a policy of coexistence with Germany. Caillaux pushed this latter experiment even further. In 1911 he had to deal with a new crisis in Morocco, where the French were again pushing toward a protectorate against German objections. When the Germans sent a gunboat to Morocco, Caillaux made an effort at appeasement, handing over to Germany a slice of the Congo as compensation. French patriots were outraged; the Caillaux Cabinet was overthrown and replaced in January 1912 by one headed by Raymond Poincaré.

Nationalist revival

There were signs of a changing intellectual mood in the country, especially among young Frenchmen. A nationalist revival affected many Frenchmen who for a decade had grown increasingly anxious about what they regarded as the puzzling and threatening attitude of Germany's post-Bismarckian leadership; they looked once more to the army as the nation's bulwark, and its prestige was on the rise. These nationalist tendencies found their embodiment in Poincaré, whose intransigent patriotism and determination to stand up to Germany were beyond doubt. As premier in 1912–13 Poincaré devoted himself to strengthening the armed forces and to reinvigorating France's alliance system. An agreement with the British provided for a new sharing of naval responsibilities: the French concentrating in the Mediterranean, the British in the North Sea. Poincaré made a state visit to Russia to revive the sagging Franco-Russian Alliance. In January 1913 he was elected to the presidency of the republic, where, he believed, he could ensure continuity of policy during his seven-year term. In 1913 the size of the standing army was increased by lengthening the conscription period from two to three years.

Poincaré found bitter opposition on the left. The socialists were strongly antimilitarist and hoped for an eventual reconciliation with Germany via collaboration between the two socialist parties. They clung to the belief that the working class everywhere could block war by resorting to a general strike. A large segment of the Radical Party followed the Caillaux line, favouring Franco-German collaboration through such ventures as banking consortia for joint investment abroad. Much of rural France also lacked enthusiasm for the new nationalistic mood. The combined strength of this opposition was revealed in the parliamentary elections of 1914, when the parties of the left won a narrow victory.

World War I. Before a change in policy could be imposed, however, a new crisis in the Balkans threatened a general war. The assassination of the Austrian archduke Francis Ferdinand in Sarajevo on June 28, 1914, inaugurated five weeks of feverish negotiations, in which France's role has been much debated. Some historians have accused Poincaré and his supporters of a willingness to go to the brink of war rather than seek a negotiated settlement or use restraint on the Serbs and Russians; Poincaré's state visit to St. Petersburg at the height of the crisis has been seen as an occasion for a French promise of full support to Russia. A more judicious view is that many French statesmen had long seen the possibility and even the likelihood of a general war, and they suspected that the German government desired such a war; the Poincaré group believed that under these circumstances France could not risk the loss of its allies. French support of the Serbs and the Russians, according to this view, was thus inspired by a calculated judgment regarding French security.

German declaration of war against France

Germany's declaration of war against France on August 3 produced a spontaneous outburst of patriotic sentiment. Trade union and Socialist leaders, some of whom had been on a governmental list of dangerous subversives to be arrested in case of war, rallied to the colours. A national union Cabinet was formed. Parliament, after voting war credits, went into an extended recess, handing over the conduct of the war to the Cabinet and the high command. During the initial months the high command made most of the crucial decisions; the Cabinet accorded almost unlimited freedom of action to the commander in chief, General Joseph Joffre, assuming that the war would last only a few weeks and that civilian interference would only prolong hostilities.

Joffre's war plans for an immediate advance across the frontier into the lost provinces of Alsace and Lorraine were suspended when German forces struck through Belgium and threatened late in August to envelop Paris. Joffre managed to blunt the German attack and force the Germans to more defensible positions. The rival armies dug into trench positions that remained largely static until 1918. Meanwhile, the French high command continued to believe that the fate of France would be decided on the Western Front. In 1916 a powerful German artillery attack on the French fortress positions surrounding Verdun lasted from February to June and cost each side some 250,000 men. For the French, the hero of Verdun was the sector commander, General Philippe Pétain.

Joffre was by now under heavy criticism in Paris. Both the Cabinet and the Chamber were determined to assert greater control over the war effort, so that the high command's authority was steadily whittled away. Joffre was finally replaced in late 1916 by General Robert Nivelle. All through 1917, rival factions in the Chamber debated the conduct of the war, backing different generals and threatening Cabinet crises. Worse still, morale among the troops reached a dangerous low point in 1917, culminating in serious mutinies that affected 54 French divisions. Pétain, who replaced Nivelle in May, managed to achieve stability by a judicious combination of severity and concessions.

Nevertheless, by autumn 1917 there was widespread defeatism in France and much talk of a "white peace." The Radical leader Caillaux was prepared to try for negotiations with the Germans; but his chance never came. When the Cabinet of Premier Paul Painlevé was overthrown in November 1917, President Poincaré recalled Georges Clemenceau to the premiership. Clemenceau stood for a fight to the finish. At age 76 he still had enormous energy and doggedness, and he infused a new spirit into the country. In March 1918, when the Germans launched a last major offensive in the West, Clemenceau replaced the cautious and pessimistic Pétain with a more attack-minded general, Ferdinand Foch, and persuaded the British as well to accept him as supreme commander. The German drive was checked. On November 11 an armistice was signed in Foch's railway car near Compiègne.

Effects of the war

The victory was won at enormous cost for France. Of the 8 million Frenchmen mobilized, 1.3 million had been killed and almost 1 million crippled. Large parts of northeastern France, the nation's most advanced industrial and agricultural area, were devastated. Industrial production had fallen to 60 percent of the prewar level; economic growth had been set back by a decade. The enormous cost of the war seriously undermined the franc and foreshadowed many years of currency fluctuation. Even deeper, though largely hidden, were the psychological lesions caused by the strain of protracted warfare and by the sentiment that France could not again endure such a test.

At the Paris Peace Conference in 1919, Clemenceau, as the principal French negotiator, declared that his goal was to ensure the nation's security against a renewed German aggression. He sought, therefore, to reduce Germany's power in every possible fashion and to hedge

Germany about by strong barrier nations. He knew, however, that France could not dictate the peace terms and that he would have to compromise with the Americans and British, to whom he looked for aid in case of German resurgence. His stubborn defense of French demands irritated France's wartime allies; but his willingness to compromise in the end alienated many Frenchmen, who charged him with sacrificing the nation's security. The critics—who included Poincaré and Foch—were particularly outraged when Clemenceau abandoned his initial demand that Germany give up all territory west of the Rhine and that the Saar basin be annexed to France. These and other concessions led many right-wing deputies to oppose the Treaty of Versailles when it was presented for ratification in the autumn of 1919. Joining the opposition were the Socialists, who argued that the treaty was too harsh and that democratic Germany should not be punished for the sins of the kaiser. A majority of the Chamber, however, reluctantly ratified Versailles and vowed to assure its enforcement to the letter.

The interwar years. Frenchmen concentrated much of their energy during the early 1920s on recovering from the war. The government undertook a vast program of reconstructing the devastated areas and had largely completed that task by 1925. To compensate for manpower losses, immigration barriers were lowered, and two million foreign workers flooded into the country. Underlying all other concerns, however, was anxiety about the nation's security and about financing the costs of war and reconstruction. The peace settlement, in the eyes of many Frenchmen, had not provided adequate guarantees; and except among Socialists and Radicals there was little confidence in the League of Nations. American and British promises to aid France in case of future attack had been written into the treaty, but they became meaningless when the United States Senate rejected Versailles.

German reparations. A clause in the treaty had ascribed war guilt to the Germans and their allies and had obligated Germany to make reparations; the total sum due was calculated in 1921 at $33 billion, but the French were aware that the British hoped to see this total reduced.

Bloc National

The general elections of November 1919 resulted in a massive majority for the right-wing coalition called the Bloc National. The new Chamber set out to enforce Versailles to the letter; it also sought traditional security guarantees, maintaining the largest standing army in Europe and attempting to encircle Germany with a ring of military allies (Belgium and Poland in 1920–21; Czechoslovakia, Romania, and Yugoslavia in 1924–27). But the central issue was that of German reparations. By the end of 1921 the British clearly favoured a reduction of the burden in order to get Germany back on its feet; this issue caused increasing strain between the British and French governments. Premier Briand, who seemed willing to compromise, was overthrown by the Chamber and replaced by the more intransigent Poincaré. Repeated German defaults on reparations deliveries led Poincaré in January 1923 to send French troops and engineers (supported by a token force of Belgians) into the Ruhr valley to force German compliance or, if necessary, to collect reparations by direct seizure. The German government attempted passive resistance but finally had to comply. Germany agreed in 1924 to a revised reparations settlement, the so-called Dawes Plan, and the French occupation forces were withdrawn. The plan enabled the Germans to meet their obligations on schedule during the rest of the decade, though only with the help of large American loans. In 1926 France and the United States finally reached agreement on another nagging problem—the repayment of French war debts for wartime deliveries of American munitions and other supplies.

Financial crisis. The aftermath of the Ruhr occupation was to cast doubt on its apparent success. The German republic was weakened by the runaway inflation of 1923 and its future clouded; the occupation had embittered Britain and the United States. Even among Frenchmen, the victory had left a sour aftertaste because the costs of the occupation forced an increase in French taxes. In the elections of 1924 Poincaré's Bloc National was beaten by a coalition of the left, the Cartel des Gauches, and the Radicals were returned to power. But their triumph was brief; they were confronted by the nation's worst financial crisis since the war. The shaky franc went into rapid decline until there seemed to be danger of complete financial collapse. Seven Cartel Cabinets in 1924–26 wrestled ineffectively with the problem; at last the Cartel gave up, and Poincaré returned. The latter's reputation for decisive character and conservative views enabled him to win the bankers' support and to embark on such measures as slashing government expenses and increasing taxes. The franc began to rise, and it finally stabilized at about one-fifth of its 1914 value. Poincaré was hailed as "saviour of the franc," and, when he resigned in 1929 for reasons of health, he was acclaimed as one of the Third Republic's outstanding statesmen.

Collective security. Poincaré, in his final term of office (1926–29), retained as foreign minister Aristide Briand, who had been named to that post by the Cartel in 1925 and who was to remain there for seven years almost without interruption. Briand sensed a change in the public mood after the Ruhr episode and proclaimed himself "the apostle of peace"; he formulated a policy that he called *apaisement.* His goal was to work for collective security through the League of Nations, for disarmament, and for a reconciliation with those Germans who favoured peaceful and cooperative methods. Briand found a ready partner in Gustav Stresemann, the German foreign minister. By the Pact of Locarno (1925), the French and German governments bound themselves not to use force to alter the existing Franco-German frontier. In subsequent years, France sponsored Germany's entry into the League of Nations and made a series of concessions softening various aspects of the Treaty of Versailles. A revised reparations agreement in 1929 (the Young Plan) further eased Germany's obligations, and in 1930 the French ended their occupation of the German Rhineland five years ahead of schedule.

Internal conflict on the left. Throughout the 1920s, however, much of the working class remained alienated from a regime that showed little concern for social reform. The CGT had emerged from the war with redoubled strength and energy, its membership swelled by the workers who had poured into new war industries in the Paris region. The Clemenceau government had rewarded labour for its war effort by legislating the eight-hour day in 1919; but when the unions pushed for more reforms, a deadlock ensued. An attempted general strike in May 1920 was easily broken, and thousands of discouraged and embittered workers abandoned the CGT. Labour's strength was further dissipated by the formation of rival Catholic and Communist trade-union federations in 1919 and 1921.

Socialist split

The political influence of the workers was further impaired by a split in the Socialist Party in 1920. During the war, Socialist opposition to the slaughter had become increasingly vocal. The Bolshevik Revolution in Russia had reinforced this trend and offered a model that attracted many French Socialists. From 1918 onward, conflict intensified among Socialists over the possibility of joining Lenin's Comintern (Third International). At the party's annual congress in Tours in December 1920 Lenin's partisans carried the day by a large majority and shortly renamed their organization the French Communist Party (SFIC). The minority, headed by Jaurès's disciple Léon Blum, walked out of the congress and retained the traditional name SFIO. Throughout the 1920s antagonisms between these two Marxist factions hampered the left and prevented workable coalitions. Neither the Socialists nor the Communists would enter bourgeois-dominated Cabinets; the Communists refused even to make electoral agreements in support of a single left-wing candidate. The trend through the 1920s was favourable to the Socialists, while the Communists steadily lost influence and members; in 1928 the Socialists won 107 seats in the Chamber, the Communists only 11. Many French Communists resented dictation from Moscow, and the decade saw a long series of resignations and purges; by 1930 the remnant had been thoroughly "bolshevized" on the pattern of Lenin's own party.

The Great Depression and political crises. France at the end of the 1920s had apparently recovered its prewar stability, prosperity, and self-confidence. For a time it even seemed immune to the economic crisis that spread through Europe beginning in 1929; France went serenely on behind its high-tariff barrier, a healthy island in a chaotic world. By 1931, however, France in its turn succumbed to the effects of the depression, and the impact was no less severe than elsewhere.

In 1932 the right-wing parties lost control of the Chamber to the Radicals and Socialists. The Radical leader Édouard Herriot returned to the premiership, with Socialist support but not participation. During the next two years Herriot and a series of successors groped for a solution to the deepening crisis. French nervousness was increased by the surge of Nazi power across the Rhine, culminating in Adolf Hitler's accession to the chancellorship in January 1933. Right-wing movements in France—some openly fascist, others advocating a more traditional authoritarianism—grew in size and activity. By 1934 the shaky coalition was at the mercy of an incident—the Stavisky scandal, a sordid affair that tarnished the reputations of several leading Radicals. Antiparliamentary groups of the far right seized the occasion to demonstrate against the regime; on February 6 a huge rally near the Chamber of Deputies degenerated into a bloody battle with armed police, during which 15 rioters were killed and 1,500 injured. Premier Édouard Daladier, confronted by a threat of civil war, resigned in favour of a national union Cabinet under former president Gaston Doumergue. The regime survived the crisis, but serious stress persisted. Right-wing agitation was countered by unity of action on the left, grouping all the left-wing parties and the CGT; even the Communists participated in this effort, which culminated in 1935 in the formation of the Popular Front.

Right-wing agitation

Doumergue's government had meanwhile disintegrated when Radical ministers resigned over the premier's increasingly authoritarian tone. Doumergue was soon replaced by Pierre Laval, a former socialist who had migrated toward the right. Laval embarked on a vigorous but unpopular attempt to combat the depression through traditional techniques: sharp cuts in government spending and increased taxes. These policies wrecked his Cabinet early in 1936 and became campaign issues in the parliamentary election that spring. That election, probably the most bitterly contested since 1877, gave the Popular Front a narrow majority of the popular vote and a large majority in the Chamber. The Socialists for the first time became the largest party; but the greatest proportional gain went to the Communists, who jumped from 10 to 72 seats.

Léon Blum, the Socialist leader, became premier. Blum, an intellectual, was the first French premier of Jewish origin. His ministers were mostly Socialists and Radicals; the Communists refused his urgent invitation to participate. At the very outset, a wave of sit-down strikes spread throughout the country, expressing workers' pent-up resentment toward past governments and their determination to get what they considered to be justice. Blum persuaded industrial leaders to grant immediate wage increases, which ended the strike. Then he pushed additional reforms through parliament: the 40-hour week, paid vacations, collective bargaining, and the seminationalization of the Bank of France. Many other reform bills, however, were stalled in committee or in the Senate, which remained much more conservative than the Chamber.

Blum's social reforms were costly and controversial and were not buttressed by a program of economic reforms that might have stimulated production and restored confidence. Production surged briefly, then lagged again; unemployment remained high, rising prices offset wage gains, a flight of capital set in. When Blum attempted to impose exchange controls, the Senate rebelled and overthrew his Cabinet (June 1937). The Popular Front held together for another year, but the Socialists and Radicals were irretrievably divided on economic policy. In April 1938 France returned once more to the usual pattern of homogeneous centre coalitions, with the Socialists in opposition. The Radical Daladier served as premier in 1938–40; his finance minister, Paul Reynaud, suspended most of the Popular Front reforms and sought economic recovery through more orthodox policies favoured by business.

German aggressions. Meanwhile, Hitler's accession had placed French governments in an increasingly grave foreign-policy dilemma. By 1934 many French leaders believed that a return of "Poincarism" was in order, and Doumergue's foreign minister, Louis Barthou, set out to reinforce and extend France's alliance system. He reaffirmed French ties with Poland and the "Little Entente" countries and sought new understandings with both Italy and the Soviet Union. Barthou's assassination in late 1934 weakened the new alliance policy, though Pierre Laval in 1935 paid visits to both Rome and Moscow and actually signed a mutual assistance treaty with the U.S.S.R.

Reinforcement and extension of alliances

Mussolini's invasion of Ethiopia in late 1935 and Hitler's military reoccupation of the Rhineland in March 1936 were serious blows to French policy. After consulting the British, the French Cabinet decided not to risk a confrontation with Hitler, who thus won a major diplomatic victory. Hitler promptly fortified the Rhine frontier, so that French guarantees of military aid to eastern European allies lost much credibility. Furthermore, Hitler and Mussolini joined forces against the status quo powers. With Italy lost, Frenchmen of the centre and right grew cool toward closer ties with the Soviet Union; they had counted on Italy to counterbalance Soviet influence. France found itself dangerously isolated, dependent on the small eastern European countries and on the uncertain prospect of British military support in crisis. Not surprisingly, French policy after 1936 showed signs of weakness and drift.

The outbreak of the Spanish Civil War in July 1936 posed a severe problem of conscience for Blum's Popular Front government: whether to send aid to the Spanish republic, the only other Popular Front regime in Europe. Reluctantly, Blum remained aloof; his Radical allies strongly opposed intervention and threatened to bring down the Cabinet. A new crisis developed in March 1938, when Hitler's troops for the first time crossed a frontier—into Austria. The French and British confined themselves to formal protests. German pressure on Czechoslovakia followed. Although France was formally committed to aid Czechoslovakia in case of aggression, Premier Daladier succumbed to British pressure to appease Hitler by a compromise settlement. The Munich Agreement of September 30 provided a breathing space but caused sharp dissension and self-doubt in France. When Hitler occupied what was left of Czechoslovakia in March 1939, it appeared to be too late for successful diplomatic or military resistance to Hitler, yet a failure to resist would hand over the Continent to German domination. From April until August the French and British sought to bring the Soviet Union into a joint pact against Hitler, with the French pressing the reluctant British to take the risks involved. A Soviet decision to break off negotiations and to sign a pact with Hitler instead was the last in a long chain of disasters for France. On September 3, two days after Germany invaded Poland, the French and British governments reluctantly declared war on Germany.

War against Germany

French and British attempts to aid the Poles would have been ineffective even if tried. Hitler's offer of peace immediately after Poland fell was rejected by the Western Allies. The Nazi armies smashed through The Netherlands and Belgium on May 10, 1940, and soon broke the French defensive lines near Sedan. The German blitz brought chaos all along the Allied front. In Paris, Premier Paul Reynaud (who had replaced Daladier in March) pleaded for emergency aid from Britain and the United States; the British sent some additional air units but were unwilling to denude their island of all air defense; U.S. President Franklin D. Roosevelt offered moral encouragement but not open intervention.

On June 10, with the Germans approaching Paris, the government departed for Tours and declared Paris an open city. British Prime Minister Winston Churchill twice flew to Tours in an effort to keep France in the war. But Reynaud, who favoured continued resistance (from North Africa, if necessary) rapidly lost ground to the defeatists in his Cabinet, headed by Pétain. On June 14 the Cabinet left Tours for Bordeaux. Churchill, in a last desperate

Surrender to Germany

effort, proposed a pact of "indissoluble union" that would merge France and Britain as a single nation. By the time the proposal reached Bordeaux on June 16, however, the Pétain faction had gotten control of the Cabinet. Reynaud resigned that evening; Pétain was appointed in his place and asked Germany for surrender terms. On June 22 an armistice was signed with the Germans, near Compiègne, in the same railway car that had been the scene of Foch's triumph in 1918. The armistice provided for the maintenance of a quasi-sovereign French state and for the division of the country into an occupied zone (northern France plus the western coast) and an unoccupied southern zone. France was made responsible for the German army's occupation costs. The French army was reduced to 100,000 men and the navy disarmed in its home ports.

Society and culture under the Third Republic. Under the Third Republic the middle and lower sectors of society came to share political and social dominance with the rich notables. Universal suffrage gave them a new political weapon; France's peculiar socioeconomic structure gave them political weight.

Economy. Republican France remained a nation of small producers, traders, and consumers. The surge of industrialization that marked the era of Napoleon III had stopped short of a full-scale industrial revolution. The new dynamic sector of the economy was far outweighed by a static or slowly changing sector. The bulk of industry remained smaller and more dispersed than in other industrializing countries. As late as the decade before 1914, 90 percent of France's industrial enterprises employed fewer than five workers each; in the extensive textile and clothing trades more than half of the employees still worked at home rather than in factories. Commerce and trade followed the same pattern, with small shops and banks surviving in profusion. Similarly, rural France was dominated by small, subsistence family farms. The proportion of farmers in the total active population, which stood at 52 percent in 1870, was still about 45 percent in 1914 and 35 percent in 1930. When grouped together, the small independent producers, traders, and farmers far outnumbered any other segment of society, including the proletariat.

The reasons given for this slow pace of socioeconomic change are varied: shortages of basic natural resources, a tradition of specialization in luxury items, a code of mores that emphasized prudent management rather than risky experiment and that regarded as ideal the "family firm," small enough to be financed and managed by the owners alone. In any case, French industrialization took a different form from that of England or Germany. An initial burst of growth in the 1850s was followed by several decades of much more gradual expansion, which did not threaten the existing structure of society and the underlying value system. Most segments of society were reasonably satisfied and felt no threat to their way of life (only the members of the working class, both urban and agricultural, considered themselves outsiders and victims rather than participants); thus, the stability of the system was ensured. Not until well into the 20th century, and especially after 1918, did this state of affairs begin to change.

Laissez-faire policy

The governments of the Third Republic were representative of the small independents and responsive to their interests. Most of the bourgeoisie and the peasantry wanted a laissez-faire policy: low taxes, hands off the affairs of private citizens. There was little popular enthusiasm for costly ventures in foreign policy or expensive social reforms; the major exception—the conquest of colonial empire—had to be accomplished somewhat secretively and with limited resources. Only in tariff policy was laissez-faire flagrantly violated by the government, with the active consent of its bourgeois supporters. When the low-tariff treaties of Napoleon III expired in 1877, the government promptly returned to protectionism. Much of French agriculture and industry was thereby protected against more efficient foreign producers and insulated against the need for modernization. The short-range interests of the small, independent producer were thus guaranteed; the prospect of harm to his longer-range interests—as well as to those of the nation as a whole—was not yet clear.

From 1873 to the mid-1890s the French economy experienced a period of slackness. This trend reflected a condition affecting most of Europe, although France suffered a special blow when an epidemic of phylloxera in 1875–87 destroyed one-third of the nation's vineyards. From 1896 to 1914 industrial output rose impressively, exports increased by 75 percent, prices returned to the pre-slump level; this upturn was also generally Europewide rather than peculiar to France; but some special factors, such as the opening of a vast new iron-ore field in French Lorraine, did increase the French rate of industrial expansion. By 1914 French Lorraine had become the major centre of French iron and steel production, and France had become the world's largest exporter of raw iron ore (primarily to Germany). Yet the French were being outpaced by rivals. In 1870 France had still ranked as the world's second industrial and trading nation; by 1914 it had fallen to a poor fourth. Much of the liquid capital that might have been used for business expansion at home was being siphoned off into foreign investment; by 1914 almost one-third of such available French capital had been placed abroad—one-fourth of that sum in Russia and only one-tenth in the French colonies. Yet few Frenchmen had serious doubts about the course of economic policy under the Third Republic.

Economic effects of World War I

Only after the war, and particularly after 1930, were such doubts widely shared. The disruptive impact of the war exceeded the understanding not only of most citizens but also of most political leaders. Efforts to return to normality were futile because the postwar world and France had changed vastly. The enormous cost of a four-year mobilization, of reconstruction, and of war debts had to be borne. By the time of the Great Depression the government had been forced to write off a large share of war costs by devaluing the franc (1928) to one-fifth of its old value, costing many Frenchmen on fixed incomes much of their savings and shaking their confidence in the future. Still, no large group of embittered déclassés was created, ripe for the appeals of a demagogue. And after 1926 there was a brief resurgence of prosperity, so that by the end of the decade the indexes of industrial production, foreign trade, and living standards had risen well above the 1914 peak. Some illusions about the future and hopes of a happy return to prewar stability could therefore be retained.

But by 1935 industrial production had fallen to 79 percent of the 1928 level and exports to 55 percent. Registered unemployment hovered at less than 500,000, but this figure concealed the fact that many urban workers were subsisting on family farms owned by relatives. Besides, the French exported much of their unemployment; thousands of immigrant workers lost their work permits and had to return home. Not until 1938–39 did a measure of recovery set in, thanks to Reynaud's business-oriented policies, plus the stimulus of rearmament. By the time war broke out again, France had barely returned to the predepression level.

The workers, always outside the bourgeois consensus, were by now largely hostile to the system; most of the gains they had finally achieved in 1936 had quickly been snatched away again. But in addition many bourgeois Frenchmen now questioned the virtues of the traditional system. The 1930s therefore brought an intense fermentation of political and social thought; dozens of study groups and movements sprang up in Paris, seeking or preaching doctrines of drastic renovation and structures of government that might carry them out.

Positivism

Cultural and scientific attainments. The cultural climate of the later 19th century in France, as in the Atlantic world generally, was strongly marked by the current called positivism. The post-1848 generation looked with contempt on what it considered the excesses and the bad taste of the preceding Romantic era. A new interest in science and a new vogue of realism in literature and the arts prevailed during the Second Empire; it was best embodied in the novels of Gustave Flaubert and the paintings of Gustave Courbet. By the 1870s this mood had formed into what its advocates regarded as a coherent philosophical system, the content and label of which they borrowed from the French thinker Auguste Comte. These self-styled positivists placed their faith in science and reason as the path to inevitable progress, with only the remnants of superstition (surviving mainly in the church) still blocking the hopeful future. The positivist temper is manifest in the novels of Émile Zola and the paintings of Impressionists such as Édouard Manet, Claude Monet, Edgar Degas, and Pierre-Auguste Renoir.

The French also showed great creativity in pure science and made major discoveries in a wide variety of fields. Among the most notable figures were Louis Pasteur in medicine, Pierre and Marie Curie in physics, Marcelin Berthelot in chemistry, Henri Poincaré in mathematics, and Jean-Martin Charcot in psychopathology. In the social sciences the work of Gustave Le Bon and Émile Durkheim had a broad and enduring impact.

Although the positivist mood prevailed at least until World War I, it was contested by a rival current of thought that from the 1890s onward began to assert itself. To some sensitive people of artistic temperament the positivist outlook seemed arid and narrow, neglecting the emotional side of man. This was the view of the school of poets, including Paul Verlaine and Stéphane Mallarmé, who called themselves Symbolists. A remarkable group of composers carried the new, romantic mood into music: mainstream works by composers such as Jules Massenet, Georges Bizet, and Camille Saint-Saëns were followed by the more experimental compositions of Claude Debussy and Maurice Ravel.

Of significance was the growing influence after 1890 of such writers and thinkers as Paul Bourget, Maurice Barrès, and Henri Bergson. Bourget's novels challenged what he called "brutal positivism" and asserted such traditional values as authority, the family, and the established order. Barrès preached what he called "integral nationalism"; he called for a return to "the sources of national energy," which he found in historic institutions, the soil of the fatherland, and the solidarity between the living and the dead. The philosopher Bergson attacked scientific dogmatism and exalted humankind's nonrational drives—notably a creative force that he called élan vital, which he held distinguishes heroic individuals and nations from the plodding herd.

This new spirit had its parallel in political thought and action as well: in the syndicalist doctrines of Georges Sorel, in the activism of a minority in the labour movement, and in the resurgent nationalism that strongly affected many French young people in the years just before 1914. It also brought a return to the church and to an emotional patriotism. In the fine arts a new generation of painters abandoned both realism and Impressionism. These so-called Postimpressionists were moved by an intense subjectivism, an urge to express in various ways the artist's inner vision and deeper emotions. The changed mood was best embodied in the work of Paul Cézanne, Paul Gauguin, and the Dutch immigrant Vincent van Gogh.

Dadaism and Surrealism

The terrible strain and disillusionment of World War I weighed heavily on French cultural life during the interwar era, leading to the development of the literary and artistic movement called Dadaism. Its program of calculated nonsense was inspired by a deep revulsion against the insanity of war and the positivist view that the world had sense and meaning. Dadaism soon gave way, though, to the more durable Surrealist movement, whose principal theorist and founder was the poet André Breton. The declared goal of Surrealist writers and artists was to free man's unconscious impulses from the distorting controls of rational reflection; creativity, they said, came from deep nonrational drives.

A number of France's most notable writers, however, remained within the older humanistic tradition, yet they likewise reflected the doubts and neuroses of an age of crisis. Marcel Proust, whose massive multivolume novel *À la recherche du temps perdu* (*Remembrance of Things Past*) began to appear in 1913, used the stream-of-consciousness technique to probe, in minutely introspective fashion, into the recesses of his own mind and memory. André Gide, in similarly sensitive and introspective fashion, wrestled with the psychological difficulties arising from the conflict between a bourgeois society's values and the individual's instinctive drives.

As the mood of crisis deepened in the 1930s, so did the intensity of the challenge to old values, bringing men of frankly fascist temper, such as Robert Brasillach, and brutally nihilistic literary experimenters, such as Louis-Ferdinand Céline. But other Frenchmen continued to create works in the older tradition, including the social commentary of Roger Martin du Gard, Georges Duhamel, Jules Romains, and François Mauriac; the Neoromantic novels of André Malraux, preaching a modern gospel of heroic activism; the first writings of Jean-Paul Sartre; and the essays of Emmanuel Mounier, who was to inspire the new Catholic left after World War II.

FRANCE SINCE 1940

Wartime France. The German victory left the French groping for a new policy and new leadership. Some 30 prominent politicians—among them Édouard Daladier and Pierre Mendès-France—left for North Africa to set up a government-in-exile there; but Pétain blocked that enterprise by ordering their arrest on arrival in Morocco. The undersecretary of war in the fallen Reynaud Cabinet, General Charles de Gaulle, had already flown to London and in a radio appeal on June 18, 1940, summoned French patriots to continue the fight; but few heard or heeded his call in the first weeks. It was to Pétain, rather, that most of the nation looked for salvation.

The Vichy government. Parliament met at Vichy on July 9–10 to consider France's future. The session was dominated by Pierre Laval, Pétain's vice premier, who was already emerging as the strongman of the government. Laval, convinced that Germany had won the war and would thenceforth control the Continent, saw it as his duty to adapt France to the new authoritarian age. By skillful manipulation, he persuaded parliament to vote itself and the Third Republic out of existence. The vote (569 to 80) authorized Pétain to draft a new constitution. The draft was never completed, but Pétain and his advisers did embark on a series of piecemeal reforms, which they labeled the National Revolution. Soon the elements of a corporative state began to emerge, and steps were taken to decentralize France by reviving the old provinces. In the early stages of Vichy, Pétain's inner circle—except for Laval and a few others—was made up of right-wing traditionalists and authoritarians. The real pro-fascists, such as Jacques Doriot and Marcel Déat, who wanted a system modeled frankly on those of Hitler and Mussolini, soon left Vichy and settled in Paris, where they accepted German subsidies and intrigued against Pétain.

The end of the Third Republic

In December 1940 Pétain dismissed Laval and placed him briefly under house arrest. Laval had offended Pétain and his followers by his arrogance and his obvious taste for intrigue. His critics charged him also with attempting to bring Vichy France back into the war in alliance with the Germans. Both Laval and Pétain had accepted Hitler's invitation to a meeting at Montoire on Oct. 24, 1940, and during the weeks that followed the French leaders had publicly advocated Franco-German "collaboration." Whether Laval hoped for a real Franco-German alliance remains somewhat controversial. If so, it was a futile effort because Hitler had no interest in accepting France as a trusted partner; "collaboration" remained a French and not a German slogan. Hitler tolerated the temporary existence of a quasi-independent Vichy state as a useful device to help police the country and to collect the enormously inflated occupation costs levied by the armistice.

Laval was succeeded by another prewar politician, Pierre-Étienne Flandin, and he, in turn, by Admiral François Darlan, who was intensely anti-British and an intriguer by nature and who followed a devious path that involved continuing efforts at active collaboration with the Germans. Hitler, meanwhile, concentrated on draining France of raw materials and foodstuffs that were useful for the conduct of the war.

In April 1942 Pétain restored Laval to power, partly under German pressure. Laval retained that post until the collapse of Vichy in 1944. His role was increasingly difficult because the terrible drain of the war in the Soviet Union caused the Germans to increase their exactions. The Germans were short of manpower for their factories, and

Laval, under heavy pressure, agreed to the conscription of able-bodied French workers in return for the release of some French prisoners of war. He also assumed the task of repressing the French underground movement, whose activities hampered the delivery of supplies and men to Germany. After the war Laval and his friends were to argue that he had played a "double game" of limited collaboration to protect France against a worse fate.

German control of all France

Most of Vichy's remaining autonomy and authority was destroyed in November 1942, in direct consequence of the Anglo-American landings in North Africa. Vichy troops in Morocco and Algeria briefly resisted the American invasion, then capitulated when Admiral Darlan, who happened to be visiting Algiers at the time, negotiated an armistice. On November 11 Hitler ordered his troops in the occupied zone to cross the demarcation line and to take over all of France. The Vichy government survived, but only on German sufferance—a shadowy regime with little power and declining prestige.

The Resistance. Vichy's decline was paralleled by the rise of the anti-German underground. Within weeks of the 1940 collapse, tiny groups of French citizens had begun to resist. Some collected military intelligence for transmission to London; some organized escape routes for British airmen who had been shot down; some circulated anti-German leaflets; some engaged in sabotage of railways and German installations. The Resistance movement received an important infusion of strength in June 1941, when Hitler's attack on the Soviet Union brought the French Communist Party into active participation in the anti-German struggle. It was further reinforced by the German decision to conscript French workers; many draftees took to the hills and joined guerrilla bands that took the name maquis ("underbrush"). A kind of national unity was finally achieved in May 1943, when de Gaulle's personal representative, Jean Moulin, succeeded in establishing a National Resistance Council (Conseil National de la Résistance) that joined all the major movements into one federation.

De Gaulle's original call for resistance had attracted only a handful of French citizens who happened to be in Britain at the time. But, as the British continued to fight, a trickle of volunteers from France began to find its way to his headquarters in London. De Gaulle promptly established an organization called Free France and in 1941 capped it with a body called the French National Committee (Comité National Français), for which he boldly claimed the status of a legal government-in-exile. During the next three years, first in London and then (after 1943) in Algiers, he insisted on his right to speak for France and on France's right to be heard as a great power in the councils of the Allies. His demands and his manner irked Churchill and Roosevelt and caused persistent tension. The American government unsuccessfully attempted in 1942 to sidetrack him in favour of General Henri Giraud, who immediately after the Allied landings in North Africa was brought out of France to command the French armies in liberated North Africa and to assume a political role as well. De Gaulle arrived in Algiers in May 1943 and joined Giraud as copresident of a new French Committee of National Liberation. By the end of the year he had outmaneuvered Giraud and emerged as the unchallenged spokesman for French resisters everywhere. Even the Communists in 1943 grudgingly accepted his leadership.

Liberation. When the Allied forces landed in Normandy on June 6, 1944, the armed underground units had grown large enough to play an important role in the battles that followed—harassing the German forces and sabotaging railways and bridges. As the Germans gradually fell back, local Resistance organizations took over town halls and prefectures from Vichy incumbents. De Gaulle's provisional government immediately sent its own delegates into the liberated areas to ensure an orderly transfer of power. On August 19 Resistance forces in Paris launched an insurrection against the German occupiers, and on August 25 Free French units under General Jacques Leclerc entered the city. De Gaulle himself arrived later that day, and on the next he headed a triumphal parade down the Champs-Élysées. Most high-ranking Vichy officials (including Pétain and Laval) had moved eastward with the Germans; at the castle of Sigmaringen in Germany they adopted the posture of a government-in-exile.

Retribution against Vichy officials

De Gaulle's provisional government, formally recognized in October 1944 by the U.S., British, and Soviet governments, enjoyed unchallenged authority in liberated France. But the country had been stripped of raw materials and food by the Germans; the transportation system was severely disrupted by air bombardment and sabotage; 2.5 million French prisoners of war, conscripted workers, and deportees were still in German camps; and the task of liquidating the Vichy heritage threatened to cause grave domestic stress. An informal and spontaneous purge of Vichy officials or supporters had already begun in the summer of 1944; summary executions by Resistance bands appear to have exceeded 10,000.

A more systematic retribution followed. Special courts set up to try citizens accused of collaboration heard 125,000 cases during the next two years. Some 50,000 offenders were punished by "national degradation" (loss of civic rights for a period of years), almost 40,000 received prison terms, and between 700 and 800 were executed.

The Fourth Republic. Shortly after his return to Paris, de Gaulle announced that the citizens of France would determine their future governmental system as soon as the absent prisoners and deportees could be repatriated. That process was largely completed by midsummer 1945, soon after Germany's defeat, whereupon de Gaulle scheduled a combined referendum and election for October. Women, for the first time in French history, were granted suffrage. By an overwhelming majority (96 percent of the votes cast), the nation rejected a return to the prewar regime. The mood of the liberation cra was markcd by a thirst for renovation and for change.

New men of the Resistance movement dominated the constituent assembly, and the centre of gravity was heavily to the left: three-fourths of the dcputics werc Communists, Socialists, or Christian Democrats who had adhered to the new party of the Catholic left—the Popular Republican Movemcnt (Mouvcment Rcpublicain Populaire).

Constitution of the Fourth Republic. It soon becamc clear that the apparent unity forged in the Resistance was supcrficial and that the new political elitc was sharply divided over the form of the new rcpublic. Some urged the need for greater stability through a strong executive; others, notably the Communists, favoured concentrating power in a one-housc legislature subject to grass-roots control by the voters. De Gaullc rcmaincd aloof from this controversy, though it was obvious that he favoured a strong presidency. In January 1946 de Gaullc suddenly resigned his post as provisional presidcnt, apparently cxpecting that a wave of public support would bring him back to power with a mandate to impose his constitutional ideas. Instead, the public was stunncd and confused, and it failed to react. The assembly promptly chose thc Socialist Fèlix Gouin to replace him, and thc embittered dc Gaullc retired to his country estatc.

The assembly's constitutional draft, submitted to a popular referendum in May 1946, was rcjected by the voters. A new assembly was quickly elected to prepare a rcvised draft, which in October was narrowly approved by the voters. De Gaulle actively intervened in the campaign for the second referendum, denouncing the proposed systcm as unworkable and urging the need for a stronger executive. His ideas anticipated the systcm that later was to be embodied in the constitution of thc Fifth Republic (1958).

Political and social changes. The structure of the Fourth Republic seemed remarkably like that of the Third; in actual operation it seemed even more familiar. The lower house of parliament (now renamed the National Assembly) was once more the locus of power; shaky coalition Cabinets again succeeded one another at brief intervals, and the lack of a clear-cut majority in the country or in parliament hampered vigorous or coherent action. Many politicians from the prewar period turned up once again in Cabinet posts.

Yet outside the realm of political structure and parliamentary gamesmanship there were real and fundamental changes. The long sequence of crises that had shaken the nation since 1930 had left a deep imprint on French attitudes. There was much less public complacency; both the routines and the values of the French people had been shaken up and subjected to challenge by a generation of upheaval. Many of the new men who had emerged from the Resistance movement into political life, business posts, or the state bureaucracy retained a strong urge toward renovation as well as to a reassertion of France's lost greatness.

This altered mood helps to explain the economic growth that marked the later years of the Fourth Republic. After a painful period of slow recovery from the war, aided by massive economic aid from the United States, a burst of industrial expansion in most branches of the economy began in the mid-1950s, unmatched in any decade of French history since the 1850s. The rate of growth for a time rivaled that of Germany and exceeded that of most other European countries. The only serious flaw in the boom was a nagging inflationary trend that weakened the franc and undermined the competitiveness of French exports. Short-lived coalition Cabinets were incapable of taking the painful measures needed to check this trend.

Industrial expansion in the 1950s

Colonial independence movements. A less fortunate aspect of the national urge to reassert France's stature in the world was the Fourth Republic's costly effort to hold the colonial empire. France's colonies had provided de Gaulle with his first important base of support as leader of Free France, and as the war continued they had furnished valuable resources and manpower. The colonial peoples, therefore, now felt justified in demanding a new relationship with France, and French leaders recognized the need to grant concessions. But most of these leaders, including de Gaulle, were not prepared to permit any infringement on French sovereignty, either immediately or in the foreseeable future. For a nation seeking to rebuild its self-respect, the prospect of a loss of empire seemed unacceptable; most of the French, moreover, were convinced that the native peoples overseas lacked the necessary training for self-government and that a relaxation of the French grip would merely open the way to domination by another imperial power. The constitution of 1946 therefore introduced only mild reforms: the empire was renamed the French Union, within which the colonial peoples would enjoy a narrowly limited local autonomy plus some representation in the French parliament.

This cautious reform came too late to win acceptance in many parts of the empire. The situation was most serious in Southeast Asia, where the Japanese had displaced the French during World War II. Japan's defeat in 1945 enabled the French to regain control of southern Indochina, but the northern half was promptly taken over by a Vietnamese nationalist movement headed by the communist Ho Chi Minh. French efforts to negotiate a compromise with Ho's regime broke down in December 1946, and a bloody eight-year war followed. In the end, the financial and psychological strain proved too great for France to bear, and, after the capture of the French stronghold of Dien Bien Phu in 1954 by the Vietnamese, the French sought a face-saving solution. A conference of interested powers at Geneva that year ended the war by establishing what was intended as a temporary division of Vietnam into independent northern and southern states. Two other segments of Indochina, the former protectorates of Laos and Cambodia, had earlier been converted by the French into independent monarchies to preserve some French influence there.

Algerian revolt

On the night of Oct. 31, 1954, barely six months after the fighting in Indochina ended, Algerian nationalists raised the standard of rebellion. By 1958 more than a half million French soldiers had been sent to Algeria—the largest overseas expeditionary force in French history. France's determination to hold Algeria stemmed from a number of factors: the presence of almost a million European settlers, the legal fiction that Algeria was an integral part of France, and the recent discovery of oil in the southern desert. Fears that the rebellion might spread to Tunisia and Morocco led the French to make drastic concessions there; in 1956 both of these protectorates became sovereign states.

The long and brutal struggle in Algeria gravely affected the political life of the Fourth Republic and ended by destroying it. A vocal minority in France openly favoured a negotiated settlement, though no political leader dared take so unpopular a position. Right-wing activists, outraged at what they saw as the spread of defeatism, turned to conspiracy; both in Paris and in Algiers, extremist groups began to plot the replacement of the Fourth Republic by a tougher regime, headed by army officers or perhaps by General de Gaulle.

These plans had not yet matured when a Cabinet crisis in April–May 1958 gave the conspirators a chance to strike. On May 13, when a new Cabinet was scheduled to present its program to the National Assembly, activist groups in Algiers went into the streets in an effort to influence parliament's vote. By nightfall they were in control of the city and set up an emergency government with local army support. De Gaulle on May 15 announced that he was prepared to take power if called to do so by his fellow citizens. Two weeks of negotiations followed, interspersed with threats of violent action by the Algiers rebels. Most of the Fourth Republic's political leaders reluctantly concluded that de Gaulle's return was the only alternative to an army coup that might lead to civil war. On June 1, therefore, the National Assembly voted de Gaulle full powers for six months, thus putting a de facto end to the Fourth Republic.

The Fifth Republic. During his years of self-imposed exile, de Gaulle had scorned and derided the Fourth Republic and its leaders. He had briefly sought to oppose the regime by organizing a Gaullist party, but he had soon abandoned this venture as futile. Back in power, he adopted a more conciliatory line; he invited a number of old politicians to join his Cabinet, but he made sure that his own ideas would shape the future by naming his disciple Michel Debré head of a commission to draft a new constitution. This draft, approved in a referendum in September by 79 percent of the valid votes cast, embodied de Gaulle's conceptions of how France should be governed. Executive power was considerably increased at the expense of the National Assembly. The president of the republic was given much broader authority; he would henceforth be chosen by an electorate of local notables rather than by parliament, and he would select the premier (renamed prime minister), who would continue to be responsible to the National Assembly but would be less subject to its whims. In the new National Assembly, elected in November, the largest block of seats was won by a newly organized Gaullist party, the Union for the New Republic (Union pour la Nouvelle République; UNR); the parties of the left suffered serious losses. In December de Gaulle was elected president for a seven-year term, and he appointed Debré as his first prime minister. The Fifth Republic came into operation on Jan. 8, 1959, when de Gaulle assumed his presidential functions and appointed a new government.

Expanded executive power

The new president's most immediate problems were the Algerian conflict and the inflation caused by the war. He attacked the latter, with considerable success, by a program of deflation and austerity. As for Algeria, he seemed at first to share the views of those whose slogan was "Algérie française"; but, as time went by, it became clear that he was seeking a compromise that would keep an autonomous Algeria loosely linked with France. The Algerian nationalist leaders, however, were not interested in compromise, while the diehard French colonists looked increasingly to the army for support against what they began to call de Gaulle's betrayal. Open sedition followed in 1961, when a group of high army officers headed by General Raoul Salan formed the Secret Army Organization (Organisation de l'Armée Secrète; OAS) and attempted to stage a coup in Algiers. When the insurrection failed, the OAS turned to terrorism; there were several attempts on de Gaulle's life. The president pushed ahead nevertheless with his search for a settlement with the Algerians that would combine independence with guarantees for the safety of French colonists and their property. Such a settlement was finally worked out, and in a referendum (April 1962) more than 90 percent of the war-weary French voters approved the agreement. An exodus of European

Free Algeria

settlers ensued; 750,000 refugees flooded into France. The burden of absorbing them was heavy, but the prosperous French economy was able to finance the process despite some psychological strains.

The Algerian crisis speeded the process of decolonization in the rest of the empire. Some concessions to local nationalist sentiment had already been made during the 1950s, and de Gaulle's new constitution had authorized increased self-rule. But the urge for independence was irresistible, and by 1961 virtually all the French territories in Africa had demanded and achieved it. De Gaulle's government reacted shrewdly by embarking on a program of military support and economic aid to the former colonies; most of France's foreign-aid money went to them. This encouraged the emergence of a French-speaking bloc of nations, which gave greater resonance to France's role in world affairs.

The Algerian settlement brought France a respite after 16 years of almost unbroken colonial wars. Prime Minister Debré resigned in 1962 and was replaced by one of de Gaulle's closest aides, Georges Pompidou. The party leaders now began to talk of amending the constitution to restore the powers of the National Assembly. Faced by this prospect, de Gaulle seized the initiative by proposing his own constitutional amendment; it provided for direct popular election of the president, thus further increasing his authority. When de Gaulle's critics denounced the project as unconstitutional, de Gaulle retaliated by dissolving the assembly and proceeding with his constitutional referendum. On October 28, 62 percent of those voting gave their approval, and in the subsequent elections (November) the Gaullist UNR won a clear majority in the assembly. Pompidou was reappointed prime minister.

The Gaullist era

When de Gaulle's presidential term ended in 1965, he announced his candidacy for reelection. For the first time since 1848 the voting was to be by direct popular suffrage. De Gaulle's challengers forced de Gaulle into a runoff, and his victory over the moderate leftist François Mitterrand in the second round by a 55–45 margin was closer than had been predicted but sufficed to assure him of seven more years in power. Although de Gaulle's leadership had not ended political division in France, his compatriots could not ignore the achievements of his first term. Not only had he disengaged France from Algeria without producing a civil war at home, but he could also point to continuing economic growth, a solid currency, and a stability of government that was greater than any living French citizen had known.

The mid-1960s were the golden years of the Gaullist era, with the president playing the role of elected monarch and respected world statesman. France had adjusted well to the loss of empire and to membership in the European Common Market, which brought the country more benefits than costs. De Gaulle could now embark on an assertive foreign policy, designed to restore what he called France's *grandeur;* he could indulge in such luxuries as blocking Britain's entry into the Common Market, ejecting NATO forces from France, lecturing the Americans on their involvement in Vietnam, and traveling to Canada to call for a "free Quebec." He continued the Fourth Republic's initiative in developing both nuclear power and nuclear weapons—the so-called *force de frappe.* His foreign policy enjoyed broad domestic support, and the French people also seemed content with the prosperity and order that accompanied his paternalistic rule.

Beneath the surface, however, basic discontents persisted, and they were startlingly revealed by the crisis that erupted in May 1968. Student disorders in the universities of the Paris region had been sporadic for some time; they exploded on May 3, when a rally of student radicals at the Sorbonne became violent and was broken up by the police. This minor incident quickly became a major confrontation: barricades went up in the Latin Quarter, street fighting broke out, and the Sorbonne was occupied by student rebels, who converted it into a huge commune. The unrest spread to other universities and then to the factories as well; a wave of wildcat strikes rolled across France, eventually involving several million workers and virtually paralyzing the nation. Prime Minister Pompidou ordered the police to evacuate the Latin Quarter and concentrated on negotiations with the labour union leaders. An agreement calling for improved wages and working conditions was hammered out, but it collapsed when the rank-and-file workers refused to end their strike.

By the end of May various radical factions no longer concealed their intent to carry out a true revolution that would bring down the Fifth Republic. De Gaulle seemed incapable of grappling with the crisis or of even understanding its nature. The Communist and trade union leaders, however, provided him with breathing space; they opposed further upheaval, evidently fearing the loss of their followers to their more extremist and anarchist rivals. In addition, many middle-class citizens who had initially enjoyed the excitement lost their enthusiasm as they saw established institutions disintegrating before their eyes.

De Gaulle, sensing the opportune moment, suddenly left Paris by helicopter on May 29. Rumours spread that he was about to resign. Instead, he returned the next day with a promise of armed support, if needed, from the commanders of the French occupation troops in Germany. In a dramatic four-minute radio address, he appealed to the partisans of law and order and presented himself as the only barrier to anarchy or Communist rule. Loyal Gaullists and nervous citizens rallied round him; the activist factions were isolated when the Communists refused to join them in a resort to force. The confrontation moved from the streets to the polls. De Gaulle dissolved the National Assembly, and on June 23 and 30 the Gaullists won a landslide victory. The Gaullist Union of Democrats for the Republic (Union des Démocrates pour la République; UDR, the former UNR), with its allies, emerged with three-fourths of the seats.

The repercussions of the May crisis were nevertheless considerable. The government, shocked by the depth and extent of discontent, made a series of concessions to the protesting groups. Workers were granted higher wages and improved working conditions; the assembly adopted a university reform bill intended to modernize higher education and to give teachers and students a voice in running their institutions. De Gaulle took the occasion to shake up his Cabinet; Pompidou was replaced by Maurice Couve de Murville. De Gaulle evidently sensed the emergence of Pompidou as a serious rival, for the prime minister had shown toughness and nerve during the crisis, while the president had temporarily lost his bearings. The economy also suffered from the upheaval; austerity measures were needed to stabilize things once more.

Although normalcy gradually returned, de Gaulle remained baffled and irritated by what the French called *les événements de mai* ("the events of May"). Perhaps it was to reaffirm his leadership that he proposed another test at the polls: a pair of constitutional amendments to be voted on by referendum. Their content was of secondary importance, yet de Gaulle threw his prestige into the balance, announcing that he would resign if the amendments failed to be approved. Every opposition faction seized upon the chance to challenge the president. On April 27, 1969, the amendments were defeated by a 53 to 47 percent margin, and that night de Gaulle silently abandoned his office. He returned to the obscurity of his country estate and turned once more to the writing of his memoirs. In 1970, just before his 80th birthday, he died of a massive stroke. His passing inspired an almost worldwide chorus of praise, even from those who up to then had been his most persistent critics.

France after de Gaulle. De Gaulle's departure from the scene provoked some early speculation about the survival of the Fifth Republic and of the Gaullist party (the UDR); both, after all, had been tailored to the general's measure. But both proved to be durable, although his successors gave the system a somewhat different tone. Georges Pompidou won the presidency in June 1969 over several left and centre rivals. He adopted a somewhat less assertive foreign policy stance and in domestic affairs showed a preference for classical laissez-faire, reflecting his connections with the business community.

The turn toward a more conservative, business-oriented line contributed to a revival of the political left, which had been decimated by the aftershocks of the events of May 1968. François Mitterrand, leader of a small left-centre party, took advantage of the change in political climate. In 1971 he engineered a merger of several minor factions with the almost moribund Socialist Party and won election as leader of the reinvigorated party. He then persuaded the Communists to join the Socialists in drafting what was called the Common Program, which was a plan to combine forces in future elections and in an eventual coalition government.

The Common Program

Unexpectedly in April 1974 President Pompidou died of cancer. Mitterrand declared his candidacy as representative of the united left, while the conservatives failed to agree on a candidate. The Gaullists nominated Prime Minister Jacques Chaban-Delmas, but a sizable minority of the UDR broke ranks and instead declared support for a non-Gaullist, Valéry Giscard d'Estaing, who was the leader of a business party, the Independent Republicans (Républicains Indépendants). Giscard won over Chaban-Delmas in the first round and narrowly defeated Mitterrand in the runoff.

Despite his conservative connections, the new president declared his goal to be the transformation of France into "an advanced liberal society." As prime minister he chose the young and forceful Jacques Chirac, leader of the Gaullist minority that had bolted the UDR in Giscard's favour. The new leadership pushed through a reform program designed to attract young voters: it reduced the voting age to 18, legalized abortion within certain limits, and instituted measures to protect the environment. But the course of reform was stalled by the oil crisis of 1973, brought on by events in the Middle East. Industrial production slowed, unemployment rose, and inflation threatened.

As discontent grew, Giscard's leadership was challenged by his ambitious prime minister, Chirac. Open rivalry between the two men led Giscard to dismiss Chirac in favour of Raymond Barre, a professional economist. Chirac retaliated by persuading the divided and disheartened Gaullists to transform the UDR into a new party, the Rally for the Republic (Rassemblement pour la République; RPR), with himself as its head. He also gained an additional power base by standing successfully for election to the revived post of mayor of Paris.

While these factional conflicts on the right seemed to assure victory for the united left in the 1978 parliamentary elections, the Socialist-Communist alliance fell apart. The Socialists had made dramatic gains at Communist expense since the Common Program had been adopted, and the Communists decided it was safer to scuttle the agreement. The collapse of leftist unity alienated a large number of left voters and enabled the conservatives to retain control of the National Assembly.

Victory of the left

When Giscard's presidential term ended in May 1981, opinion polls seemed to indicate that he would be elected to a second term. He overcame a vigorous challenge by Chirac in the first round of voting and seemed well placed to defeat the Socialist Mitterrand in the runoff. But Mitterrand surprised the pollsters by scoring a slim victory—the first major victory for the left in three decades. Profiting from the wave of euphoria that followed, Mitterrand dissolved the National Assembly and succeeded once again. The Socialists won a clear majority of seats (269 of the total 491) and seemed in a position to transform France into a social democratic state.

France under a Socialist presidency. *Mitterrand's first term.* Mitterrand moved at once to carry out what appeared to be the voters' mandate. He named as prime minister a longtime Socialist militant, Pierre Mauroy, whose Cabinet was almost solidly Socialist except for four Communists. Major reforms followed quickly. A broad sector of the economy was nationalized (including 11 large industrial conglomerates and most private banks); administrative decentralization shifted part of the state's authority to regional and local councils; social benefits were expanded and factory layoffs made subject to state controls; tax rates were increased at the upper levels; and a special wealth tax was imposed on large fortunes.

The Socialists hoped that other industrial countries would adopt similar measures and that this joint effort would stimulate a broad recovery from the post-1973 recession. Instead, most of the other Western nations took the opposite course, turning toward conservative retrenchment. Isolated in an unsympathetic world and hampered by angry opposition at home, the Socialist experiment sputtered: exports declined, the value of the franc fell, unemployment continued to rise, and capital fled to safe havens abroad. The government was soon forced to retreat. Mauroy was replaced by a young Socialist technocrat, Laurent Fabius, who announced a turn from ideology to efficiency, with modernization the new keynote.

Many leftist voters were disillusioned by this shift. On the far left the Communists withdrew their ministers from the Cabinet. On the far right a new focus of discontent emerged in Jean-Marie Le Pen's National Front (Front National), which scored successes with its xenophobic campaign to expel immigrant workers. To nobody's surprise the Socialists lost control of the National Assembly to the conservative coalition in the March 1986 elections.

Cohabitation

Mitterrand's presidential term still had two years to run. But the Fifth Republic now faced a long-debated test: Could the system function when parliament and president were at odds? Mitterrand chose the path of prudent retreat. He named as prime minister the conservatives' strongest leader, Jacques Chirac of the Gaullist RPR, and abandoned to him most governmental decisions (except on foreign and defense policy, which de Gaulle himself had reserved for the president). This uneasy relationship was promptly labeled "cohabitation"; it lasted two years and in the end worked in Mitterrand's rather than Chirac's favour.

Chirac acted at once to reverse many of the Socialists' reforms. He began the complex process of privatizing the nationalized enterprises, reduced income tax rates at the upper levels and abolished the wealth tax, and removed some of the regulatory controls on industry. These moves brought Chirac praise but also criticism. His popularity suffered in addition from a series of threats to public order—notably a long transport strike and a wave of terrorist attacks on the streets of Paris—that cast some doubt on the government's promise to ensure law and order. As Chirac's approval ratings fell, Mitterrand's recovered. Cohabitation enabled him to avoid making sensitive decisions, and voters gave him credit for faithfully respecting his constitutional limitations.

Mitterrand's second term. Restraint paid dividends when Mitterrand ran for a second term in April–May 1988 and scored a clear victory against Chirac. The resurgent president chose the Socialist Michel Rocard as prime minister and once again dissolved the National Assembly in the hope that the voters would give him a parliamentary majority. However, the Socialists and their allies fell short of a clear majority.

Mitterrand's choice of Rocard as prime minister caused some surprise, for the two men had headed rival factions within the Socialist Party, and they were temperamentally alien. Rocard was a brilliant financial expert and an advocate of government by consensus of left and centre, while Mitterrand was considered a master of political gamesmanship. The uneasy relationship lasted three years, and Rocard managed the economy well enough to maintain his high approval rating in the polls until the end.

Mitterrand's decision to replace Rocard in 1991 with France's first woman prime minister, Edith Cresson, provoked serious controversy. Cresson, a Mitterrand loyalist, had held a variety of Cabinet posts during the 1980s and was seen as an able but tough and abrasive politician. Brash public statements hurt her approval rating, and, after the Socialists suffered disastrous losses in regional elections (March 1992), Mitterrand replaced Cresson with a different sort of Socialist, Pierre Bérégovoy.

Pierre Bérégovoy

Bérégovoy was a rare example of a proletarian who had risen through trade union ranks to political eminence. He had a reputation as an expert on public finance and as an incorruptible politician. His promise to end the plague of financial scandals that had beset recent Socialist governments won applause but left him vulnerable when he, in turn, was accused of having accepted a loan under compromising circumstances. Although no illegality was involved, Bérégovoy's reputation for integrity suffered. In the 1993 parliamentary elections, the Socialists suffered a crushing defeat by the right-wing coalition (RPR and UDR). Bérégovoy resigned as prime minister and a few weeks later shocked the country by committing suicide.

Although the triumphant conservatives called on Mitterrand to resign, he refused; his presidential term still had two years to run. But he had to face cohabitation again, this time with another Gaullist, Édouard Balladur. Chirac chose to avoid the risks of active decision making while he was preparing his own campaign for the presidency.

Mitterrand entered his second cohabitation with his prestige damaged by his party's recent misfortunes. He had also lost stature by a mistaken judgment in his own "reserved" sector of foreign policy. He had been a leading drafter of the Maastricht Treaty (1991), designed to strengthen the institutional structures of the European Community. When the treaty encountered hostile criticism, he gambled on a popular referendum in France to bolster support. The outcome was a bare 51 percent approval by the French voters, and, although it was enough to put Maastricht into effect, the evidence of deep division in France further reduced the president's prestige. Still another embarrassment was the revelation in 1994 that Mitterrand had accepted a bureaucratic post in Pétain's Vichy regime in 1942–43. There were cries of outrage from Socialists and former resisters, yet the shock and fury quickly faded. In some circles he was credited with throwing his critics off balance by his clever management of the news. Prior to his death in January 1996, Mitterrand left his mark culturally on Paris as well, where grandiose architecture projects such as the Opéra de la Bastille, the expanded Louvre, the towering Grande Arche de la Défense, and the new Bibliothèque Nationale de France became his legacy.

Mitterrand's second cohabitation (1993–95) proved more helpful to Prime Minister Balladur than to the president. It also proved deeply disappointing to Jacques Chirac, who had engineered Balladur's appointment on the assumption that the latter would step aside when the presidential election approached. Chirac had failed to see that his stylish and courteous stand-in might develop into his own most serious rival. By 1995 Balladur was the clear front-runner and announced his presidential candidacy against his own party leader, Chirac. Meanwhile, the Socialists, after some initial scrambling to find a viable candidate, endcd by choosing party official Lionel Jospin, who led the field in the first round of voting. Chirac, a vigorous campaigner, outpaced Balladur, and in the runoff he won again, this time against Jospin. His victory brought to an end the 14-year Socialist presidency. (G.Wr.)

Chirac's presidency

The right-of-centre triumph did not last. In the anticipated elections that Chirac called in 1997, a Socialist majority swept back to power, and Jospin returned to head a coalition of Socialists, Communists, and Greens. Whereas the policies of Mitterrand's second term had made concessions to the free market, Chirac's moderate prime minister, Alain Juppé (1995–97), had made serious concessions to the welfare state. Under Jospin, as under Juppé, pragmatic cohabitation struggled to maintain both economic growth and the social safety net. Privatization proceeded apace, inflation remained under control, and the introduction of the euro (the single European currency) in January 1999 boosted competition and investment. Unemployment, however, stubbornly hovered around 12 percent in the last decade of the century, casting doubt on Jospin's hope that growth and social progress would be reconciled. In 2002 Chirac won reelection over extremist Le Pen, whose surprisingly strong showing in the first round of voting led Jospin to announce his resignation. This socioeconomic balancing act remained in place, though, pitting the popularity of progressive social legislation against the difficulties of high taxes, restrictive social security demands on employers, and precarious funding for health and welfare projects.

When France hosted and won the football (soccer) World Cup in 1998, it had been a triumph not only for national sporting pride but for cohabitation at the highest levels, as it showcased multiracial cooperation on a winning squad made up of Arabs, Africans, and Europeans, reflecting France's increasingly diverse society.

France took the world spotlight again in 2003, when the Chirac administration—believing the regime of Iraqi leader Saddam Hussein to be cooperating with United Nations inspectors searching for weapons of mass destruction—led several members of the UN Security Council in effectively blocking UN authorization of the use of force against Iraq.

Two years later, French triumph in diversity crumbled when the accidental deaths of two immigrant teenagers sparked violence in Paris that spread rapidly to other parts of the country in the weeks that followed. Nearly 9,000 cars were torched and nearly 3,000 arrests made during the autumn riots, which were fueled by high unemployment, discrimination, and lack of opportunity within the immigrant community.

Society since 1940. The surge of economic growth that lasted from the mid-1950s to the mid-1970s brought extensive changes in French lifestyles and in some of the society's basic structures. As the century neared its end, most French people had come to enjoy greater comfort and security than their forebears; they took for granted automobiles, modern household appliances, and vacation homes in the country, which had been regarded as luxuries not too long before. The French had been converted to installment buying and supermarket shopping; they spent lcss on food and drink and more on health and leisure. Thanks to the social security system that was expanded after World War II, they were better-protected against the hazards of illness, unemployment, and a neglected old age.

Urbanization

The most striking structural change taking place in France was rapid urbanization. The farm population, which stood at about one-third of the total population in 1940, fell to less than 5 percent in the 1990s; yet farm production increased as modern techniques spread, making France one of the world's leading agricultural exporters. In the industrial regions, modern technology and a new managerial spirit brought France to the threshold of the postindustrial age. The proportion of unskilled workers declined in favour of technically trained specialists, and even more dramatic was the explosive growth in the numbcr of white-collar employees and middle-lcvcl managcrs. At thc basc of this social pyramid was a new prolctariat of immigrants from southern Europe and Africa, who provided the manual labour that most French workers were no longcr willing to perform. In the 1990s thcse immigrants constituted between 5 and 10 percent of France's population, and their presence, aggravated by widespread joblessness, fed social and racial tensions. Anti-immigrant rcsentmcnt spurred the rise of Le Pen's National Front, which called for casting out aliens and reclaiming "France for the French" but benefited more from morosc protest against thc sitting government than from prcjudice. In 1999 the National Front, which always stood more for protcst than principle, succumbcd to internal dissensions and broke apart. With radical factions on the political far right and far lcft in disarray, the next test of French socicty, as of thc national economy, would come from a Europe henceforth without borders or national currencies—where workers, students, businesses, and immigrants from beyond the European Union could move freely from one country to another.

The cultural scene. Paris after World War II quickly regained its stature as one of the world's great centrcs of intellectual creativity. A cluster of brilliant thinkers and writers competed for influence, attracting acolytes both in France and abroad. The first postwar wave was lcd by Jean-Paul Sartre, whose influence made existentialism the leading ideology of the time. Sartre saw the world as "absurd" and irrational, lacking guideposts for humans adrift in a meaningless universe. People, said Sartre, know only that they exist and are free to cast their own lot. In the absence of any guiding power, individuals are condemned to freedom (hence responsibility), forced to forge their own lives, however insecure and contingent these may be, and to give them meaning by commitment to a course of action. Sartre's essays and novels made him the most admired intellectual of his generation and won him the Nobel Prize for Literature in 1964 (which he refused). His rival

Albert Camus, also a Nobel Prize winner, broke with Sartre over the latter's support of the Soviet Union and over Sartre's inability to define an ethical base for commitment to a cause. Camus's agnostic humanism led him to insist that even in an absurd world commitment must rest on clearly defined ethical principles—on the need to resist oppressors and fanatics and to respect the shared humanity of all people.

The dark postwar mood that lent existentialism its appeal faded when economic recovery set in. In the 1960s it was replaced by a new vogue called structuralism, whose scientific aspirations better suited a technological age. Drawing on the ideas of anthropologist Claude Lévi-Strauss, the structuralists stressed the persistence of "deep structures" that were held to underlie all human cultures through time, leaving little room for historical change or human initiative.

Structuralism

For a time structuralism became the dominant intellectual wave both in France and abroad; it showed signs of crystallizing into an ideology or worldview. But by the 1970s it gave way to a cluster of doctrines loosely labeled "post-structuralist," each variety identified with its own master-thinker: the philosopher Jacques Derrida, the intellectual historian Michel Foucault, the psychoanalyst Jacques Lacan, and the Marxologist Louis Althusser.

The structuralist vogue also affected the novelists who, beginning in the mid-1950s, launched *le nouveau roman*. More interested in theory and the subversive play of language than in storytelling, Alain Robbe-Grillet, Nathalie Sarraute, Michel Butor, and their imitators attracted much media and critical attention; but their provocative output stimulated more publicity than sales. Their iconoclastic aspirations were paralleled by those of a *nouvelle vague* of filmmakers such as Claude Chabrol, Jean-Luc Godard, Alain Resnais, and François Truffaut, whose movies of the late 1950s, '60s, and '70s revolutionized French cinema. "New novels" and "new wave" films may be compared to another contemporary creation popularized by the media: nouvelle cuisine, whose aesthetic objectives also evoked more critical than gourmandizing interest.

Those discouraged by pretentious fiction were turning to biography and general history, a realm dominated by the contributions of scholars such as Fernand Braudel, Emmanuel Le Roy Ladurie, and Pierre Nora. Marked by pathbreaking investigation of long-term perspectives and by a vivid, seductive style, their explorations of social, cultural, and economic history proved broadly appealing.

High culture has always seeped into popular culture and coloured it, perhaps more so in France than in other countries. Today, in France as elsewhere, the reverse is also true: the culture of everyday life encourages dislocations that elude socioeconomic and national boundaries. Differences of taste or of opinion, once dismissed as superficial, aggravate moral and political rifts. Sponsored by past Socialist governments as popular art, pop music in the 1960s called *yé-yé* ("yeah-yeah") and hip-hop music and graffiti art at the end of the 20th century were perceived by some as playful and by others as threatening. Multiculturalism was both welcomed as emancipating and scorned as divisive, as was the diffuse anti-Americanism, which for many stood in for antimodernism. All these disruptions were by-products of accelerated societal change, yet on all these cultural fronts French works and ideas continued to generate worldwide attention and, often, imitation.

(G.Wr./Eu.W.)

For later developments in the history of France, see the BRITANNICA BOOK OF THE YEAR.

For coverage of related topics in the *Macropædia* and *Micropædia,* see the *Propædia,* sections 912, 921, 923, 924, 961, 963, and 972, and the *Index*.

BIBLIOGRAPHY

Geography. *General works:* Comprehensive surveys of the country, using both descriptive and analytic approaches, include PHILIPPE PINCHEMEL *et al., France: A Geographical, Social, and Economic Survey* (1987; originally published in French, 1964); CHRISTOPHER FLOCKTON and ELEONORE KOFMAN, *France* (1989); HILARY P.M. WINCHESTER, *Contemporary France* (1993); and XAVIER DE PLANHOL, *An Historical Geography of France* (1994; originally published in French, 1988), all with important bibliographies. See also MICHELIN PNEU, *Michelin: atlas routier et touristique*, 3rd ed. (1999), a useful reference source with more detailed information than its title suggests.

Land: Characteristics of major physical regions of France are provided in CLIFFORD EMBLETON (ed.), *Geomorphology of Europe* (1984); and GÉRARD MOTTET, *Géographie physique de la France*, 3rd rev. and enlarged ed. (1999). COMITÉ NATIONAL FRANÇAIS DE GÉOGRAPHIE, *Atlas de la France rurale: les campagnes françaises* (1984), contains maps and photographs illustrating aspects of rural France, both by type of agriculture and by region; and ANDRÉ BRUN *et al., Le Grand Atlas de la France rurale* (1989), provides documentation on all aspects of life from the point of view of agricultural geography. IAN SCARGILL, *Urban France* (1983), includes case studies of new towns.

Human geography: General overviews of regional planning, demography, social structure, economic conditions, culture, and politics are found in JOHN ARDAGH, *France in the New Century: Portrait of a Changing Society* (1999); J.E. FLOWER (ed.), *France Today: Introductory Studies*, 8th ed. (1997); ROBERT GILDEA, *France Since 1945* (1996, updated 2002); and EMMANUEL TODD, *La Nouvelle France* (1988, reissued 1990). Urban France is discussed in MARYSE FABRIÈS-VERFAILLIE, PIERRE STRAGIOTTI, and ANNIE JOUVE, *La France des villes: le temps des métropoles*, 2nd ed. (2000). Demographic analyses are provided in DANIEL NOIN and YVAN CHAUVIRÉ, *La Population de la France*, 5th ed., updated (1999); and ALEC G. HARGREAVES, *Immigration, 'Race,' and Ethnicity in Contemporary France* (1995).

Economy: Comprehensive surveys of modern economic conditions include JOHN TUPPEN, *The Economic Geography of France* (1983); JEAN-FRANÇOIS ECK, *La France dans la nouvelle économie mondiale*, 3rd ed. updated (1998); MARCEL BALESTE, *L'Économie française*, 13th ed. rev. (1995); and JOHN TUPPEN, *France Under Recession, 1981–1986* (1988). Additional surveys include COLIN GORDON and PAUL KINGSTON, *The Business Culture in France* (1996); JOSEPH SZARKA, *Business in France: An Introduction to the Economic and Social Context* (1992); DOMINIQUE TADDEI and BENJAMIN CORIAT, *Made in France: l'industrie française dans la competition mondiale* (1993); and JEAN JACQUES TUR, *Géographie humaine et économique de la France* (1994). Comprehensive regional studies can be found in MARCEL BALESTE *et al., La France: les 22 régions*, 5th ed. (2001); and PIERRE ESTIENNE, *Les Régions françaises*, 2 vol. (1999). Current developments are brought together in ORGANISATION FOR ECONOMIC CO-OPERATION AND DEVELOPMENT, *OECD Economic Surveys: France* (annual). Studies of special features of the French economy include DOMINIQUE GAMBIER and MICHEL VERNIERES, *L'Emploi en France*, new ed. (1998); NACIMA BARON-YELLÈS, *Le Tourisme en France: territoires et stratégies* (1999); LAURENCE BANCEL-CHARENSOL, JEAN-CLAUDE DELAUNAY, and MURIEL JOUGLEUX, *Les Services dans l'economie française* (1999); and PIERRE BLOC-DURAFFOUR, *L'Industrie française* (1999).

Politics and society: Studies of political administration include SUDHIR HAZAREESINGH, *Political Traditions in Modern France* (1994); ALISTAIR COLE, *French Politics and Society* (1998); JAMES F. MCMILLAN, *Twentieth-Century France: Politics and Society 1898–1991* (1992); NICK HEWLETT, *Modern French Politics: Analysing Conflict and Consensus Since 1945* (1998); and MAURICE LARKIN, *France Since the Popular Front: Government and People 1936–1996*, 2nd ed. (1997). Law is treated in CHRISTIAN DADOMO and SUSAN FARRAN, *The French Legal System*, 2nd ed. (1996); and JOHN BELL *et al., Principles of French Law* (1998). The more specific question of decentralization is examined in JEAN MARC OHNET, *Histoire de la décentralisation française* (1996). Health care is discussed in MARC DURIEZ *et al., Le Système de santé en France*, 2nd updated ed. (1999). Social conditions and organizations in the social sphere are the focus of PIERRE LAROQUE (ed.), *Les Institutions sociales de la France*, updated ed. (1963, reissued 1980). A general view of contemporary features of French society is given in INSEE, *Données sociales: la société française* (1999), as well as *France, portrait social 1998–1999*, 2nd ed. (1999). A detailed discussion of urban policy is provided in ANTOINE ANDERSON, *Politiques de la ville* (1998).

Culture: Philosophical perspectives of French cultural life are examined in ALAIN FINKIELKRAUT, *The Defeat of the Mind* (1995; also published as *The Undoing of Thought*, 1988; originally published in French, 1987). BERNARD-HENRI LÉVY, *Éloge des intellectuels* (1987), is an introduction to intellectual life. DENIS HOLLIER (ed.), *A New History of French Literature* (1989, reissued 1994), discusses the literature from 842 onward. General views of the culture are given in JILL FORBES and MICHAEL KELLY (eds.), *French Cultural Studies: An Introduction* (1995); MAX SILVERMAN, *Facing Postmodernity: Contemporary French Thought on Culture and Society* (1999); MARTIN COOK (ed.), *French Culture Since 1945* (1993); and ALEX HUGHES and KEITH READER, *Encyclopedia of Contemporary French Culture* (1998, reissued 2002). (T.H.El./J.N.T./J.F.P.B./Jo.E.F.)

History. *General works:* A great historian's review of the long sweep of French history, from prehistoric times to the mod-

ern era, is FERNAND BRAUDEL, *The Identity of France*, 2nd ed. (1988–90; originally published in French, 1986), and *The Identity of France: People and Production* (1990; originally published in French, 1986). Excellent thematic treatments are provided in MARC BLOCH, *French Rural Society: An Essay on Its Basic Characteristics* (1966; originally published in French, 1931), a classic study; FERNAND BRAUDEL and ERNEST LABROUSSE (eds.), *Histoire économique et sociale de la France* (1970–82); GEORGES DUBY and ARMAND WALLON (eds.), *Histoire de la France rurale*, 4 vol. (1975–76, reprinted 1992); and GEORGES DUBY (ed.), *Histoire de la France urbaine*, 5 vol. (1980–85).

Gaul: A stimulating overview of Gaul in the context of French prehistory and early history is found in J.M. WALLACE-HADRILL and JOHN MCMANNERS (eds.), *France: Government and Society*, 2nd ed. (1970). Outstanding investigations of particular sites and areas of relevance to the study of Gaul as a whole are EDITH MARY WIGHTMAN, *Gallia Belgica* (1985); and A.L.F. RIVET, *Gallia Narbonensis: With a Chapter on Alpes Maritimae: Southern France in Roman Times* (1988). Life in later Roman Gaul is studied in JOHN MATTHEWS, *Western Aristocracies and Imperial Court, A.D. 364–425* (1975, reissued 1998); and RAYMOND VAN DAM, *Leadership and Community in Late Antique Gaul* (1985, reissued 1992). (J.F.Dr./J.D.P.)

Merovingian and Carolingian age (Early Middle Ages): A comprehensive introduction to the period is found in J.M. WALLACE-HADRILL, *The Barbarian West, 400–1000*, 3rd rev. ed. (1998). The Merovingians are considered in PATRICK J. GEARY, *Before France and Germany* (1988), and J.M. WALLACE-HADRILL, *The Long-Haired Kings and Other Studies in Frankish History* (1962, reprinted 1982). PIERRE RICHÉ, *The Carolingians: A Family Who Forged Europe* (1993; originally published in French, 1983) focuses on the Carolingians. Special studies of the civilization of the period include J.M. WALLACE-HADRILL, *The Frankish Church* (1983); SUZANNE FONAY WEMPLE, *Women in Frankish Society: Marriage and the Cloister, 500 to 900* (1981, reprinted 1985); and GEORGES DUBY, *The Early Growth of the European Economy: Warriors and Peasants from the Seventh to the Twelfth Century* (1974, reissued 1978; originally published in French, 1973). (G.Fo./B.S.Ba./J.D.P.)

The emergence of France, c. 850–1180: This period as a whole is well treated in JEAN DUNBABIN, *France in the Making, 843–1180* (1985). The political history of this and the succeeding periods is surveyed best in ELIZABETH M. HALLAM and JUDITH EVERARD, *Capetian France, 987–1328*, 2nd ed. (2001); but ROBERT FAWTIER, *The Capetian Kings in France: Monarchy & Nation, 987–1328* (1960, reissued 1982; originally published in French, 1942), is still a useful classic. Social change and feudalization are studied in MARC BLOCH, *Feudal Society* (1961, reprinted 1989; originally published in French, 1939–40), a seminal work. An alternative to Bloch's model has been developed by GEORGES DUBY, *La Société aux XI^{e} et XII^{e} siècles dans la région mâconnaise* (1953, reissued 1988), and *The Three Orders: Feudal Society Imagined* (1980; originally published in French, 1978). DOMINIQUE BARTHELEMY, *La Mutation de l'an mil, a-t-elle eu lieu?: servage et chevalerie dans la France des X^{e} et XI^{e} siècles* (1997).

France in the later Middle Ages, 1180–1490: The general political history of the period cited is covered in the works of HALLAM and EVERARD and FAWTIER listed in the previous section. Individual reigns are studied in JOHN W. BALDWIN, *The Government of Philip Augustus: Foundations of French Royal Power in the Middle Ages* (1986); and WILLIAM CHESTER JORDAN, *Louis IX and the Challenge of the Crusade: A Study in Rulership* (1979). Economy and society are studied in GEORGES DUBY, *Rural Economy and Country Life in the Medieval West* (1968, reprinted 1998; originally published in French, 1962). Social unrest is discussed in MICHEL MOLLAT and PHILIPPE WOLFF, *The Popular Revolutions of the Late Middle Ages* (1973; originally published in French, 1970). CHARLES PETIT-DUTAILLIS, *The French Communes in the Middle Ages* (1978; originally published in French, 1947), remains the standard account on the cities and towns. (T.N.B./J.D.P.)

France from 1490 to 1715: JANINE GARRISSON, *History of Sixteenth-Century France* (1995; originally published in French, 1991); and EMMANUEL LE ROY LADURIE, *The Royal French State, 1460–1610* (1994; originally published in French in 1987), offer clear summaries of French history from the Renaissance through the Wars of Religion. DAVID POTTER, *A History of Modern France, 1460–1560* (1995), is institutional rather than chronological in approach. J. RUSSELL MAJOR, *Representative Government in Early Modern France* (1980), and *From Renaissance Monarchy to Absolute Monarchy: French Kings, Nobles & Estates* (1994), explain the role of representative assemblies. SARAH HANLEY, *The Lit de Justice of the Kings of France: Constitutional Ideology in Legend, Ritual, and Discourse* (1983), analyzes one particularly important aspect of the relationship between monarch and institutions. See also R.J. KNECHT, *Renaissance Warrior and Patron: The Reign of Francis I*, rev. and expanded ed. (1994); and DAVID PARKER, *Class and State in Ancien Régime France: The Road to Modernity?* (1996). DONALD R. KELLEY, *The Beginning of Ideology: Consciousness and Society in the French Reformation* (1981), is a study of political thought.

ROBIN BRIGGS, *Early Modern France, 1560–1715*, 2nd ed. (1998), is a reliable introduction to 17th-century history. On the religious wars, MACK P. HOLT, *The French Wars of Religion, 1562–1629* (1995), is an able synthesis. BARBARA B. DIEFENDORF, *Beneath the Cross* (1991), shows the social origins of the rival religious parties. ROLAND MOUSNIER, *The Assassination of Henry IV* (1973; originally published in French, 1964), is a brilliant analysis of the intersection of politics and religion at the beginning of the 17th century.

YVES-MARIE BERCÉ, *The Birth of Absolutism: A History of France, 1598–1661* (1996; originally published in French, 1992), is an admirably clear narrative of the rise of the absolutist monarchy. JAMES B. COLLINS, *The State in Early Modern France* (1995, reissued 1999), is an overview of the development of monarchical institutions from 1600 to the Revolution. DAVID BUISSERET, *Henry IV* (1984, reissued 1992), is a good life of the monarch who ended the religious wars. A. LLOYD MOOTE, *Louis XIII, the Just* (1989), brings Henri IV's enigmatic successor to life. Other works on the period's political developments include JOSEPH BERGIN, *Cardinal Richelieu: Power and the Pursuit of Wealth* (1985); J.H. SHENNAN, *The Parlement of Paris*, rev. ed. (1998); N.M. SUTHERLAND, *The French Secretaries of State in the Age of Catherine de Medici* (1962, reprinted 1976); RICHARD BONNEY, *The King's Debts: Finance and Politics in France, 1589–1661* (1981), and *Society and Government in France Under Richelieu and Mazarin, 1624–61* (1988); and SHARON KETTERING, *Patrons, Brokers, and Clients in Seventeenth-Century France* (1986). YVES-MARIE BERCÉ, *History of Peasant Revolts* (1990; originally published in French, 1986), synthesizes scholarship on popular movements. OREST RANUM, *The Fronde: A French Revolution* (1993), is a concise summary of the confusion of conflicts from 1648 to 1653. GEOFFREY TREASURE, *Mazarin: The Crisis of Absolutism in France* (1995), is a thorough biography of the man who preserved Richelieu's handiwork and set the stage for Louis XIV's reign. ELIZABETH RAPLEY, *The Dévotes: Women and Church in Seventeenth-Century France* (1990, reissued 1993), highlights the role of women in the period's Catholic revival.

JAMES R. FARR, *Hands of Honor: Artisans and Their World in Dijon, 1550–1650* (1988); and GEORGES VIGARELLO, *Concepts of Cleanliness: Changing Attitudes in France Since the Middle Ages* (1988; originally published in French, 1985), discuss social conditions.

The Age of Louis XIV: PIERRE GOUBERT, *Louis XIV and Twenty Million Frenchmen* (1970; originally published in French, 1966), provides a synthesis of Louis's reign. FRANÇOIS BLUCHE, *Louis XIV* (1990; originally published in French, 1986), is the most recent full biography of France's most famous king. DANIEL DESSERT, *Louis XIV prend le pouvoir* (1989, reissued 2000), offers a revisionist account of the reign's beginnings. ALBERT N. HAMSCHER, *The Parlement of Paris After the Fronde, 1653–1673* (1976), and *The Conseil Privé and the Parlements in the Age of Louis XIV: A Study in French Absolutism* (1987), provide good introductions to the period. ROGER METTAM, *Power and Faction in Louis XIV's France* (1988); and ROGER METTAM (ed.), *Government and Society in Louis XIV's France* (1977), analyze the political structure. WILLIAM BEIK, *Absolutism and Society in Seventeenth-Century France* (1985), demonstrates in detail how Louis XIV's government enlisted the collaboration of the nobility. JOHN A. LYNN, *Giant of the Grand Siècle: The French Army 1610–1715* (1997), recounts the rise of the main tool of France's international power. WARREN C. SCOVILLE, *The Persecution of Huguenots and French Economic Development, 1680–1720* (1960), is important in assessing the effects of the revocation of the Edict of Nantes. PETER BURKE, *The Fabrication of Louis XIV* (1992), shows the interconnection between politics and art under the "Sun King." (J.H.Sh./J.D.P.)

France from 1715 to 1789: ALEXIS DE TOCQUEVILLE, *The Old Régime and the French Revolution* (1955, reprinted 1978; originally published in French, 1856), is still a basic source for the study of the period. Comprehensive histories include DANIEL ROCHE, *France in the Enlightenment* (1998; originally published in French, 1993), a detailed survey of the period's society and culture; and vol. 1 of ALFRED COBBAN, *A History of Modern France*, 3 vol. (1969). MICHEL ANTOINE, *Louis XV* (1989), is both a biography and an exhaustive account of high politics in that monarch's reign. GUY CHAUSSINAND-NOGARET, *The French Nobility in the Eighteenth Century* (1985; originally published in French, 1986), explains the changing nature of the country's ruling elite.

STEVEN LAURENCE KAPLAN, *Provisioning Paris: Merchants and Millers in the Grain and Flour Trade During the Eighteenth Century* (1984), describes a basic feature of the period's economy. Economic histories make much use of the 18th-century travelogue of ARTHUR YOUNG, *Travels During the Years 1787, 1788 & 1789: Undertaken More Particularly with a View of Ascertain-*

ing the Cultivation, Wealth, Resources, and National Prosperity of the Kingdom of France, 2nd ed., 2 vol. (1794), available in many later editions. There are fascinating glimpses of urban life in LOUIS-SÉBASTIEN MERCIER, *Panorama of Paris: Selections from Tableau de Paris* (1999; originally published in French, 1781); and JACQUES-LOUIS MÉNÉTRA, *Journal of My Life* (1986; originally published in French, 1982). The culture and ideology of the period are explored in ROBERT DARNTON, *The Forbidden Best-Sellers of Pre-Revolutionary France* (1995); LIESELOTTE STEINBRÜGGE, *The Moral Sex: Woman's Nature in the French Enlightenment* (1995; originally published in German, 1992); DENA GOODMAN, *The Republic of Letters: A Cultural History of the French Enlightenment* (1994); and THOMAS E. CROW, *Painters and Public Life in Eighteenth-Century Paris* (1985). DAVID BELL, *The Cult of the Nation* (2001), offers an important new analysis of the growth of national identity. A classic analysis of Rousseau's thought is JEAN STAROBINSKI, *Jean-Jacques Rousseau, Transparency and Obstruction* (1988; originally published in French, 1957). KEITH MICHAEL BAKER, *Inventing the French Revolution* (1990); and DALE K. VAN KLEY, *The Religious Origins of the French Revolution* (1996), show how revolutionary ideas developed out of prerevolutionary political discourse. (P.Hi./J.D.P.)

France from 1789 to 1815: Reliable overviews of the period include D.M.G. SUTHERLAND, *France 1789–1815: Revolution and Counter-Revolution* (1985); WILLIAM DOYLE, *The Oxford History of the French Revolution* (1989); and NORMAN HAMPSON, *A Social History of the French Revolution* (1963, reissued 1995).

The origins of the Revolution are considered in JEAN EGRET, *The French Pre-Revolution* (1977; originally published in French, 1962); and WILLIAM DOYLE, *Origins of the French Revolution*, 3rd ed. (1998). The best book on the Terror is still R.R. PALMER, *Twelve Who Ruled: The Year of the Terror in the French Revolution* (1941, reissued 1989). GEORGE RUDÉ, *Robespierre* (1967), provides excerpts from the Jacobin leader's speeches. MARTYN LYONS, *France Under the Directory* (1975), surveys the Revolution's later phase. FRANÇOIS FURET and MONA OZOUF (eds.), *A Critical Dictionary of the French Revolution* (1989; originally published in French, 1988), is an important and original collection of short essays on selected events, actors, institutions, ideas, and historians of the French Revolution. LYNN HUNT, *Politics, Culture, and Class in the French Revolution* (1984), analyzes the imagery and sociology of Revolutionary politics. Notable thematic studies include GEORGES LEFEBVRE, *The Great Fear of 1789: Rural Panic in Revolutionary France* (1973, reissued 1989; originally published in French, 1932); P.M. JONES, *The Peasantry in the French Revolution* (1988); ALBERT SOBOUL, *The Parisian Sans-culottes and the French Revolution, 1793–4*, trans. from French (1964, reprinted 1979); GEORGE RUDÉ, *The Crowd in the French Revolution* (1959, reprinted 1986); DOMINIQUE GODINEAU, *The Women of Paris and Their French Revolution* (1998; originally published in French, 1988); JOHN MCMANNERS, *The French Revolution and the Church* (1969, reprinted 1982); JEAN-PAUL BERTAUD, *The Army of the French Revolution* (1988; originally published in French, 1979); EMMET KENNEDY, *A Cultural History of the French Revolution* (1989); and JACQUES GODECHOT, *The Counter-Revolution: Doctrine and Action, 1789–1804* (1971, reissued 1981; originally published in French, 1961). The international dimension of the Revolution is interpreted in R.R. PALMER, *The World of the French Revolution* (1971). The best biography of a Revolutionary leader is LEO GERSHOY, *Bertrand Barère: A Reluctant Terrorist* (1962). JOHN HARDMAN, *Louis XVI* (1993), is a life of the movement's most illustrious victim; and the reasons for his fate are explained in DAVID JORDAN, *The King's Trial* (1979, reprinted 1993). ISSER WOLOCH, *The New Regime* (1994), shows how the Revolution's principles were institutionalized. JEREMY D. POPKIN, *Revolutionary News* (1990), explains the "media revolution" that was an integral part of the upheaval after 1789.

MARTYN LYONS, *Napoleon Bonaparte and the Legacy of the French Revolution* (1994), is a good overview. Napoleon's life is the subject of FELIX MARKHAM, *Napoleon* (1963); JEAN TULARD, *Napoleon: The Myth of the Saviour* (1984; originally published in French, 1977); and GEOFFREY ELLIS, *Napoleon* (1997, reissued 2000). The best volume on the Napoleonic regime in France is LOUIS BERGERON, *France Under Napoleon* (1981; originally published in French, 1972). OWEN CONNELLY, *Blundering to Glory: Napoleon's Military Campaigns*, rev. ed. (1999), is a critical and incisive analysis. (I.Wo./J.D.P.)

France since 1815: Vol. 2 and 3 of the already mentioned ALFRED COBBAN, *A History of Modern France*, 3 vol. (1957–62, reprinted 1969), present the period from the First Empire to the Republics in a sophisticated synthesis. GORDON WRIGHT, *France in Modern Times: From the Enlightenment to the Present*, 5th ed. (1995); and JEREMY D. POPKIN, *History of Modern France*, 2nd ed. (2001), are general surveys. Good introductions to the periods they cover are H.A.C. COLLINGHAM and R.S. ALEXANDER, *The July Monarchy 1830–1848* (1988); MAURICE AGULHON, *The Republican Experiment 1848–1852* (1983; originally published in French, 1973); ALAIN PLESSIS, *Rise and Fall of the Second Empire 1852–1871* (1985); JEAN-MARIE MAYEUR and MADELEINE RÉBERIOUX, *The Third Republic from Its Origins to the Great War 1871–1914* (1984; originally published in French, 1973); EUGEN WEBER, *The Hollow Years: France in the 1930s* (1994); JULIAN JACKSON, *France: The Dark Years, 1940–1944* (2002); JEAN-PIERRE RIOUX, *The Fourth Republic 1944–1958* (1987; originally published in French, 1980–83); and SERGE BERSTEIN, *The Republic of de Gaulle 1958–1969* (1993). SERGE BERSTEIN, *La France de l'expansion: l'apogée Pompidou 1969–1974* (1995), continues the story through the presidency of de Gaulle's successor. ANNIE MOULIN, *Peasantry and Society in France Since 1789* (1991; originally published in French, 1988); and GÉRARD NOIRIEL, *Workers in French Society in the 19th and 20th Centuries* (1990; originally published in French, 1986), are good introductions to social history.

Surveys of special topics on all or most of the period since 1815 include RENÉ RÉMOND, *The Right Wing in France from 1815 to de Gaulle*, 2nd ed. (1969; originally published in French, 1954), tracing change and continuity of the political right; GÉRARD CHOLVY and YVES-MARIE HILAIRE, *Histoire religieuse de la France contemporaine*, 3 vol. (1985–88, reissued 2000), an analysis of the role of various religions; and RAOUL GIRARDET, *La Société militaire dans la France contemporaine, 1815–1939*, updated ed. (1998), on the changing role and composition of the military corps. The role of France in world affairs is emphasized in PIERRE RENOUVIN, *Le XIX^e*, 2 vol. (1954–55), on the developments of the 19th century, part of the series *Histoire des relations internationales*. FRANÇOIS CARON, *An Economic History of Modern France*, trans. from French (1979, reissued 1983), revises older views about France's rate of growth. THEODORE ZELDIN, *France, 1848–1945*, 2 vol. (1973–77), explores modern French society, stressing its complexity and continuity. EUGEN WEBER, *Peasants into Frenchmen: The Modernization of Rural France: 1870–1914* (1976), argues that a sense of nationhood came to rural France only in the late 19th century.

Period studies include GUILLAUME DE BERTIER DE SAUVIGNY, *The Bourbon Restoration* (1966; originally published in French, 1955), the standard work on the period 1815–30; CLAIRE GOLDBERG MOSES, *French Feminism in the Nineteenth Century* (1984), which narrates the growth of women's movements; BONNIE G. SMITH, *Ladies of the Leisure Class* (1981), a model study of women's lives; DAVID H. PINKNEY, *Decisive Years in France, 1840–1847* (1986), arguing that France changed fundamentally in these years; PHILIP NORD, *The Republican Moment* (1995), which analyzes the rise of opposition to the Second Empire; MICHAEL B. MILLER, *The Bon Marché: Bourgeois Culture and the Department Store, 1869–1920* (1981); MICHAEL HOWARD, *The Franco-Prussian War: The German Invasion of France, 1870–1871*, 2nd ed. (2001), a model study; and EUGEN WEBER, *France fin de siècle* (1986). ROGER SHATTUCK, *The Banquet Years: The Origins of the Avant Garde in France, 1885 to World War I*, rev. ed. (1968, reissued 1984), is a brilliant survey of Parisian culture of the period. D.W. BROGAN, *France Under the Republic: The Development of Modern France (1870–1939)* (1940, reprinted 1974), is a classic account. JEAN-DENIS BREDIN, *The Affair: The Case of Alfred Dreyfus* (1986; originally published in French, 1983), provides a highly readable account of the great crisis.

The 20th century is studied in EUGEN WEBER, *Action Française: Royalism and Reaction in Twentieth Century France* (1962), a full analysis of this right-wing movement; ZEEV STERNHELL, *La Droite révolutionnaire, 1885–1914: les origines françaises du fascisme*, new ed., enlarged (2000), a controversial argument that fascism was born in France; JEAN-JACQUES BECKER, *The Great War and the French People* (1985, reissued 1993; originally published in French, 1980), which shows how France endured the ordeal of total war; ROBERT O. PAXTON, *Vichy France: Old Guard and New Order, 1940–1944* (1972, reissued 2001), a critical analysis of the Pétain regime; JEAN-BAPTISTE DUROSELLE, *La Décadence, 1932–1939*, 3rd rev. ed. (1985), and *L'Abîme: 1939–1945*, 2nd rev. ed. (1986, reissued 1990), 2 vol. of devastating analysis of French foreign policy before and during World War II; PHILIPPE BURRIN, *France Under the Germans* (1996; originally published in French, 1995), a synthesis of research on the occupation; CHARLES DE GAULLE, *War Memoirs*, 3 vol. (1955–60; originally published in French, 1954–60), and *Memoirs of Hope: Renewal and Endeavor* (1971; originally published in French, 2 vol., 1970–71), indispensable for an understanding of the Gaullist era; JEAN LACOUTURE, *Charles de Gaulle*, 3 vol. (1984–86), a full and perceptive biography; ROBERT GILDEA, *France Since 1945*, rev. ed. (2001), good on the postwar period; and ALFRED GROSSER, *Affaires extérieures: la politique de la France, 1944–1989* (1989), a penetrating analysis of postwar France's role in the world. JULIUS W. FRIEND, *The Long Presidency: France in the Mitterrand Years, 1981–1995* (1998), is a handy guide. HUGH DAUNCEY and GEOFF HARE (eds.), *France and the 1998 World Cup: The National Impact of a World Sporting Event* (1999), examines France as the host country and winner of the 1998 football (soccer) championships. (G.Wr./Eu.W.)

Franklin

Benjamin Franklin, next to George Washington possibly the most famous 18th-century American, by 1757 had made a small fortune, established the Poor Richard of his almanacs (written under the pseudonym Richard Saunders) as an oracle on how to get ahead in the world, and become widely known in European scientific circles for his reports of electrical experiments and theories. What is more, he was then just at the beginning of a long career as a politician, in the course of which he would be chief spokesman for the British colonies in their debates with the king's ministers about self-government and would have a hand in the writing of the Declaration of Independence, the securing of financial and military aid from France during the American Revolution, the negotiation of the treaty by which Great Britain recognized its former 13 colonies as a sovereign nation, and the framing of the Constitution, which for two centuries has been the fundamental law of the United States of America.

Franklin, portrait by Joseph-Siffred Duplessis, *c.* 1784.

And as impressive as Franklin's public service was, it was perhaps less remarkable than his contributions to the comfort and safety of daily life. He invented a stove, still being manufactured, to give more warmth than open fireplaces; the lightning rod and bifocal eyeglasses also were his ideas. Grasping the fact that by united effort a community may have amenities which only the wealthy few can get for themselves, he helped establish institutions one now takes for granted: a fire company, a library, an insurance company, an academy, and a hospital. In some cases these foundations were the first of their kind in North America.

One might expect universal admiration for a man of such breadth and apparent altruism. Yet Franklin was disliked by some of his contemporaries and has ever since occasionally been attacked as a materialist or a hypocrite. D.H. Lawrence, the English novelist, regarded him as the embodiment of the worst traits of the American character. Max Weber, the German sociologist, made him the exemplar of the "Protestant ethic," a state of mind that contributed much, Weber thought, to the less admirable aspects of modern capitalism. Those who admire Franklin believe that his detractors have mistakenly identified him with Poor Richard, a persona of his own creation, or that they have relied too largely upon the incomplete self-portrait of his posthumously published *Autobiography.*

Youth in Boston

Early life (1706–23). Franklin was born in Boston, Massachusetts, on Jan. 17 (Jan. 6, Old Style), 1706, the 10th son of the 17 children of a man who was both soapmaker and candlemaker. He learned to read very early and had one year in grammar school and another under a private teacher, but his formal education ended when he was 10. At 12 he was apprenticed to his brother James, a printer. His mastery of the printer's trade, of which he was proud to the end of his life, was achieved between 1718 and 1723. In the same period he read tirelessly and taught himself to write effectively.

His first enthusiasm was for poetry, and in the first years of his apprenticeship he wrote two occasional ballads, no copies of which have survived. His father told him that "Verse-makers were always Beggars," and thereafter his interest in poetry was sporadic. Prose was another matter. *The Spectator,* Joseph Addison and Richard Steele's famous periodical of essays, had appeared in England in 1711–12 and was to be imitated for the greater part of a century but seldom with the persistence of Franklin, the printer's apprentice. He would read an essay, make a short note of the idea of each sentence, lay aside his notes for a few days, and then try to rewrite the essay. Comparison of his version with the original showed him the need to enlarge his vocabulary. Turning some *Spectator* papers into verse, and some days later reconverting them into prose, helped.

Influence of *The Spectator*

In 1721 James Franklin founded a *Spectator*-like weekly newspaper, the *New-England Courant,* to which readers were invited to contribute. Benjamin, now 16, read and perhaps set in type these contributions and decided that he could do as well himself. In 1722 he wrote a series of 14 essays signed "Silence Dogood." Satire of New England funeral elegies and of the lip service paid the learned languages at Harvard College foreshadowed later literary techniques to be used by Franklin.

Late in 1722 James Franklin got into trouble with the provincial authorities and was forbidden to print or publish the *Courant.* To keep the paper going, he discharged his younger brother from his original apprenticeship and made him the paper's nominal publisher. New indentures were drawn up but not made public. Some months later, after a bitter quarrel, Benjamin walked out, sure that James would not go to law and reveal the subterfuge he had devised. "It was not fair in me to take this Advantage," he wrote later, "and this I therefore reckon one of the first Errata [mistakes, in printer's lingo] of my Life."

Arrival in Philadelphia

Youthful adventures (1723–26). Failing to find work in Boston or New York City, Franklin proceeded to Philadelphia. One of the dramatic scenes of the *Autobiography* is the description of his arrival on a Sunday morning, tired and hungry. Finding a bakery, he asked for three pennies' worth of bread and got "three great Puffy Rolls." Carrying one under each arm and munching on the third, he walked up Market Street past the door of the Read family, where stood Deborah, his future wife. She saw him "& thought I made as I certainly did a most awkward ridiculous Appearance."

A few weeks later he was rooming at the Reads' and employed as a printer. By the spring of 1724 he was enjoying the companionship of other young men with a taste for reading and he was also being urged to set up in business for himself by the governor of Pennsylvania, Sir William Keith. At Keith's suggestion, Franklin returned to Boston to try to raise the necessary capital. His father thought him too young for such a venture, so Keith offered to foot the bill himself and arranged Franklin's passage to England so that he could choose his type and make connections with London stationers and booksellers. Franklin exchanged "some promises" with Deborah Read and, with a young friend, James Ralph, as companion, boarded the *London Hope* in November, expecting to find the letters of credit and introduction that Keith had promised. Not until the ship was well out at sea did he realize that the governor had not kept his promise. A fellow passenger, a Quaker merchant by the name of Thomas Denham, told him that Keith was unreliable; eventually Franklin could write charitably: "He wish'd to please every body; and, having little to give, he gave Expectations."

Years in London

In London Franklin quickly found employment in his trade and was able to lend money to Ralph, who was trying to establish himself as a writer. The two young men enjoyed the theatre and the other pleasures of the city; before long Ralph found a milliner for a mistress. When Ralph was in the country, teaching school, the milliner occasionally borrowed money from Franklin. "I grew fond of her Company," he remembered, "and being at this time under no Religious Restraints, & presuming on my Importance to her, I attempted Familiarities (another Erratum) which she repuls'd with a proper Resentment, and acquainted him with my Behaviour."

Still another "erratum" in retrospect was *A Dissertation on Liberty and Necessity, Pleasure and Pain* (1725), a deistical pamphlet he was inspired to write after having set type for William Wollaston's moral tract *The Religion of Nature Delineated.* Franklin argued therein that since man has no real freedom of choice he is not morally responsible for his actions, perhaps consoling himself for his treatment of Deborah, to whom he had written only once.

By 1726 Franklin was tiring of London. He considered becoming an itinerant teacher of swimming, but when Denham offered him a clerkship in his store in Philadelphia, with a prospect of fat commissions in the West Indian trade, he decided to return home.

Achievement of security and fame (1726–52). Denham died, however, a few months after Franklin entered his store. The young man, now 20, returned to his trade and in 1728 was able to set up a partnership with a friend. Two years later he borrowed money to become sole proprietor.

His private life at this time was extremely complicated. Deborah Read had married, but her husband had deserted her and disappeared. One matchmaking venture failed because Franklin wanted a settlement to pay off his business debt. A strong sexual drive, "that hard-to-be-govern'd Passion of Youth," was sending him to "low Women," and in the winter of 1730–31 he had a son, William, whose mother has never been identified. Franklin must have known that the child was expected when, his affection for Deborah having "revived," he "took her to Wife" on Sept. 1, 1730. Their common-law marriage lasted until Deborah's death in 1774. They had a son, who died at age four, and a daughter, Sarah, who survived them both. William was brought up in the household.

Wife and children

Franklin and his partner's first coup was securing the printing of Pennsylvania's paper currency. Franklin helped get this business by writing *A Modest Enquiry into the Nature and Necessity of a Paper Currency* (1729), and later he also became public printer of New Jersey, Delaware, and Maryland. Other money-making ventures included the *Pennsylvania Gazette,* published by Franklin from 1729 and generally acknowledged as among the best of the colonial newspapers, and the *Poor Richard's* almanacs, printed annually from 1732 to 1757. Some failures, of course, occurred: a German-language newspaper that lasted less than a year and a monthly magazine that expired after six issues in 1741. Franklin was nevertheless generally prosperous; he made enough to invest capital in real estate and in partnerships or working arrangements with printers in the Carolinas, New York, and the British West Indies. In 1748 he became a silent partner in the printing firm of Franklin and Hall, realizing in the next 18 years an average profit of almost £500 annually.

The first of his projects for social improvement by collective effort was the Junto, or Leather Apron club, organized in 1727 to debate questions of morals, politics, and natural philosophy and to exchange knowledge of business affairs. The need of Junto members for easier access to books led in 1731 to the organization of the Library Company of Philadelphia. Through the Junto, Franklin proposed a paid city watch, or police force. A paper read to the same group resulted in the organization of a volunteer fire company. In 1743 he called for a "constant correspondence" of men with scientific interests throughout the colonies, and later that year the American Philosophical Society was functioning. In 1749 he published *Proposals Relating to the Education of Youth in Pennsilvania;* in 1751, the Academy of Philadelphia, from which grew the University of Pennsylvania, was founded. So successful was Franklin as a promoter that anyone with a good cause in mind was likely to turn to him for help.

Franklin was also early involved in politics. He was clerk of the Pennsylvania legislature from 1736 until 1751 and postmaster of Philadelphia from 1737 until 1753. Prior to 1748, though, his most important political service was his part in organizing a militia for the defense of the colony against possible invasion by the French and the Spaniards, whose privateers were operating in the Delaware River. His skill in appealing to the self-interest of the various factions in the commonwealth is demonstrated in *Plain Truth; or, Serious Considerations on the Present State of the City of Philadelphia and Province of Pennsylvania* (1747).

Investigations in electrical science

In the 1740s electricity was a novel and fashionable subject. It was introduced to Philadelphians by an electrical machine sent to the Library Company by one of Franklin's English correspondents. In the winter of 1746–47, Franklin and three of his friends began to investigate electrical phenomena. The Philadelphia weather favoured them, as did the availability of talented instrument makers. Ingenious experiments and machines were devised and described in personal letters to England, which were relayed to the Royal Society of London or the *Gentleman's Magazine.* These papers were collected in 1751 as *Experiments and Observations on Electricity* and were translated into French (1752), German (1758), and Italian (1774).

Franklin's fame spread rapidly. The experiment he suggested to prove the identity of lightning and electricity was first made in France before he is believed to have tried the simpler but dangerous expedient of flying a kite in a thunderstorm. He and his associates concluded early that the "Electrical Fire" was "an Element diffused among, and attracted by other matter, particularly by Water and Metals." When a body with an overquantity approached one with an underquantity, a discharge equalized the electrical fire in the two. This "one fluid" theory accounted for more of the observable phenomena than had any previous hypothesis, and his suggestion that buildings be protected from lightning by erecting pointed iron rods proved both practical and dramatic. Franklin may not have been as original as some admirers have thought, and his collaborators may not have received their full share of credit, but he invented many terms still used in discussing electricity (positive, negative, battery, conductor, and so on) and described the experiments with lucidity.

Intercolonial concerns

Public service (1753–85). In 1753 Franklin became deputy postmaster general, in charge of mail in all the northern colonies. Thereafter he began to think in intercolonial terms. His "Plan of Union," adopted by the Albany Congress in 1754, would have established a general council, with representatives from the several colonies, to organize the common defense against the encroaching French and to supervise Indian relations with new settlements. Reason was on Franklin's side, but neither the colonial legislatures nor the king's advisers were ready for such union, and this conflict has been regarded by some authorities as the key to his entire political career.

In 1755 Franklin was nearly ruined when he promised to stand good for the loss of horses and wagons supplied by Pennsylvania farmers to support General Edward Braddock's ill-fated campaign against Fort-Duquesne in the French and Indian War. For more than two months he faced the possibility of having to pay almost £20,000 out of his own pocket. The government eventually paid.

The need for funds to defend the frontier led the Pennsylvania legislature to seek to tax the lands of the Penn family, the proprietors under the colony's charter. Either their consent or a change in the form of government was required. In the spring of 1757 Franklin was chosen to represent the legislature in this matter, which occupied him in London for most of his time until August 1762. He negotiated a compromise, under which the Penns agreed to taxation of improved lands but not those unsurveyed. During this first mission he made close friends in England

and wrote *The Interest of Great Britain Considered with Regard to Her Colonies and the Acquisitions of Canada and Guadaloupe* (1760). It was designed to urge the annexation of Canada when the war was over. There were Englishmen who preferred to leave Canada to the French, as a check on the growing strength of the 13 colonies. A simpler check, Franklin wrote, would be for Parliament to pass a law requiring midwives to stifle every third or fourth child as soon as it was born.

The Treaty of Paris (1763), ending the Seven Years' War, gave Canada to Great Britain. By that time Franklin was back in Philadelphia, where, in conflict with the proprietors, the legislature decided that Pennsylvania ought to become a crown colony, and by the end of 1764 Franklin was back in London to negotiate in vain for a new charter.

Role in the Stamp Act crisis

The tribulations of Pennsylvania were submerged, however, in the flood of feeling surrounding the so-called Stamp Act crisis. Franklin opposed the Stamp Act, asserting that taxation ought to be the prerogative of the representative legislatures, but when it had been passed he made the mistake of underestimating American emotions; he ordered stamps for Franklin and Hall and nominated a friend for the post of stamp officer in Philadelphia. His fellow citizens were so outraged that Deborah, fearful of her house being mobbed, called on male relatives for armed defense. In London Franklin, recognizing his error, quickly did an about-face and threw himself into the campaign for repeal of the statute. He regained his prestige by a dramatic appearance before the House of Commons, where he answered 174 questions from an audience partly friendly and partly hostile. The stenographic report of the exchange showed him returning often to the right of the colonies to levy internal taxes by their own legislation.

Although he failed to get the new charter, Franklin was kept on as London agent for Pennsylvania, and three other colonies relied on him to represent their interests—Georgia (1768), New Jersey (1769), and Massachusetts (1770). With this support and that of the British Whigs, the party of industrialists and dissenters in favour of parliamentary and philanthropic reform, he weathered the succession of crises ending with armed clashes at Lexington and Concord. He was gradually forced to the realization that there could be no reconciliation and that his dream of a British empire of self-governing nations would not come true. He did his best to present the American case to the British. Between 1765 and 1775 he published 126 newspaper articles on current controversies. At the end he was bitter, in such articles as "Rules by Which a Great Empire May Be Reduced to a Small One" and "An Edict by the King of Prussia," both first printed in 1773. Taken together, they are a capsule history of the long-drawn-out contest. In January 1774, because he had helped publish the letters of Thomas Hutchinson, governor of Massachusetts, to his British superiors, Franklin was dismissed from the post office. In March 1775, aware that there might be war, he left for Philadelphia. The day after his arrival he was a delegate to the Second Continental Congress, for which he served on committees for the organization of a postal system and for the drafting of the Declaration of Independence and on a commission that vainly attempted to bring Canada into the war as an ally.

Mission in Paris

In September 1776, the Congress agreed to send a commission to France to seek economic and military assistance. As one of three commissioners, Franklin arrived in Paris just before Christmas and was immediately engaged in secret negotiations with Charles Gravier, Count de Vergennes, minister of foreign affairs. Spies and informers infested his house, but Franklin was soon the hero of France, personifying the unsophisticated nobility of the New World, leading his people to freedom from the feudal past. His portrait was everywhere, on objets d'art from snuffboxes to chamber pots, his society sought after by diplomats, scientists, Freemasons, and fashionable ladies alike. The adulation was not without its ridiculous side, but Franklin, with his fur hat and spectacles, rose to the occasion with wit and social grace.

The sought-for treaties were signed in February 1778 after the British general John Burgoyne and 5,000 men surrendered at Saratoga, N.Y., and it was clear that the rebellion would not be crushed easily. Substantial loans were given to the revolutionists, and by the final victory at Yorktown in 1781, an estimated 12,000 soldiers and 32,000 sailors had left France to support General George Washington.

Despite these strong bonds, the peace was difficult. Spain had entered the war in 1779, hoping to recover Gibraltar, but, because of the conflict of interests in Florida and Louisiana, refused to recognize American independence. France had guaranteed that there would be no separate peace. Franklin worked with Vergennes until his fellow commissioners, John Adams and John Jay, overruled him on procedure, signing preliminary agreements with Great Britain late in 1782 without prior consultation with France. The formal treaty was signed Sept. 3, 1783.

Franklin wanted to return home but was kept in Paris for two more years to help make trade treaties. His popularity unabated, he observed the first balloon ascension and served on a committee appointed by Louis XVI to report on "animal magnetism," or hypnotism, thought by a German physician to cure many, if not all, diseases.

Role in the U.S. Constitutional Convention

Last years (1785–90). At 79, with a large stone in his bladder that made travel by carriage an agony, Franklin was carried to the port of Le Havre in a litter. Back in Philadelphia he lived quietly but continued to take some part in public life. His most important service was as a member of the Constitutional Convention of 1787. There he failed to convince his associates that an executive committee would be better than a president as head of state and that there should be a unicameral legislature. On the last day of the convention, a colleague read for him a plea that objections to the new form of government, his own among them, should be forgotten and that delegates should unanimously support the instrument that they had hammered out. Franklin's motion was promptly carried.

For the last year of his life he was bedridden, escaping severe pain only by the use of opium. He died on April 17, 1790, aged 84. Philadelphia gave him the most impressive funeral the city had ever seen, and in France, where Louis XVI was imprisoned, eulogies poured forth to the man who, to the French, was the symbol of enlightenment and freedom. All Europeans remembered the epigram of Anne-Robert-Jacques Turgot, the French economist: "He snatched the lightning from the skies and the sceptre from tyrants."

MAJOR WORKS

POLITICAL AND ECONOMIC: *A Modest Enquiry into the Nature and Necessity of a Paper Currency* (1729); *Plain Truth; or Serious Considerations on the Present State of the City of Philadelphia* (1747); *Proposals Relating to the Education of Youth in Pensilvania* (1749); *Observations Concerning the Increase of Mankind* (1755); *The Way to Wealth* (1757); *The Interest of Great Britain Considered with Regard to Her Colonies and the Acquisition of Canada and Guadaloupe* (1760); *Positions to be Examined Concerning National Wealth* (1769); *Journal of the Negotiations for Peace* (1782).

RELIGIOUS, PHILOSOPHICAL, AND SCIFNTIFIC: *A Dissertation on Liberty and Necessity, Pleasure and Pain* (1725); *Articles of Belief and Acts of Religion* (1728); *Experiments and Observations on Electricity* (1751).

OTHER WORKS: *Poor Richard's* (1732–57), an almanac that has many famous maxims; Franklin's *Autobiography* (1771–88); *Information to Those Who Would Remove to America* (1784).

BIBLIOGRAPHY. *The Papers of Benjamin Franklin*, 22 vol., ed. by LEONARD W. LABAREE *et al.* (1959–82), with additional volumes expected, is the definitive collection. *The Writings of Benjamin Franklin*, 10 vol., ed. by ALBERT H. SMYTH (1905–07, reprinted 1970), has heretofore been the chief collection. A full biography is CARL VAN DOREN, *Benjamin Franklin* (1938, reissued 1980); a good brief biography is VERNER W. CRANE, *Benjamin Franklin and a Rising People* (1954). See also RONALD W. CLARK, *Benjamin Franklin* (1983), a popular biography; THOMAS J. FLEMING, *The Man Who Dared the Lightning: A New Look at Benjamin Franklin* (1971); ARTHUR B. TOURTELLOT, *Benjamin Franklin: The Shaping of Genius, 1706–1723* (1977), a study of his heritage and youth; CLAUDE-ANNE LOPEZ and EUGENIA W. HERBERT, *The Private Franklin: The Man and His Family* (1975); BRIAN M. BARBOUR (ed.), *Benjamin Franklin: A Collection of Critical Essays* (1979), with emphasis on his roles as writer and shaper of the American national character; and BRUCE INGHAM GRANGER, *Benjamin Franklin, An American Man of Letters* (1964, new ed. 1976). Frederick the Great

Frederick II the Great, third king of Prussia from 1740 to 1786, ranks among the two or three dominant figures in the history of modern Germany. Under his leadership Prussia became one of the great states of Europe. Its territories were greatly increased and its military strength displayed to striking effect. From early in his reign Frederick achieved a high reputation as a military commander, and the Prussian army rapidly became a model admired and imitated in many other states. He also emerged quickly as a leading exponent of the ideas of enlightened government, which were then becoming influential throughout much of Europe; indeed, his example did much to spread and strengthen those ideas. Notably, his insistence on the primacy of state over personal or dynastic interests and his religious toleration widely affected the dominant intellectual currents of the age. Even more than his younger contemporaries, Catherine II the Great of Russia and Joseph II in the Habsburg territories, it was Frederick who, during the mid-18th century, established in the minds of educated Europeans a notion of what "enlightened despotism" should be. His actual achievements, however, were sometimes less than they appeared on the surface; indeed, his inevitable reliance on the landowning officer (Junker) class set severe limits in several respects to what he could even attempt. Nevertheless, his reign saw a revolutionary change in the importance and prestige of Prussia, which was to have profound implications for much of the subsequent history of Europe.

Frederick II, portrait by Antoine Pesne (1683–1757). In the Gemäldegalerie, Berlin.

Tension between father and son

Early life. Frederick was born on Jan. 24, 1712, in Potsdam, near Berlin. He was the eldest surviving son of Frederick William I, king of Prussia, and Sophia Dorothea of Hanover, daughter of George I of Britain. Frederick's upbringing and education were strictly controlled by his father, who was a martinet as well as a paranoiac. Encouraged and supported by his mother and his sister Wilhelmina, Frederick soon came into bitter conflict with his father. Frederick William I deeply despised the artistic and intellectual tastes of his son and was infuriated by Frederick's lack of sympathy with his own rigidly puritanical and militaristic outlook. His disappointment and contempt took the form of bitter public criticism and even outright physical violence, and Frederick, beaten and humiliated by his father, often over trifling details of behaviour, took refuge in evasion and deceit. This personal and family feud culminated spectacularly in 1730, when Frederick was imprisoned in the fortress of Küstrin after planning unsuccessfully to flee initially to France or Holland. Lieutenant Hans Hermann von Katte, the young officer who had been his accomplice in the plan, was executed in Frederick's presence, and there was for a short time a real possibility that the prince might share his fate. During the next year or more Frederick, as a punishment, was employed as a junior official in local administration and deprived of his military rank. The effects of this terrible early life are impossible to measure with accuracy, but there is little doubt that the violent and capricious bullying of his father influenced him deeply.

In 1733, after a partial reconciliation with his father, Frederick was married to a member of a minor German princely family, Elizabeth Christine of Brunswick-Bevern, for whom he never cared and whom he systematically neglected. In the following year he saw active military service for the first time under the great Austrian commander Eugene of Savoy against the French army in the Rhineland. In the later 1730s, in semiretirement in the castle of Rheinsberg near Berlin and able for the first time to give free rein to his own tastes, he read voraciously, absorbing the ideas on government and international relations that were to guide him throughout his life. These years were perhaps the happiest that Frederick ever experienced. However, his relations with his father, though somewhat improved, remained strained.

Accession to the throne and foreign policy. Frederick William I died on May 31, 1740, and Frederick, on his accession, immediately made it clear to his ministers that he alone would decide policy. Within a few months he was given a chance to do so in a way that revolutionized Prussia's international position. The Holy Roman emperor Charles VI, of the Austrian house of Habsburg, died on October 20, leaving as his heir a daughter, the archduchess Maria Theresa, whose claims to several of the heterogeneous Habsburg territories were certain to be disputed. Moreover, her army was in a poor state, the financial position of the Habsburg government very difficult, and her ministers mediocre and in many cases old. Frederick, however, thanks to his father, had a fine army and ample funds at his disposal. He therefore decided shortly after the emperor's death to attack the Habsburg province of Silesia, a wealthy and strategically important area to which the Hohenzollerns, the ruling family of Prussia, had dynastic claims, though weak ones. The most important threat to his plans was Russian support for Maria Theresa, which he hoped to avert by judicious bribery in St. Petersburg and by exploiting the confusion that was likely to follow the imminent death of the empress Anna. He also hoped that Maria Theresa would cede most of Silesia in return for a promise of Prussian support against her other enemies, but her refusal to do so made war inevitable.

Invasion of Silesia

The first military victory of Frederick's reign was the battle of Mollwitz (April 1741), though it owed nothing to his own leadership; in October Maria Theresa, now threatened by a hostile coalition of France, Spain, and Bavaria, had to agree to the Convention of Klein-Schnellendorf, by which Frederick was allowed to occupy the whole of Lower Silesia. However, the Habsburg successes against the French and Bavarians that followed so alarmed Frederick that early in 1742 he invaded Moravia, the region south of Silesia, which was under Austrian rule. His rather incomplete victory at Chotusitz in May nonetheless forced Maria Theresa to cede almost all of Silesia by the Treaty of Berlin of 1742 in July. This once more allowed Habsburg forces to be concentrated against France and Bavaria, and 1743 and the early months of 1744 saw Maria Theresa's position in Germany become markedly stronger. Frederick, again alarmed by this, invaded Bohemia in August 1744 and rapidly overran it. However, by the end of the year lack of French support and threats to his lines of communication had forced him to retreat. Moreover, the elector Augustus III (king of Poland and the elector of Saxony) now joined Maria Theresa in attacking him in Silesia. He was rescued from this threatening situation by the prowess of his army; victories at Hohenfriedberg in June 1745 and at Soor in September were followed by a Prussian invasion of Saxony. The Treaty of Dresden, signed on Dec. 25, 1745, finally established Prussian rule in Silesia and ended for the time being the complex series of struggles that had begun five years earlier.

Silesia was a valuable acquisition, being more developed economically than any other major part of the Hohenzollern dominions. Moreover, military victory had now made Prussia at least a semigreat power and marked Frederick as the most successful ruler in Europe. He was well aware, however, that his situation was far from secure. Maria Theresa was determined to recover Silesia, and the peace she signed with France and Spain at Aix-la-Chapelle in 1748 allowed her to accelerate significant improvements in the administration of her territories and the organization of her army. Frederick's alliance with France, which dated from an agreement of June 1741, was based merely on mutual hostility toward the Habsburgs and had never been effective. More serious, anti-Prussian feeling was now running high in Russia, where both the empress Elizabeth, who had ascended the throne in 1741, and her chancellor, Aleksey Bestuzhev-Ryumin, bitterly disliked Frederick. Moreover, Great Britain, under George II, seeking an effective continental ally against France, seemed to be moving closer to Maria Theresa and Elizabeth. In September 1755 Britain signed an agreement with Russia by which Russia, in return for British subsidies, was to provide a large military force in its Baltic provinces to protect, if necessary, the electorate of Hanover, ruled by George II, against possible French or Prussian attack. Frederick was deeply alarmed by this: a hostile Austro-Russian alliance backed by British money seemed to threaten the destruction of Prussia. In January 1756 he attempted to escape from this menacing situation by an agreement with Britain for the neutralization of Germany in the Anglo-French colonial and naval war that had just begun. This, however, deeply antagonized Louis XV and the French government, who saw the agreement as an insulting desertion of France, Frederick's ostensible ally. The result was the signature in May of a Franco-Austrian defensive alliance. This did not in itself threaten Frederick, but he soon became convinced that a Russo-Austrian attack on him, with French support, was imminent. He determined to forestall his enemies and, in a daring move, invaded Saxony in August 1756 and marched on into Bohemia. This action has been more actively debated by historians than any other event of Frederick's reign because it raised in an acute form the general issue regarding the morality of preventive military action. Though Frederick took the offensive and thus unleashed a great military struggle, there is no doubt that he was by 1756 seriously threatened, indeed, even more seriously than he himself realized, and that his enemies, most of all the empress Elizabeth, meant to destroy Prussia's newly won international status.

Invasion of Saxony and Bohemia

The Seven Years' War, on which he embarked thus soon became a life-and-death struggle. In 1757 France, Sweden, Russia, and many of the smaller German states joined the ranks of his opponents, while the Prussian invasion of Bohemia collapsed after a serious defeat at Kolín in June. Brilliant victories over the French and Austrian armies, respectively, at Rossbach and Leuthen in November and December partially reestablished Frederick's position, but it still remained extremely precarious. Ruthless exploitation of every available resource (notably of much of Saxony, which was under Prussian military occupation during most of the war), debasement of the currency, and a British subsidy that he received in 1758–62 allowed Frederick with increasing difficulty to keep up the unequal struggle. More than anything, however, he was helped by the complete failure of his enemies to cooperate effectively, while a partly British and British-financed army in western Germany from 1758 onward neutralized the French military effort. Nevertheless, the strain was immense; in October 1757 a cabinet order suspended all payment of salaries and pensions to Prussian civil servants and judges apart from diplomats serving abroad. Frederick could still win victories in the field, as, for example, at Zorndorf (August 1758) against the Russians at heavy cost or at Liegnitz and Torgau (August and November 1760) against the Austrians. But he also suffered serious defeats at Hochkirch in October 1758 and above all at the hands of a Russian army at Kunersdorf in August 1759. This disaster temporarily reduced him to despair and thoughts of suicide; if it had been effectively followed up by his adversaries, he could not have continued the struggle. As the forces he could put in the field dwindled and resistance grew among his subjects to the unprecedented burdens imposed by the war (in 1760 the landowners of Brandenburg refused to contribute further), the Prussian position became increasingly difficult; by 1761 it was desperate. However, the death in January 1762 of the empress Elizabeth, the most bitter of all Frederick's enemies, completely changed the situation. Her successor, Peter III, a fanatical admirer of Prussia and Frederick, signed an armistice in May, followed by a Russo-Prussian peace treaty. This turn of events ended Maria Theresa's hopes of recovering Silesia. The Treaty of Hubertusburg (Feb. 15, 1763), which ended the war in Germany, left the province in Frederick's hands. Prussia had survived, and its military reputation was now greater than ever. The cost had been enormous, however. The Prussian army had lost 180,000 men during the struggle, and some Prussian provinces had been completely devastated.

The Treaty of Hubertusburg

Henceforth Frederick was determined to avoid another such conflict: the alliance with Russia that he signed in 1764 and which lasted until 1780 was directed largely to this end. Nevertheless, he still firmly opposed any growth of Habsburg power in Germany, and in July 1778 a new Austro-Prussian struggle broke out over the efforts of the emperor Joseph II, the son of Maria Theresa, to gain a large part of Bavaria. This War of the Bavarian Succession was half-hearted and short-lived, and the Treaty of Teschen ending it in May 1779 was a severe check to Joseph's ambitions and a diplomatic victory for Frederick. But this new conflict showed unmistakably that Austro-Prussian rivalry stemming from the events of 1740–41 was now a deeply ingrained fact of German political life. Fear of Habsburg ambitions continued to haunt Frederick to the end of his reign. His last significant achievement was to inspire the formation, in July 1785, of the League of Princes (Fürstenbund), which united a number of German states—the most important being Hanover, Saxony, and the archbishopric of Mainz—in successful opposition to Joseph II and his renewed efforts to acquire the whole of Bavaria in exchange for the Austrian Netherlands.

The first partition of Poland

The most important foreign policy development in the second half of Frederick's reign was the first partition of Poland, in 1772. By this Prussia gained the Polish province of West Prussia (though without the great commercial city of Danzig), and thus Brandenburg and Pomerania, the core of the monarchy, became linked with the theretofore isolated East Prussia. This gave the state a much greater territorial coherence and more defensible frontiers. It also moved its geographic centre decisively to the east and sharpened the social and political differences that tended to separate it from the states of western Europe.

Frederick had always hoped for territorial gains of this kind, and, as the weakness and confusion of the internally divided Polish republic increased during the 1760s, the possibilities of realizing them grew. In 1769 he tried indirectly to interest Catherine II of Russia in a partition but in vain. By January 1771, however, faced by strong Austrian opposition to her expansionist ambitions in southeastern Europe, the empress had changed her mind. The visit to St. Petersburg in that month of Frederick's younger brother Prince Henry played a decisive role in making a partition possible; the Habsburg government, which had hoped to recover Silesia or gain territory in the Balkans, was persuaded to join in the process. Frederick bears much of the responsibility for the partition, for he alone of the monarchs who took part had consciously desired it. Since both Russia and Austria were persuaded to follow a policy that was largely Prussian in inspiration, it ranks as perhaps his greatest diplomatic success.

Domestic policies. In administrative, economic, and social policy Frederick's attitudes were essentially conservative. Much of what he did in these areas was little more than a development of policies pursued by his father. He justified these policies in terms of the rationalizing rhetoric of "enlightened despotism," whereas the devoutly Protestant Frederick William I had done so in terms of religious obligation, but many of the objectives, and the means used to attain them, were the same. Frederick, in spite of his appalling personal relationship with his father, admired him as a ruler and freely acknowledged the debt he owed him. "Only his care," he wrote during the Seven Years' War, "his untiring work, his scrupulously just policies, his great and admirable thriftiness and the strict discipline he introduced into the army which he himself had created, made possible the achievements I have so far accomplished."

Concept of rulership

Like Frederick William I, Frederick thought of kingship as a duty. To him it entailed obligations to be met only by untiring and conscientious work. It was his duty to protect his subjects from foreign attack, to make them prosperous, to give them efficient and honest administration, and to provide them with laws that were simple and adapted to their wants and their particular temperament. In order to achieve these objectives, the ruler must sacrifice his own interests and any purely personal or family feeling. *Raison d'état,* the needs of the state, took precedence over these and also over the immediate comfort and happiness of his subjects. The ruler could carry out his duties effectively only if he kept the reins of government firmly in his own hands. His rule must be personal. He must not rely on ministers who were likely to be influenced by selfish ambitions or factional feeling and who might well keep important information from their master if they were allowed to. Personal rule alone could produce the unity and consistency essential to any successful policy. In his *Anti-Machiavel,* a somewhat conventional discussion of the principles of good government published in 1740 just before his accession, Frederick wrote that there were two sorts of princes—those who ruled in person and those who merely relied on subordinates. The former were "like the soul of a state" and "the weight of their government falls on themselves alone, like the world on the back of Atlas," whereas the second group were mere phantoms. Yet he would have rejected outright, and on the whole with justification, any suggestion that he ruled as a despot. On the contrary, he would have claimed that his power, however great, was exercised only within limits set by law and that the obligations inherent in his position made it impossible for him to govern in an arbitrary way.

The insistence that any effective monarchical rule must be intensely personal had obvious potential dangers. As Frederick grew older, these showed themselves with increasing clarity. His whole psychology was hostile to the development in the Prussian administration or army of any real originality, new ideas, or willingness to take initiatives or accept individual responsibilities. He fostered among those who served him a tendency to play safe and to perform their duties conscientiously but to do no more than that. Under him the Prussian administration was the most honest and hardworking in Europe. Its achievements, however, stemmed from the impetus supplied from above by the king rather than from any creative force inherent in the system itself. The provincial War and Domains Chambers established by Frederick William I in 1722 remained very important, and their number grew from 9 to 12. The General Directory, again created by Frederick William, as the main organ of central government with wide-ranging powers, acquired under Frederick several new departments (for commerce and manufactures in 1740, for mines and metallurgy in 1768, for forestry a few years later) but tended, as the reign went on, to become ossified and to lose a good deal of its former importance. The administration of Silesia after its acquisition in the 1740s was notably efficient, and its resources helped greatly in carrying Frederick through the dark days of the Seven Years' War. But tradition and continuity rather than innovation were the hallmarks of the Prussian administration under him; many of what new departures there were (for example, an effort in 1770 to introduce a system of state examinations for entry into the civil service) were not very effective. Many of the truly successful innovations were in the judicial system, where the reforming efforts of Samuel von Cocceji resulted in all judges in higher and appellate courts being appointed only after they had passed a rigorous examination. Cocceji also inspired the establishment in 1750 of a new Superior Consistory to supervise church and educational affairs and began the process of legal codification that culminated after Frederick's death in the issue of the Prussian Common Law (Das Allgemeine Preussische Landrecht) of 1794, one of the most important 18th-century efforts of this kind. Yet Frederick's unwillingness ever to admit a mistake or change his mind tended, as he grew older, to make the processes of government increasingly rigid and inflexible. The government's refusal to adapt and adjust, which was already visible during the monarch's later years, culminated in the Prussian collapse of 1806 before the armies of Napoleon.

The Prussian army

The overriding objective of Frederick's rule was to increase the power of the state. His desire to foster education and cultural life was sincere, but these humanitarian goals were secondary compared with the task of building a great army and gaining the financial resources needed to maintain it. The army was the pivot around which all else turned, and the administrative system existed essentially to recruit, feed, equip, and pay it. In proportion to the resources available to support it, its size was unequaled anywhere in Europe. In 1740 Frederick inherited a standing army of 83,000 men; when he died, this figure had risen to 190,000 (though of these only about 80,000 were Prussian subjects). Under him it remained a force of peasants and of numerous foreign recruits obtained often by outright kidnapping, officered by landowners. In Prussia the army was recruited almost entirely in the countryside; the function of townsmen was to pay for it through their taxes, not to serve in it. Up to a point Frederick tried to protect the peasants and the soldiers against the demands of the Junker landlord-officers. In 1749 and 1764 he issued decrees limiting the obligations of the peasant to his lord, and in 1748 he ordered officers not to treat their men "like serfs"; but these were essentially efforts to prevent the plight of the peasant from becoming so desperate that he would be driven into flight and thus jeopardize the supply of recruits. Throughout Frederick's reign, army service was for the majority of his subjects the most onerous of all the burdens imposed by the state. In order to finance the great army, heavy demands were made on territories that for the most part were poor. Nothing, however, seemed more important to the monarch than amassing a large reserve of cash to be used for the recruitment of men in case of war. The financial demands that a serious conflict would make were constantly on his mind, and the desperate struggles of 1756–62 confirmed him in his beliefs.

Much of the tax system, based on the excise (largely a tax on food) paid by the towns and the contribution (a complex property tax) raised in the countryside, supplemented by the profits of the extensive royal domains, remained essentially unchanged. Still, Frederick experimented with a number of new taxes, notably with a new system of taxing tobacco and some less important commodities (introduced in 1766 under the supervision of a French entrepreneur, Le Haye de Launay), but these innovations did not bring about significant changes. Indeed, many of Frederick's fiscal policies were ill-judged; for example, the maintenance of a great reserve of cash, which removed from circulation much of the liquid capital of a poor society, was economically damaging. Yet strict control of expenditure and relatively efficient tax collection meant that the government, unlike many others of the age, was never hamstrung by lack of money.

Frederick's economic policies were squarely in the mercantilist tradition. "The foundation of trade and manufactures," he wrote in his *Testament Politique* of 1752, "is to prevent money leaving the country and to make it come in." The direct and simplistic way in which these ideas were sometimes applied can be seen in an order of 1747 forbidding individuals to take more than 300 thalers

Economic policies

in specie out of their territories. So far as possible Prussia was to avoid importing foreign manufactured goods, and to this end domestic producers were to be helped by privileges and even outright grants of money. Exports were to be encouraged in the same way. In particular, much money was spent on efforts to develop a substantial silk industry, with generally disappointing results. By the end of the reign textiles of all kinds accounted for two-thirds of Prussia's industrial production, and the textile industry employed about 90 percent of the industrial labour force, but this situation owed little to Frederick's economic policies. Efforts to foster the production of porcelain—which, like silk, was one of the industrial status symbols of a number of 18th-century rulers—were also costly and not very effective. A small number of favoured industrialists, notably David Splitgerber and Johann Ernst Gotzkowsky in the 1750s, benefited by these policies, but for Prussia as a whole they were largely a misuse of resources. Other new creations such as the Maritime Trading Company (Seehandlung), a government-backed corporation set up in 1772 to develop overseas trade, and even the Royal Bank of Berlin, established in 1765, were also marginal to the economic life of Frederick's territories, which, except to some extent in Silesia, in the area around Berlin, and in the little county of Mark in western Germany, continued to be based on agriculture.

Some of the state's programs, however, achieved real success, though sometimes at high cost. Most important was the sustained effort, in the 1760s and '70s, to attract immigrants and to settle them on waste or depopulated land; this settlement program formed the central feature of the *rétablissement,* the making good of the losses of the Seven Years' War. During Frederick's reign more than 300,000 settlers were attracted to Prussia from other parts of Europe—a substantial addition to a population that in 1740 had numbered only about 2,200,000. In addition, the army provided a large market for arms and woolen cloth for uniforms and thus did something to stimulate economic growth. Moreover, in peacetime the soldiers served with their regiments only for a few months of the year, spending the remaining part in agriculture or some urban employment. The fact that they were in this way integrated into society helped to offset the burden that so great a military effort placed on the economy.

The importance of the nobility

Frederick's social policies were as conservative as his economic ones. He considered the nobility the most important class in Prussian society. From it were drawn the majority of the army officers and virtually all the higher-ranking ones. It also produced the majority of his officials and all his ministers and completely dominated local government in the countryside. In Frederick's eyes, the nobility alone of all the social groups had a sense of personal honour and responsibility. The continued existence of the state depended on it, and the regime could not function without its cooperation. Thus its interests were always to be safeguarded. In particular, it was not to be diluted by the grant of noble status to self-made bourgeois, and land owned by noble families was to be protected against purchase by members of the urban middle class, however wealthy. Frederick stated these ideas repeatedly in his voluminous writings on statecraft, notably in the political testaments of 1752 and 1768 drawn up for his successor. Given this attitude, it is not surprising that his reign saw little practical improvement for the peasantry, much of which, in Pomerania, Brandenburg, and East Prussia, was still personally unfree, owing labour services to noble landowners. In principle, Frederick sincerely disliked serfdom. In practice, however, he realized that any rapid move against it risked the disruption of Prussia's agricultural life and the erosion of the position of the all-important nobility. His efforts to improve the lot of his peasant subjects were therefore little more than gestures. As part of his commitment to stimulate recovery from the losses of the Seven Years' War, he tried to abolish serfdom in Prussian Pomerania and also to give the peasantry of Upper Silesia greater security of tenure, but none of this had much practical effect because he never contemplated any significant change in the social order.

Frederick prided himself on being, among rulers, the leading representative of the high culture of his day. He was a prolific writer on contemporary history and politics; his *Histoire de mon temps* (1746) is still a source of some value for the period it covers. He produced large quantities of mediocre poetry and composed music. He invited to Prussia several of the leading French intellectuals of the age, notably Voltaire (with whom he soon quarreled). But here again his outlook was essentially conservative. Culture to him meant French culture: he wrote and spoke French by preference, using German only when necessary. He had no interest in the profound intellectual stirrings occurring in Germany. Berlin under him never became an important intellectual centre. Gotthold Ephraim Lessing, perhaps the greatest German writer of the mid-18th century, described Prussia as "the most slavish country in Europe," and Carl Philipp Emanuel Bach, the most distinguished of the musicians serving Frederick, did so rather reluctantly. Frederick's religious tolerance, however, was genuine: it was one of the things that helped to mark him in the eyes of contemporaries as a truly enlightened ruler. The abolition of judicial torture, one of his first acts as king, also showed his genuine belief in this aspect of enlightened reform. On an even more fundamental level, the General Education Regulations (General-Landschul-Reglement) of 1763 attempted to create a system of universal primary education throughout the Prussian monarchy. Lack of resources limited its practical effect, but it was the most ambitious effort of the kind theretofore seen anywhere in Europe.

Enlightened reforms

Significance of Frederick's reign. Both by his accomplishments and by his example Frederick deeply influenced the course of German history. In the struggles of the 1740s and '50s he weakened still further the tottering structure of the Holy Roman Empire. The bitter Austro-Prussian rivalry that he began was to be a dominant political force in Germany and central Europe for well over a century. Not until the final Prussian victory over Austria in 1866 was the long contest for leadership in Germany finally resolved. For his share in creating the division of the German world Frederick was later attacked, sometimes bitterly, by a number of historians who saw him as having prevented the emergence of a united Great Germany that included all the major German-speaking areas of Europe. Certainly, he had no sympathy, and indeed no understanding, for the embryonic German nationalism. The efforts of some writers of the 19th and 20th centuries to present him as a forerunner of German national unity are quite misleading. His renewed attack on Maria Theresa of Austria in 1744, for example, frustrated an Austrian invasion of Alsace and its possible return from French to German control, and during the Seven Years' War he offered more than once to cede to France territory in western Germany in the hope of breaking up the coalition that threatened him. Moreover, by his part in the first partition of Poland he helped to create an important common interest with Russia: thenceforth both states had as one of their major objectives the suppression, or at least the strict control, of Polish nationalist aspirations. For generations to come this was to be a factor turning Prussia's attention to eastern Europe and making it less Western in some of its political attitudes than might otherwise have been the case. Yet in many ways Frederick deserved the admiration that later generations, especially in Germany, increasingly felt for him. For all his social and intellectual conservatism he never ceased to feel himself in sympathy with the enlightened intellectual currents and political strivings of the age and with their tolerant and humanitarian aspects. Building on the foundations laid by his father, he consolidated a Prussian ethos of duty, effort, and discipline that, despite some serious negative features, was to become for several generations one of the major political traditions of Europe.

BIBLIOGRAPHY. Frederick's voluminous writings are collected in *Oeuvres de Frédéric le Grand,* 31 vol. in 33, ed. by J.D.E. PREUSS (1846–57), while selections from his correspondence, *Politische Correspondenz Friedrichs des Grossen,* 47 vol. (1879–1939), offer a mine of information on his foreign policy. Writings on his wars were assembled by the Prussian General Staff in *Die Kriege Friedrichs des Grossen,* 19 vol. in 18 (1890–1914). Among the biographies, THOMAS CARLYLE, *History of*

Friedrich II of Prussia, Called Frederick the Great, 6 vol. (1858–65, reissued in 8 vol., 1974), is famous and comprehensive but disappointing in its hero worship. J.D.E. PREUSS, *Friedrich der Grosse: Eine Lebensgeschichte,* 5 vol. (1832–34, reprinted in 9 vol., 1981), is an excellent work of official historiography of its time. REINHOLD KOSER, *Geschichte Friedrichs des Grossen,* 4 vol. (1912–14), available in many later editions, remains a standard large-scale treatment, complete on war and diplomacy. ARNOLD BERNEY, *Friedrich der Grosse: Entwicklungsgeschichte eines Staatsmannes* (1934), takes the story only to 1756; G.P. GOOCH, *Frederick the Great, the Ruler, the Writer, the Man* (1947, reissued 1990), offers essays on different aspects of the subject; D.B. HORN, *Frederick the Great and the Rise of Prussia* (1964), is a short introduction; and PETER PARET (ed.), *Frederick the Great: A Profile* (1972), collects useful extracts from German periodicals and books. A perceptive general discussion is presented in GERHARD RITTER, *Frederick the Great: A Historical Profile* (1968, reprinted 1974; originally published in German, 1954). RUDOLF AUGSTEIN, *Preussens Friedrich und die Deutschen* (1968, reprinted 1986), is extremely hostile but stimulating.

Frederick's early years are described in the old but still useful ERNEST LAVISSE, *The Youth of Frederick the Great* (1892, reissued 1972; originally published in French, 1891). HUBERT C. JOHNSON, *Frederick the Great and His Officials* (1975); and WALTHER HUBATSCH, *Frederick the Great of Prussia: Absolutism and Administration,* trans. from German (1975), study his regime in Prussia. Other special studies include W.O. HENDERSON, *Studies in the Economic Policy of Frederick the Great* (1963); CHRISTOPHER DUFFY, *The Army of Frederick the Great* (1974); HERBERT BUTTERFIELD, *The Reconstruction of an Historical Episode: The History of the Enquiry into the Origins of the Seven Years' War* (1951), a summary of the historical controversy over the attack on Saxony in 1756; HERBERT H. KAPLAN, *The First Partition of Poland* (1962, reissued 1972), analyzing Frederick's share in the dismemberment of the Polish republic; and two works focusing on the conflict over Bavaria: HAROLD TEMPERLEY, *Frederick the Great and Kaiser Joseph: An Episode of War and Diplomacy in the Eighteenth Century,* 2nd ed. (1968); and PAUL P. BERNARD, *Joseph II and Bavaria: Two Eighteenth Century Attempts at German Unification* (1965).

French Literature

Since the Middle Ages, France has enjoyed an exceptional position in European intellectual life. Though its literary culture has no single figure comparable to Dante in Italy or Shakespeare in England, its writers and their language have exercised influence far beyond its borders. In medieval times, because of the political link with Britain, the universality of Latin, and the similarities of the languages derived from Latin, there was a continual process of exchange, in form and content, among the literatures of western Europe. The evolution of the nation-states and the rise in prestige of the vernaculars gradually eroded this relationship, however, and France developed a cultural tradition based on the imitation of Classical models.

The French tradition prized reason, formal perfection, and purity of language and was admired for its thinkers as much as for its writers. By the end of the ancien régime the logic of Descartes, the restraint of Racine, and the wit of Voltaire were seen as the hallmarks of French culture and were emulated throughout the Continent.

The political and intellectual revolutions at the end of the 18th century led to a revaluation. From the 1820s Romanticism openly challenged the Classical ideal and asserted the claims of the imagination against reason and the individual against the social norm. The 12-syllable alexandrine remained the standard line in verse but the form was relaxed, and the domain of poetry was extended successively by Victor Hugo, Charles Baudelaire, and Arthur Rimbaud. All poetic forms were redefined as a result of the Modernist revolutions of the 20th century. In the novel, the dominant literary form from the 19th century, French writers explored the possibilities of the genre, from the novel cycle of Honoré de Balzac to the social realism of Émile Zola. But in the work of writers as different as Stendhal, Gustave Flaubert, and Marcel Proust an analytical approach to questions of style and human motivation seemed both to characterize the French mind and to form a link with the French Classical tradition.

During the first half of the 20th century, Paris was the hub of European intellectual and artistic life, but its position was challenged after World War II, and the international status of the French language declined steadily. Nevertheless, French was the medium of expression for many in Europe, North America, Africa, and Asia, and foreign Francophone (French-speaking) authors contributed significantly to French culture. The *nouveau roman*, or new novel, and such later movements as deconstruction mounted a radical attack on genres, the relationship between writer and reader, and language itself. This, too, was consistent with a cultural tradition notable for its intellectual rigour as well as its appreciation of literary style. (R.C.Bu./Ed.)

This article surveys French literature from the 9th century (to which the earliest surviving fragmentary texts belong) to the present day. See also the section on literature in French in the article BELGIAN LITERATURE and, for the medieval period, the *Early Middle English* section of ENGLISH LITERATURE. Literary works written in French by Canadian authors are discussed in CANADIAN LITERATURE: *Canadian literature in French.*

The article is divided into the following sections:

The Middle Ages

EARLY OLD FRENCH LITERATURE

The origins of the French language. By 50 BC, when the Roman occupation of Gaul under Julius Caesar was complete, the region's population had been speaking Gaulish, a Celtic language, for some 500 years. Gaulish, however, gave way to the conquerors' speech, Vulgar Latin, which was the spoken form of the non-Classical Latin used by the soldiers and settlers throughout the Roman Empire. In different regions, local circumstances determined Vulgar Latin's evolution into the separate tongues that today constitute the family of Romance languages, to which French belongs. This linguistic development was speeded by the empire's collapse under the impact of the 5th-century barbarian invasions. Gaul was overrun by Germanic tribes, in the north principally by the Franks (who gave France its name), and by the Visigoths in the south. But the Latin speech survived: it not only was the language of the majority of the population but also was backed by its associations with the old Roman culture and with the new Christian religion, which used Low Latin, its own form of the Roman tongue. Although it retained relatively few Celtic words, the developing language had its vocabulary greatly enriched by Germanic borrowings, and its phonetic development was influenced by Germanic speech habits. The 9th-century Norse incursions and settlement of Normandy, however, left few traces in the language.

The Romans had introduced written literature, and until the 12th century almost all documents and other texts were in Latin. The first text in recognizable Old French is the Romance version of the Oath of Strasbourg (842), an oath sworn by Louis the German and Charles the Bald against their brother Lothair in the partitioning of the empire of their grandfather Charlemagne. A German version also survives. Only a few other texts, all religious in content, survive from before about 1100.

The Oath of Strasbourg

By about the 9th century a broad division had emerged between the speech of the north of Gaul, which had suffered most from the invasions, and that in the more stable, cultured, and linguistically conservative south. The tongue spoken to the north of an imaginary line running roughly from the Gironde River to the Alps was the *langue d'oïl* (the future French), and to the south was spoken the *langue d'oc* (Provençal or Occitan), terms derived from the respective expressions for "yes."

Vulgar Latin's development had not been uniform throughout the area of the *langue d'oïl;* and, by the time a recognizable Old French had developed, various dialects had evolved, notably Francien (in the Île-de-France, the region around Paris), Picard, Champenois, and Norman. From the latter stemmed Anglo-Norman, the French used alongside English in Britain, especially among the upper classes, from even before the Norman Conquest (1066) until well into the 14th century. Each dialect had its own literature. But for various reasons the status of Francien increased until it achieved dominance in the Middle French period (after 1300); and from it Modern French developed. Old French was a fine literary medium, enlarging its vocabulary from other languages such as Arabic, Provençal, and Low Latin. It had a wide phonetic range and, until the decay of its two-case system inherited from Latin, had syntactic flexibility.

The context and nature of French medieval literature. Whatever Classical literature survived the upheavals of the early Middle Ages was preserved, along with pious Latin works, in monastic libraries. By encouraging scholars and writers, Charlemagne had increased the Latin heritage available to educated vernacular authors of later centuries. He also left his image as a great warrior-emperor to stimulate the legend-making process that generated the Old French epic. There one finds exemplified the feudal ideal, evolved by the Franks to combat social fragmentation and insecurity. The warrior's code of morality, founded on loyalty, bolstered the entire political system. As stability increased under the Capetians, windows opened onto other cultures and elements: that of the Arabs in Spain and, with the Crusades, the East; the advanced Provençal civilization; and the legends of Celtic Britain. The Roman Catholic Church grew in wealth and power, and by the 12th century its schools were flourishing, training generations of clerks in the liberal arts. Society itself became less embattled, and the nobility became more leisured and sophisticated. The muscularity of the epics was tempered by the social graces of *courtoisie:* generosity, modesty, and consideration for others, especially the weak and distressed, and with love regarded no longer as a weakness in a knight but as an objective inspiring and not hindering chivalry.

By the 13th century an additional source of patronage for writers and performers was the bourgeoisie of the developing towns. New genres emerged, and, as literacy increased, prose found favour as a less frivolous medium than verse. There is in much of the literature a rather irreverent spirit, a sometimes cynical realism, yet, at the same time, a countercurrent of deep spirituality. In the 14th and 15th centuries France was ravaged by war, plague, and famine. Alongside a preoccupation in literature with death and damnation appeared a contrasting refinement of expression and sentiment bred of nostalgia for the courtly, chivalric ideal. At the same time a new humanistic learning anticipated the coming Renaissance.

Oral "literature" of the jongleurs

Before 1200 almost all French "literature" had been in verse and had been communicated orally to its public. The jongleurs, professional minstrels, travelled and performed their extensive repertoires, which ranged from epics to the lives of saints (the lengthy romances were not designed for memorization), sometimes using mime and musical accompaniment. Seeking an immediate impact, most poets made their poems strikingly visual in character, more dramatic than reflective, and revealed psychology and motives through action and gesture. Verbal formulas and clichés were used by the better poets as an effective narrative shorthand, especially in the epic. Such oral techniques left their mark throughout the period.

The chansons de geste. More than 80 chansons de geste ("songs of deeds") are known, the earliest and finest being the *Chanson de Roland* (*c.* 1100). Most are anonymous and are composed in lines of 10 or 12 syllables grouped into *laisses* (tirades) based on assonance or, later, rhyme. Their length varies from about 1,500 to more than 18,000 lines. They are exemplary stories of warfare, often pitting Franks against Saracens, that fire the emotions with their insistent rhythms. Under the influence of the genre known as romance, however (see below), the chansons de geste lost some of their early vigour. Their story lines became looser, their adventures more exotic, and their tone often amatory or even humorous. Many were eventually turned into prose.

Cycles formed as new songs were composed featuring heroes, families, or themes already familiar. The *Chanson de Roland* belongs to the cycle known as the "Geste du Roi," or "Geste of the King," the king being Charlemagne, Roland's uncle, in whose service he perished with the rear guard at Roncevaux. Charlemagne is treated less reverently in the parodic *Pèlerinage de Charlemagne* ("Charlemagne's Pilgrimage"), describing his journey to Jerusalem and Constantinople. Dominating the "Geste de Garin de Monglane" is Garin's great-grandson, Guillaume d'Orange, whose historical prototype was count of Toulouse and Charlemagne's cousin. His dogged loyalty to an unworthy monarch (Charlemagne's son Louis) is the subject of a group of poems including the *Chanson de Guillaume* ("Song of William"). The epics in the "Geste de Doon de Mayence" deal with rebellious vassals, among them Raoul de Cambrai, in a gripping story of injustice and strained loyalties. The fanciful 13th-century *Huon de Bordeaux,* which introduces the fairy king Auberon (Shakespeare's Oberon), has been placed here and in the "Geste du Roi." The First Crusade is handled, with legendary embellishment, in a minor cycle.

Controversy surrounds the origins of the genre. It is not known how most of the poems came to contain elements, somewhat garbled, from Carolingian history some 300 years before their composition. Some scholars believe in a continuous process of oral transmission and elaboration culminating in the writing down of the epics as they have survived. Others suppose the historical facts were retrieved much later by poets wishing to celebrate certain heroes, many of whom were associated with pilgrim routes which the jongleurs could then ply with profit. Some evolutionary process seems probable; yet the author of the *Chanson de Roland* (perhaps the Turoldus named in the last line) was undoubtedly a poet of both genius and learning.

The romance. The romance, which came into being in the middle of the 12th century in France, was a creation of formally educated poets. The earliest took their subjects from antiquity: Alexander the Great, Thebes, Aeneas, and Troy were all treated at length, and shorter *contes* ("tales") were derived from Ovid. Other romances, like *Floire et Blancheflor* (adapted in Middle English as *Flores and Blancheflur*), exploited Greco-Byzantine sources; but by about 1150 the Celtic legends of Britain were capturing the public's imagination.

The romance's standard metre is octosyllabic rhyming couplets. It differs from the chanson de geste in concentrating on individual rather than communal exploits and presenting them in a more detached fashion. It offers fuller descriptions, freer dialogue, and more authorial intervention. Christian miracles and fervour are replaced by Eastern or Celtic marvels and the cult of *courtoisie* and *amour courtois* ("courtly love"). There is more interest in psychology, especially in the love situations.

The universally popular legend of Tristan and Iseult had evolved by the mid-12th century, apparently from a fusion of Scottish, Irish, Cornish, and Breton elements. The main French versions (both fragmentary) are by the Anglo-Norman poet Thomas (*c.* 1170) and the Norman Béroul (rather later and possibly composite). The legend was reworked in French prose and widely translated (Thomas' version can be reconstructed from Gottfried von Strassburg's German rendering and another in Old Norse). Chrétien de Troyes's treatment, mentioned in his *Cligès,* has been lost.

Arthurian romance

The deep-rooted British tradition of King Arthur was firmly established on the Continent by Geoffrey of Monmouth's *Historia regum Britanniae* (*c.* 1136; *History of the Kings of Britain*), translated and romanticized by the Jerseyman Wace as the *Roman de Brut* (1155). The Bretons and Anglo-Normans were likely intermediaries in the transmission of further Arthurian material to French writers such as Chrétien de Troyes, the virtual founder of Arthurian romance, who wrote between about 1165 and 1182. His first known romance, *Erec et Enide,* is a serious study of marital and social responsibilities and contains elements of Celtic enchantment. *Cligès,* a partly Greco-Byzantine tale of young love and an adulterous relationship, uses the motif of feigned death later familiar from *Romeo and Juliet. Lancelot,* or *Le Chevalier de la charrette,* relates the infatuated hero's rescue of the abducted queen Guinevere. *Yvain,* or *Le Chevalier au lion,* treats the converse of the situation depicted in *Erec.* Chrétien's ironies and ambiguities invited divergent interpretations, and of no work more than the incomplete *Perceval,* or *Le Conte du Graal,* which may be the conflation of two unfinished poems. The grail, first introduced here, was to become, as the Holy Grail, a remarkably potent symbol. The romance genre was diversely exploited well into the 14th century, but by 1384 Jean Froissart's contribution, *Méliador,* was only a ponderous valediction to romance's golden age. On the genre's periphery were short courtly tales and lais like those of Marie de France, treating Celtic themes and probably composed in England. The unique *Aucassin et Nicolette,* a charmingly comic idyll told in alternating sections of verse (to be sung) and prose (to be recited), pokes sly fun at the conventions of epic and romance alike.

Lyric poetry to the 13th century. The 12th century saw the revolution in sexual attitudes that has come to be known as *amour courtois,* or courtly love. Its first exponents were the Provençal troubadours, poet-musicians of the 12th and 13th centuries, of whom some 400 are known by name. Among them are nobles of both sexes and even clerics. The troubadours no longer considered women to be the disposable assets of men. On the contrary, the enjoyment of a woman's love was a man's aspiration, achievable, if at all, only after the suitor had served a period of amorous vassalage modelled on the subject's service to his lord. This is the main theme of the troubadours' songs, whose origins have been sought in Arabic poetry, the writings of Ovid, Latin liturgical hymns, and other less likely sources. The *canso* (French *chanson*), made of five or six stanzas with a summary envoi, was the favourite vehicle for their love poetry; but they used various other forms, from dawn songs to satirical or debating poems, all usually highly crafted. Guillaume IX, duke of Aquitaine, the first known poet in the Provençal language, mixed obscenity with his courtly sentiments. Among the finest are the graceful Bernard de Ventadour; Jaufré Rudel, who expressed an almost mystical longing for a distant love; and the soldier and poet Bertran de Born.

The *langue d'oïl* had a tradition of dance and spinning songs before the troubadours exerted by the mid-12th century an influence encouraged by, among others, Eleanor of Aquitaine, granddaughter of Guillaume IX and queen of France and later England. The troubadours' verse inspired a number of northern trouvères, including Chrétien de Troyes, two of whose songs are extant, and some nobles such as Thibaut (Theobald I), count of Champagne and king of Navarre.

More interesting is the work of certain bourgeois poets, notably, in the 13th century, a group from Arras and especially Rutebeuf, a Parisian often compared with Villon. Rutebeuf wrote very personal verse on a variety of subjects: his own pitiful circumstances, the quarrel between the University of Paris and the religious orders, the need to support the Crusades, his reverence for the Virgin, and his disgust at clerical corruption. But he did not treat love, nor was his verse set to music.

Satire, the fabliaux, and the Roman de Renart. Medieval literature in both Latin and the vernacular is full of sharp, often bitter criticism of the world's evils: the injustice of rulers, churchmen's avarice and hypocrisy, corruption among lawyers, doctors' quackery, and the wiles and deceits of women. It appears in pious and didactic literature and, as authorial comment, in other genres but more usually in general terms than as particular, corrective satire. Human vice and folly also serve purely comic ends, as in the fabliaux. These fairly short verse tales, most of which are anonymous though some are by leading poets, generate laughter from situations extending from the obscene to the mock-religious, built sometimes around simple wordplay and frequently around elaborate deceptions and counter-deceptions. They are played out in all classes of society but predominantly among the bourgeoisie. Many fabliaux carry mock morals, inviting comparison with the didactic fables. Realistic in tone, they paint instructive pictures of everyday life in medieval France. After the 13th century, when the majority were composed, they yielded in importance to the farces, bequeathing a fund of anecdotes to later writers such as Chaucer and Boccaccio.

Inspired partly by the popular animal fable and more specifically by the Latin poem *Ysengrimus* by Nivard of Ghent (*c.* 1150), Pierre de Saint-Cloud composed about 1175 a poem chronicling the rivalry of Reynard the Fox and the wolf Ysengrin, or Isengrin. This seems to have prompted other writers to relate more of the lively and largely scandalous goings-on in the animal kingdom ruled by Noble the Lion. By the 14th century about 30 branches existed, forming a veritable beast epic. Full of close social observation, they exude the earthy humour of the fabliaux; but, particularly in some of the later branches, this is sharpened into true satire directed against abuses in church and state, with the friars and rapacious nobility as prime targets.

Allegory. Allegory, popular from early times, was employed in Latin literature by such authorities as Augustine, Prudentius, Martianus Capella, and, in the late 12th century, Alain de Lille. It was used widely in religious and moralizing works, as in the long *Pèlerinage de la vie humaine* ("Pilgrimage of Human Life") by Guillaume de Deguileville, Dante's contemporary and a precursor of Bunyan. But the most influential allegorical work in French was the *Roman de la Rose* (*Romance of the Rose*), where courtly love is first celebrated, then undermined. The first 4,058 lines were written about 1230 by Guillaume de Lorris, a sensitive, elegant poet who, through a play of allegorical figures, analyzed the psychology of a young couple's venture into love. The affair is presented as a dream, in which the plucking of a crimson rose by the dreamer/lover would represent his conquest of the lady. Guillaume, however, left the poem unfinished, with the dreamer frustrated and his chief ally imprisoned. Forty years or more later, a poet of very different temperament, Jean de Meun (or de Meung), added more than 17,700 lines to complete it, submerging Guillaume's delicate allegory with debates and disquisitions, laden with medieval and ancient learning, by the characters. Courtly idealism is shunned for a practical, often critical or cynical view of the world. Love, only one of many topics treated in the completed version, is synonymous with procreation; and a misogynistic tone pervades the writing. Embodying these two characteristically medieval but diametrically opposed attitudes to love, the *Roman* was immensely popular until well into the Renaissance (which in some respects is foreshadowed by Jean's humanistic learning) and gave rise to a long-running literary quarrel on the nature and role of women.

The *Roman de la Rose*

Lyric poetry in the 14th century. Allegory and similar conceits abound in much late medieval poetry, as with Guillaume de Machaut, the outstanding musician of his day, who composed for noble patronage a number of narrative *dits amoureux* and a quantity of lyric verse. A talented technician, Machaut did much to popularize and develop the relatively new fixed forms: ballade, rondeau, and virelai. Eustache Deschamps, his great admirer and perhaps also his nephew, struck in his verse a more personal note than many of his contemporaries. A prolific writer, he dealt with public and private affairs, sometimes satirically; but he composed little love poetry, and his work was not set to music. Jean Froissart wrote pleasantly in a variety of lyric forms; but more individual is the varied output of Christine de Pisan, the gifted daughter of an Italian astrologer and physician at the French court. Widowed at 25, she expressed her grief in some of her finest verse. Elsewhere, a prime mover in the controversy provoked by the *Roman de la Rose,* she espouses the feminist cause. Most court verse of this period has an unreal air as if, amid the political and social agonies of the Hundred Years' War, the poets were voicing a yearning for humane and gracious living founded on the ideals of *courtoisie.* Thus Alain Chartier, a political polemicist in both French and Latin, was most admired for *La Belle Dame sans merci,* which tells of the death of a lover rejected by his lady.

Poetry of Christine de Pisan

Villon and his contemporaries. One distinguished victim of the Hundred Years' War was Charles, duc d'Orléans, who was captured at Agincourt at the age of 21 and was held prisoner in England for 25 years. There is an elegiac tone to much of his graceful verse. On his return to France, his court at Blois became a literary centre. For one of his poetry competitions François Villon produced a ballade that, while not outstanding, is remarkable for its individuality and relative lack of contrivance.

Born in Paris in 1431 as François de Montcorbier, Villon adopted the name of his uncle, a priest, who saw to his upbringing. At the University of Paris, where he became Master of Arts in 1452, he acquired some learning but also loose habits that involved him in manslaughter and robbery. His forced departure from Paris was the occasion for his *Lais,* or *Le Petit Testament* (1456; *The Legacy*). This mock legacy in eight-line octosyllabic stanzas is conversational and often facetious in tone, full of allusions to people and events sometimes made cryptic by Villon's taste for antiphrasis. His main work, the *Testament* (or *Le Grand Testament*), was written five or six years later after a spell in the Bishop of Orléans's dungeons. It uses the octets of the *Lais* interspersed with ballades and rondeaux and is similarly packed with personal gossip, often tongue-in-cheek, but leaving a bitter aftertaste. Following more brushes with justice, he disappeared for good. Commonly considered to have been the first modern French poet, he was more traditional than innovative in his themes. Apart from the *Lais* and *Testament,* he produced a variety of lyrics, none provided with music in his day. His verse shows great technical skill and an economy of expression that not only enhances his lively wit but produces moments of intensely focussed vision and, in individual poems, moving statements of human experience.

None of his contemporaries or immediate successors was able to match the vigour of his verse. Often obsessed by metrical ingenuity, extravagant rhymes, and other conceits, they favoured Italian as well as Classical models, thus heralding the Renaissance. It is unfair, however, to judge them by their words alone, since the music was, for most, a vital ingredient of their art.

Prose literature. Prose flourished as a literary medium from about 1200. A few years earlier Robert de Borron had used verse for his *Joseph d'Arimathie* (recounting the Holy Grail's sacred origins) and his *Merlin;* but both were soon turned into prose. Other Arthurian romances adopted it, notably the great Vulgate cycle with its five branches by various hands. These included the immensely popular *Lancelot,* the *Queste del Saint Graal* (whose Cistercian author used Galahad's Grail quest as a vehicle for the mystic pursuit of Christian truth and ecstasy), and *La Mort le Roi Artu,* powerfully describing the collapse of the Arthurian world. The Tristan legend was reworked and extended in prose. To spin out their romances while maintaining their public's interest, authors wove in many characters and adventures, producing complex interlacing patterns, which Sir Thomas Malory simplified when he drew on them for his *Morte Darthur.*

As well as traditional material, new fictions appeared in prose. Early in the 15th century the ironically titled *Les Quinze Joies de mariage* amusingly pursued the antifeminist line. In *Petit Jehan de Saintré* (1456) Antoine de la Sale took a misogynistic view of an ill-starred courtly love relationship, and the work's realism and psychological interest have made it for some the first French novel. The bawdy tales of the *Cent Nouvelles Nouvelles* (*c.* 1465), loosely modelled on Boccaccio, are more in the spirit of the fabliau, though written for the Burgundian court.

Chronicles

Pious and instructional works abound. More interesting are the chronicles, which avoid the romantic extravagances of their verse predecessors. Geoffroi de Villehardouin's *Conquête de Constantinople* ("Conquest of Constantinople") is a sober, if biassed, eyewitness account of the Fourth Crusade (1199–1204). Jean, sire de Joinville, was 84 when, in 1309, he completed his *Histoire de Saint Louis,* a flattering biographical portrait of his intimate friend Louis IX, whom he had accompanied on the Seventh Crusade. Jean Froissart, who travelled extensively in England and Scotland and on the Continent, projected his admiration of chivalry into his four books of chronicles. Covering the years 1325 to 1400, they contain much picturesque detail, largely from personal observation. A far more cynical view of people, politics, and feudal values is found in the *Mémoires* of Philippe de Commynes, with whom modern French historiography may be said to begin.

Religious drama. Classical theatre having disappeared, serious drama was reborn in the Middle Ages within the Roman Catholic Church. There, from early times, dramatic elements were introduced into certain offices, particularly at Easter and Christmas. From this practice liturgical drama sprang. Performances took place inside churches, with the cast of clergy moving from place to place in the sanctuary. At first only Latin was used, though occasionally snatches of vernacular verse were included, as in the early 12th-century *Sponsus* ("The Bridegroom"), which uses the Poitevin dialect. Stories from the Bible and lives of the saints were dramatized; and as the scope of the dramas broadened, more plays were performed outside the church and used only the vernacular. The all-male casts employed multiple setting (*décor simultané*) and moved from one setting, or mansion, to another as the action demanded.

The first extant *mystère,* or mystery play, with entirely French dialogue (but elaborate stage directions in Latin) is the *Jeu d'Adam* ("Play of Adam"). It is known from a copy in an Anglo-Norman manuscript, and it probably originated in England in the mid-12th century. With lively dialogue and the varied metres characteristic of the later *mystères* (all of which were based on Biblical stories), it presents the Creation and Fall, the story of Cain and Abel, and an incomplete procession of prophets. Neither it nor the later *Résurrection du Sauveur* ("Resurrection of the Saviour"; also Anglo-Norman and fragmentary) shows the events preceding the Crucifixion; these first appeared in the early 14th century in the *Passion du Palatinus* ("Passion of Palatinus"). Of relatively modest proportions, this contains diversified dialogue with excellent dramatic potential and probably drew on earlier plays now lost.

The oldest extant *miracle,* or miracle play (a real or fictitious account of the life, miracles, and martyrdom of a saint), is the remarkable *Jeu de Saint Nicolas* ("Play of Saint Nicholas"), by Jean Bodel of Arras, in which exotic crusading and boisterous tavern scenes alternate. Rutebeuf's *Miracle de Théophile* is an early version of the Faust theme, in which the Virgin Mary secures Théophile's salvation. From the 14th century comes the *Miracles de Notre-Dame,* a collection of 40 miracles, partly based on a nondramatic compilation by Gautier de Coincy. These miracles probably were performed by the Paris goldsmiths' guild.

By the 15th century, societies had been formed in various towns for the performance of the increasingly elaborate mystery plays. In Paris the Confrérie de la Passion (Confraternity of the Passion) survived until 1676, though its production of sacred plays was banned in 1548. Notable authors of *mystères* are Eustache Marcadé; Arnoul Gréban, organist and choirmaster at Notre-Dame, and his brother Simon; and Jean Michel. Arnoul Gréban's monumental *Mystère de la Passion* (*c.* 1450, reworked by Michel in 1486) took four days to perform. Other plays took up to eight days. Biblical material was supplemented with legend, theology, and elements of lyricism and slapstick, and spectacular stage effects were employed.

Secular drama. A crucial factor in the emergence of the comic theatre was the oral presentation of much medieval literature. A natural consequence was complete dramatization and collaborative performances by jongleurs and later by guilds or *confréries* formed for the purpose.

Comic plays

The earliest comic plays extant date from the second half of the 13th century. *Le Garçon et l'aveugle* ("The Boy and the Blind Man"), a simple tale of trickster tricked, could have been played by a jongleur and his boy and ranks as the first farce. The Arras poet Adam de la Halle composed two unique pieces: *Le Jeu de la feuillée* ("The Play of the Bower"), a kind of topical revue for his friends, and *Le Jeu de Robin et de Marion,* a dramatized *pastourelle* (a knight's encounter with a shepherdess and her friends) spiced with song and dance. The first serious nonreligious play was *L'Estoire de Griseldis* (1395), the story of a constant wife.

The profane theatre eventually had its own societies of actors, such as the Basoches (associations of lawyers and clerks) and the Enfants sans Souci (probably a special group of Basochiens) in Paris. The societies frequently presented plays in triple bills: first a *sotie,* a slight, sometimes satirical, sketch; next a *moralité* (morality play), a didactic and often allegorical piece; and finally a farce. Some 150 farces have survived from the 15th and 16th centuries. Most are of less than 500 lines and involve a handful of characters acting out plots similar to those of the fabliaux. They use the octosyllabic rhyming couplet and may include songs, commonly in rondeau form. By far the best is the unusually long *La Farce de maistre Pierre Pathelin* (*c.* 1465), a tale of trickery involving a sly lawyer, a dull-witted draper, and a crafty shepherd. Its multifaceted humour is worthy of Molière.

ANGLO-NORMAN LITERATURE

Anglo-Norman is an important and in some respects pioneering branch of medieval French literature. Most genres are represented; and although scholars know of no chanson de geste composed in England, the sole manuscripts of the *Chanson de Roland, Chanson de Guillaume,* and *Pèlerinage de Charlemagne* were copied there. The earliest copy of the *Vie de Saint Alexis* ("Life of Saint Alexis") is likewise Anglo-Norman. The first examples of "scientific" writing in French, from the early 12th century, are the *Cumpoz* or *Comput* (an ecclesiastical calendar), a bestiary, and a lapidary, all allegorical, by a cleric, Philippe de Thaon. He enjoyed patronage at the court of Henry I, as did another cleric and far superior poet, Benedeit, who dedicated his *Vie de Saint Brendan* ("Life of Saint Brendan") to Henry's queen before about 1125. It describes the Irish saint's marvellous voyage in search of Heaven and Hell. Other firsts for Anglo-Norman writers are in the fields of chronicle and drama: Gaimar's verse *Estorie des Engleis* (*c.* 1150), and the *Jeu d'Adam* mentioned above. The first significant prose texts in French seem also to have been produced in England: versions of the Psalter and a translation of the Books of Samuel and Kings.

Anglo-Norman literature is particularly rich in homiletic, devotional, and didactic works, including numerous lives of saints. The trend was encouraged by the church's concern for the instruction of the laity, as expressed by the Fourth Lateran Council (1215). However, a substantial number of chronicles, romances, and even courtly lyrics was produced. Among major writers working in England were Thomas, the author of *Tristan,* and his namesakes Master Thomas, who composed the romance of *Horn,* and Thomas, author of the *Roman de toute Chevalerie,* dealing with Alexander the Great. To Marie de France, author of the lais (see above), are also attributed a collection of fables and an account of St. Patrick's Purgatory, translated from Latin. John Gower, in the late 14th century, was the last notable Englishman to write in any form of French. (D.D.R.O.)

The 16th century

LANGUAGE AND LEARNING IN 16TH-CENTURY EUROPE

The literature of the 16th century does not date precisely from 1500 or 1501. The writers who are identified with Renaissance humanism (a term adapted in France in the 19th century from the German word *Humanismus*) had certain aspirations in common, but they never formed a school. They thought of themselves as the heirs of their predecessors: of Marsilio Ficino, for example, who died in Italy in 1499 but in his lifetime spread Neoplatonic thought widely in Europe, or of Petrarch, who wrote in the 14th century. On the other hand, the period called the Middle Ages in some aspects continued well into the Renaissance, judging by certain titles and subjects of works (even those to which François Rabelais, so "Gothic" in 1532, referred to produce his *Pantagruel*).

Many of the thinkers and writers of the 16th century belong to Europe as a whole more than to a particular nation. This is true of Erasmus, who came originally from Rotterdam but lived in France, England, and Switzerland. The assignment of Jean Lemaire de Belges to a particular country is equally difficult, for he was a Walloon who wrote in French and travelled among various courts. During this period writers made many journeys, either by choice or by necessity. Rabelais, Joachim du Bellay, and Michel de Montaigne all made the trip from France to Italy. Clément Marot died in Turin and Marc-Antoine de Muret, after a long exile, died in Rome. The sometimes intense cultural exchanges (which can be pondered at the crossroads city of Lyon, turned as much toward Italy as toward Paris) explain the influences sometimes submitted to, sometimes acted upon. An example is the rapidity and importance of the diffusion of Martin Luther's writings through France during the decades 1520–40. And the Geneva Reformation made excellent use of Geneva's publishing trade to introduce Luther's ideas in John Calvin's native France. At the time of the Reformation religious literature belonged to all of Europe.

Cultural influences and diffusion

THE ELEVATION OF THE FRENCH LANGUAGE

The communication of ideas was facilitated by the use of Latin, which remained the language of theologians, philosophers, and jurists. Erasmus polemicized in Latin with the Sorbonne or with Luther. Calvin used Latin to write his first version of *Institutio christianae religionis* (1536; definitive Latin version, 1559; *Institutes of Christian Religion*). Petrus Ramus (Pierre de la Ramée) created a sensation when, after earlier writings in Latin, he produced his *Dialectique* (1555) in the vernacular French.

La Pléiade. The group known as La Pléiade was formed in the mid-16th century by seven poets who wished to elevate the French language to the level of Classical languages. Du Bellay's *Deffence et illustration de la langue francoyse* (1549; *The Defence and Illustration of the French Language*) served as La Pléiade's manifesto. In response in part to du Bellay's plea on behalf of French, in the second half of the century a great number of scholarly works were written in the vernacular language. Among them were *Les Dialogues philosophiques,* by Pontus de Tyard, and *Six livres de la République* (1576; *The Six Books of a Commonweale*) by Jean Bodin. Latin did not disappear, however, from the literature of ideas.

The grands rhétoriqueurs. Not all of those mistakenly labelled *grands rhétoriqueurs* ("great rhetoricians") belong chronologically to the 16th century. But Guillaume Crétin, Jean Marot, Jean Bouchet, and above all Lemaire de Belges are all sons of the Renaissance. They left considerable works, sometimes by circumstance (many worked at one time or another as official court historians) and sometimes by desire. As historians, they were "seekers of an origin," to quote Claude-Gilbert Dubois. For example, Lemaire de Belge's *Illustrations de Gaule et singularitez de Troye* (*c.* 1510; "Illustrations of Gaul and Singularities of Troy") tells the legendary origin of the French people, claiming that they are the issue of Francus, the son of

Hector who escaped from Troy. The historians cultivated a sumptuous prose as the expression of their wish for permanence and a desire for glory. The poetry of the *grands rhétoriqueurs* was often sacrificed for circumstance, as seen in Clément Marot, in *Le Voyage de Gênes* (1507) and *Le Voyage de Venise* (1509), and in Lemaire de Belges, in *Le Temple d'honneur et de vertus* (1504) and *La Plainte du désiré* (1509). The poets were fervent partisans of the French language, and the most enthusiastic was Lemaire de Belges, who dared to compare French with Italian in *Concorde des deux langages* (1513). Strictly speaking, it is less their poetic art than their innovations in form that continue to interest scholars.

MAJOR AUTHORS AND INFLUENCES

Poetry. Without the *rhétoriqueurs* the art of Clément Marot could not have been possible. From them, at least at the beginning of his career, he took his inspirations and borrowed the forms to express it, as in the allegorical poem "Le Temple de Cupidon" or in "L'Épître de Maguelonne." But a certain humanist culture; the life at court, which he called his schoolmistress (he became *valet de chambre* to Francis I in 1527); and, above all, the events of his day gave his works a new dimension. As the author of occasional poems Marot preferred the epistle because of its freedom of style and the epigram for its vivacity. With the epistle he reached the summit of the highly subtle art by which he defined himself, a poet of the court but also a Protestant, plagued by the Sorbonne and aspiring to a pure and simple happiness of true religious faith. His allegorical satire on justice, *L'Enfer,* written in 1526 after his brief imprisonment on charges of violating Lenten regulations, and his religious beliefs explain his voluntary exile after the Affaire des Placards in 1534. His return to Paris in 1537 made him no more prudent, as he continued his translations of the Psalms (published in the late 1530s and early 1540s), which were a brilliant literary achievement but were suspect in the eyes of the religious authorities. Marot's translation, continued by the Protestant leader Theodore Beza (Théodore de Bèze), became the Huguenot psalter.

Ronsard

Marot had been dead for six years when Pierre de Ronsard made a remarkable entry into the French literary scene with the publication of the first four books of his *Odes* in 1550. In the *Odes* he sings alternately of the great figures of his day and of the Vendôme countryside. Ronsard indicated in his preface, however, that he started work on his poems at the same time Marot was translating the psalter. The new "school," which at first was merely a group of friends calling itself La Brigade (the name La Pléiade coming into use later), deliberately diverged from the paths taken by their predecessors. The group broke less, on the other hand, with the Lyon school, whose members included Maurice Scève (*Délie,* 1544), Pernette du Guillet (*Rymes,* 1545), and Louise Labé (*Oeuvres,* 1555). Scève, above all, left a very important literary work in *Délie,* in which he mixed Platonism and Petrarchianism in a purposefully difficult language. The poets of La Pléiade were not content to sing of love, the favourite theme of the Lyon poets. True humanists were familiar with antiquity, having read and translated Greek as well as Latin, and antiquity opened to them a vast horizon. They did publish numerous collections of love poems: du Bellay, *L'Olive* (1549); Ronsard, *Les Amours* (1552), *La Continuation des amours* and *La Nouvelle Continuation des amours* (1555–56), and *Les Sonnets pour Hélène* (1578); and Jean-Antoine de Baïf, *Les Amours de Méline* (1552) and *Les Amours de Francine* (1555). But love for them was not only individual sentiment. Love presided over the life of the entire cosmos, as sung by Jacques Peletier in *L'Amour des amours* (1555) and by all the poets influenced by the Neoplatonic view of life. The most celebrated collection by du Bellay, *Les Regrets* (1558), thus draws to a close on a loving vision of beauty. Others engaged in philosophical poetry, of which Ronsard's *Les Hymnes* (1555–56) is the best example.

The spectacle of nature enchanted the poets who, like Peletier, were also learned men. A "scientific" poetry appeared and expressed itself in many ways, from the hymn reinvented by Ronsard to the highly polished verse form chosen by Rémy Belleau in his *Amours et nouveaux échanges des pierres précieuses* (1576). This poetry found its justification in the idea that the poet, because of his inspiration, acceded to knowledge of the world, which conferred upon him a dignity at least equal to that of a priest.

When the civil wars broke out in 1562, the members of La Pléiade sided with the monarchy and the church, which Ronsard eloquently defended in *Discours* (1562–63). Their commitment was guided by a conviction that the French monarchy was the best and that the Roman Catholic Church, subject perhaps to internal reforms, was the true heir of the church established in the first centuries after Christ. If their beliefs at times led them to write cruel verse, notably at the time of the Massacre of Saint Bartholomew's Day (beginning August 23, 1572, when Catholics rampaged and murdered some 3,000 Huguenots in Paris alone), all defended their sincere convictions and, at the same time, certain ideas of literary expression.

Influence of Calvin

The Reformation, in fact, was not limited to dogmatic, liturgical, or ecclesiastical changes. It brought cultural change as well. Ronsard became aware of it when Protestant ministers launched against him a series of scurrilous charges, to which he replied with the *Responce . . . aux injures et calomnies* (1563). Calvin and his disciples allowed neither humanism's global admiration for antiquity nor the poets' taste for mythology. Calvin assigned to the poet an imperative and even exclusive duty: to praise God and serve his Word. This is why Calvin had encouraged Marot's translation of the Psalms and why, after Marot, many Protestant poets, such as Theodore Beza, Jean de Sponde, and Théodore-Agrippa d'Aubigné, paraphrased or pondered them.

Humanist tragedy was born in 1553 with *Cléopâtre captive* by Étienne Jodelle. But before him, in a totally different spirit, Beza had written (and produced in Lausanne) *Abraham sacrifiant* (1550), which retained many qualities of the medieval *mystère* and, using a celebrated biblical episode, illustrated above all the combat of faith. The formula chosen by Beza was taken up again by Loys Desmasures, also a Protestant, in his *tragédies saintes* (1563): *David combattant, David triomphant,* and *David fugitif.* But this formula had no influence on the development of regular tragedy that blossomed in the works of Robert Garnier, published from 1568 to 1580.

Théodore-Agrippa d'Aubigné represented the perfect synthesis of humanism and Calvinism. He studied to perfection the three traditional languages, Latin, Greek, and Hebrew; and he was familiar with modern languages, especially Italian. He was so faithful to his church that he was given the sobriquet "Le Bouc du Désert" ("Goat of the Desert," implying "scapegoat") at a time (during the reign of Henri IV) when religious compromise and the rallying of numerous Protestants rendered his intransigence almost inappropriate. Earlier he had written of love, and he had written verse modelled on Petrarch in *Printemps* (composed between 1568 and 1580). These poems would not be distinguished from so many other collections were it not for the melancholy inspiration and force of their rhetoric. His rhetoric is found, without the melancholy, in his master poem *Les Tragiques,* composed for the most part at the end of the century but not published until 1616. The seven cantos of the poem invited the reader to a theological understanding of history. The first cantos ("Misères," "Princes," and "Chambre dorée") successively depicted a sombre tableau of France exhausted by the civil wars, the debauchery of Henri III's court, and the corrupt and cruel institutions of justice. In the fourth and fifth cantos, "Feux" and "Fers," Aubigné began a long list of the Protestant martyrs and of the fight of their coreligionists in defense of their faith. Aubigné's theological vision is even more accentuated in the last two cantos, "Vengeances" and "Jugement." In "Vengeances" the poet explains the judgments made by God against tyrants and then turns his attention to those who God will lift up at the end of time. "Jugement" is the apotheosis of the poem, the cry of joy of those murdered by history. It is the summit of a work that draws to a close—rare in Protestant works—with a mystical vision.

The term baroque has been used for a style that gives precedence to forms. It would be more just to underline the importance of a rhetoric of persuasion, with all its means: apostrophe, antithesis, descriptions. The pen that wrote *Les Tragiques* is not the same pen that wrote, albeit at the same time, the *Histoire universelle,* in which objectivity regained its hold. With Aubigné flickered the last light of 16th-century poetry. The *Histoire universelle,* his masterpiece, was published in the 17th century but escaped notice. Aubigné was foreign to Classical taste, which Malherbe inaugurated early in the 17th century.

Prose. The production of poetry in the 16th century did not outdo the other genres in quantity. Readers turned above all to works in prose, many of which do not belong to literature as strictly defined: accounts of voyages, lives of saints, and collections of diverse *leçons* or *lectures* (readings). Prose was slow in freeing itself from the heavy yoke thrown over it by the medieval humanists in their concern for the use of language. With Lemaire de Belges prose became eloquent, and with François Rabelais it became a prodigious domain of experimentation.

Rabelais

The work of Rabelais, who Voltaire called a "drunken philosopher," escapes all labels. Humanism rightfully claims *Pantagruel* (1532) and *Gargantua* (1534 or 1535), with their celebrated pages on education, war and peace, and the true religion. They resound with the voice of the man who called Erasmus his spiritual father and who befriended numerous Protestants. But it is important to remember that Rabelais in the first two books of his great work intended to laugh and to give laughter and that nothing, not even the most beautiful humanist philosophy, escaped the corrosive power of laughter.

The humanist reading of the work is embarrassed when it comes to interpreting the last three books, published long after the first two: *Le Tiers Livre* in 1546, *Le Quart Livre* in 1552, and the *Cinquième Livre* in 1564 (and of questionable authenticity). Certain episodes, such as Panurge's posing of the question of marriage, or the voyage of Pantagruel and his companions, often derail the critic who interprets on too high a level.

It is possible, as Verdun-Louis Saulnier thought, that Rabelais tried to deliver an essentially religious message for the world to decode, that of the Protestant humanists who, at the moment of persecution, abandoned the fight for doctrine and took refuge in silence and prayer. It is also quite possible that Pantagruel's voyage is the philosophical symbol for the search for truth against the dogmatism of all orders: dogmas are represented by the islands encountered on the voyage. Perhaps the work of Rabelais makes evident the crisis of pre-Cartesian philosophy, which oscillates between the for and the against, the *doxa* and the paradox, without arriving at the desired synthesis. But if the philosophy is blocked, the language is liberated, alternately solemn and clownish, clear and obscure.

Rabelais was acquainted with the milieu of learned men and their jokes and delighted in multiplying their ambiguity, their implications, and their wordplay. He produced a unique work that no one could imitate. Contemporaries did not err in calling Rabelais a poet.

Montaigne

Michel de Montaigne ranked Rabelais among the "simply pleasant" authors. Indeed, the purpose of Montaigne's *Essais* (*Essays*) had little in common with any of Rabelais's intentions. This is not to say that Montaigne disdained laughter and, above all, humour. But if he retired to the tower of his château while still young, it was to write something other than buffoonery. He too produced adventure novels, but he also invented a new genre, that of the *Essais.* At first he devoted his time to putting down on paper all the thoughts inspired by his numerous readings. But soon he took an interest in himself and became the material of his own book. The first two volumes of the *Essais* were published in 1580. A third was added in 1588, along with an enlarged edition of the first two. When he died in 1592 he left his own copy of the *Essais,* with numerous revisions written in his own hand. This revised text was published in 1595. Montaigne had stated that he could have continued to write indefinitely. The subject given him—his own self—was fathomless, as each day revealed anew, and introspection was endless.

Montaigne rejected any form of dogmatism (though leaving aside the question of the truths of religion). He was constantly on the watch for whatever he could learn about man, from conversation or from books, and especially from books on history and accounts of travels. He declared himself to be a Pyrrhonist, not a Skeptic, because the error of the Skeptic is to say that he knows nothing, while the Pyrrhonist refuses to make even that affirmation.

The essay as Montaigne conceived it adapts itself perfectly to that philosophy. Free in form, the essay permits the author to pass from one idea to another at will, according to his whim, and to the despair of those who seek a plan in his chapters. If there is no plan, it is because Montaigne invented a spontaneous style of writing that invites spontaneity in cognizant readers as well.

In contrasting ways Montaigne and Aubigné both enlightened the end of the 16th century. Aubigné was a party man, a herald of religion, and he deliberately put his poetry at the service of these. Montaigne was a man without party who invented a literature for the *honnête homme* ("gentleman"; the ideal of refinement), which may explain his success in the 17th century. But the qualities represented by Aubigné do not disappear in the 17th century, "the century of saints," which saw the birth of many great religious works. The richness of the 16th century is found also in its legacy. (D.Mé.)

The 17th century

LITERATURE AND SOCIETY

Refinement of the language. At the beginning of the 17th century the full flowering of the Classical manner was still remote, but various signs of a tendency toward order, stability, and refinement can be seen. A widespread desire for cultural self-improvement is reflected in the numerous manuals of politesse, or formal politeness, which appeared through the first half of the century; while at the celebrated salon of Mme de Rambouillet men of letters, mostly of bourgeois origin, and the nobility and leaders of fashionable society mixed in an easy relationship to enjoy the pleasures of the mind. Such gatherings did much to refine the literary language and also helped to prepare a cultured public for the serious analysis of moral and psychological problems.

The earliest imaginative literature to reflect the new taste was written in imitation of the pastoral literature of Italy and Spain; the masterpiece of the genre was *L'Astrée* (1607–27) by Honoré d'Urfé. Manners are stylized, settings are conventional, and the plot is highly contrived; but the psychology of the characters is handled with insight.

Influence of Malherbe

Refinement of the language of poetry was the self-imposed task of François de Malherbe: resolutely opposed to the exalted conception held by La Pléiade of the poet as inspired favourite of the Muses, he owes his place in literary history not to his undistinguished creative writing but to a critical doctrine imposed on fellow poets by word of mouth and personal example. Malherbe called for a simple, harmonious metre and a sober, almost prosaic vocabulary, pruned of imaginative poetic fancy. His influence helped to make French lyric verse, for nearly two centuries, elegant and refined but lacking imaginative inspiration. Malherbe's alexandrine, however—clear, measured, and energetic—was a metre marvellously suited to be a vehicle for Pierre Corneille's dramatic verse.

Not all poets of the 1620s accepted Malherbe's lead. The most distinguished of the independents was Théophile de Viau (referred to as Théophile), who not only opposed Malherbe in style and technique but also expressed the free thought inherited from Renaissance Italy. Théophile's verse, with its engaging flavour of spontaneity and sincerity, shows a sensual delight in the natural world. His whole way of life was a provocation to the *bien-pensants* ("right-minded"): he was the leader of a freethinking bohemia of young noblemen and men of letters, practicing and preaching social and intellectual unorthodoxy. His persecution, imprisonment, and early death ended all this, however: libertinage went underground, and repressive orthodoxy was entrenched for a century or more. The poetry of Théophile and other independents exemplifies that manner to which modern criticism has given the name baroque. The baroque poet has been said to possess "a vision of life distorted through imagination and sensibility." Whereas in the case of Malherbe and his school sensibility is constantly controlled by common sense, baroque writers embellish their descriptions of nature by subjective flights of fancy that may even assume an absurd or surrealist flavour, resulting in an intensely personal picture of the world, far removed from Malherbe's cliché-like generalizations.

Development of drama. Unlike the humanist playwrights of previous generations, Alexandre Hardy was nothing if not a man of the theatre. *Poète à gages* (staff poet) to the Comédiens du Roi company at the Hôtel de Bourgogne in Paris, he wrote hundreds of plays, of which 34 were published (1623–28). In addition to writing tragedies, he developed the tragicomedy and pastoral, which became the most popular genres between 1600 and 1630. While Hardy's plays possess the vigour and colour of Elizabethan and Jacobean drama, his style is unattractive; but, in the theatre as elsewhere, the pastoral was a refining influence, providing a vehicle for the subtle analysis of feeling. Although the finest play of the 1620s is a tragedy, Théophile's *Pyrame et Thisbé* (1623), which shares the fresh, lyrical charm of the pastorals, tragicomedy is without a doubt the baroque form at its best. Here, the favourite theme of false appearances, the episodic structure, and devices such as the play within the play reflect the essentials of baroque art. During the 1630s a crucial struggle took place between this irregular type of drama and a simpler and more disciplined alternative. Theoretical discussion focussed on the conventional rules (the unities of time, place, and action, mistakenly ascribed to Aristotle), but the *bienséances* (conventions regarding subject matter and style) were no less important in determining the form and idiom the mature Classical theatre was to adopt.

Comedy gained a fresh impetus about 1630; and the new style, defined by Corneille as "une peinture de la conversation des honnêtes gens" ("a painting of the conversation of the gentry"), simply transposes the pastoral into an urban setting. At the same time, ambitious young playwrights competing for public favour and the support of the two Paris theatre companies, the Hôtel de Bourgogne and the Marais, did not neglect other types of drama; and Corneille, together with Jean Mairet, Tristan (François L'Hermite), and Jean de Rotrou, inaugurated "regular" tragedy. But it was some time before Corneille, any more than his rivals, turned exclusively to tragedy. The eclecticism of these years is illustrated by *L'Illusion comique* (1635), a brilliant exploitation of the interplay between reality and illusion that characterizes baroque art.

Corneille's *Le Cid*

The two trends come together in Corneille's theatre in *Le Cid* (1637), which, though often called the first Classical tragedy, was created as a tragicomedy. The emotional range Corneille achieves with his verse in *Le Cid* is something previously unmatched. Contemporary audiences at once recognized the play as a masterpiece, but it was subjected to an unprecedented critical attack. The *querelle du Cid* (quarrel of *Le Cid*) caused such a stir that it led to the intervention of the Cardinal de Richelieu, who referred the play to the judgment of the newly founded Académie Française.

The formation of the Académie, an early move to place cultural activity under the patronage of the state, dates from 1634; examination of *Le Cid* on Richelieu's orders was an exception to its normal functions, which concerned the standardization of the French language. This effort bore fruit in the Académie's own *Dictionnaire* of 1694, though by then rival works had appeared in the dictionaries of Richelet (1680) and Furetière (1690).

A similar desire for systematic analysis inspired Claude Favre, sieur de Vaugelas, also an Academician, whose *Remarques sur la langue françoise* (1647) record polite usage of the time. In the field of literary theory the same rational approach produced the *Poétique* of La Mesnardière (1639) and the Abbé d'Aubignac's *Pratique du théâtre* (1657), both treatises, which strongly influenced the establishment of Classical doctrine being instigated by Richelieu's personal patronage.

Meanwhile another protégé, Jean Chapelain, began in the 1630s to exert an influence similar to that of Malherbe a generation earlier. Although he produced no important doctrinal work and made his mark in the salons and in occasional writings, Chapelain was nevertheless a major architect of Classicism in France. More liberal than Malherbe, he made allowance for that intangible element ("le je ne sais quoi") that rules cannot produce. The *Sentiments de l'Académie* (1638), compiled by Chapelain as a judgment on *Le Cid*, reflect prudent compromise, but one can sense beneath the pedantry of certain comments a genuine feeling for the harmony and regularity that Classical tragedy was to achieve.

The effect of the *querelle du Cid* on Corneille's evolution is unmistakable: all his experimentation was henceforth to be carried out within the stricter Classical formula. A remarkable spell of creative activity produced in quick succession *Horace* (1640), *Cinna* (1640), and *Polyeucte* (1643), which, with *Le Cid*, represent the playwright's highest achievement: a triumphant justification of the formula that Mairet and others had helped to develop but which Corneille himself perfected. The essence of Classical tragedy is a single action, seized at crisis point. Despite the prominence always given to the unities of time and place, it is unity of action that gives Classical tragedy its essential character. The other unities merely help to make unity of action effective.

Tragicomedy lingered on as a popular alternative. Rotrou's *Saint-Genest* (1647), for example, provides an interesting contrast with *Polyeucte*, treating in the baroque manner similar themes of divine grace and conversion. But by the 1640s writers and their public had become more responsive to various standardizing influences. René Descartes's *Discours de la méthode* (1637; *Discourse on Method*), with its opening sentence, "Le bon sens est la chose du monde la mieux partagée . . ." ("Good sense is of all things in the world the most equally distributed . . ."), clearly assumes that the mental processes of all men, if properly conducted, will lead to identical conclusions. A similar assumption is implicit, as regards the psychology of the passions, in Descartes's *Traité des passions de l'âme* (1649; *Treatise on Passions*). In the field of creative writing, poets sometimes come to distrust their individual sensibilities and prefer to mold their imaginations to the common denominator of a social group. In lyric poetry, the linguistic tendencies crystallized by the reforms of Malherbe and Vaugelas combine with the preoccupations of the salons to produce writing that is seldom more than mannered wordplay.

Generally speaking, such tendencies toward a literature expressing the cultural values of a homogeneous society affect form more than content. For the self-centred aristocratic idealism that inspired the Fronde (a series of civil wars between 1648 and 1653) also finds expression in the literature of the period, and nowhere more clearly than in Corneille's tragedies. His self-reliant heroes, meeting every challenge and overcoming every obstacle, are motivated by the self-conscious moral code that animated the Cardinal de Retz, Mme de Longueville, and other leaders of the heroic but futile resistance to Cardinal Mazarin. In neither case is devotion to a cause free from self-glorification; in both, the approbation of others is as necessary as the desire to leave an example for posterity. Such optimistic, heroic attitudes may seem incompatible with a tragic view of the world; indeed, Corneille provides the key to his originality in substituting for the traditional Aristotelian emotions of pity and fear a new goal of admiration. Corneille asks that his audience admire something larger than life, and the best of his plays are still capable of arousing this response.

The heroic ideal. The same appetite for heroic subject matter is reflected in the mid-century novels. These resemble *L'Astrée* in that they are long-winded, multivolume adventure stories with highly complicated plots, but they have moved from the world of the pastoral to that of ancient history. The two best known examples, *Artamène ou le grand Cyrus* (1649–53) and *Clélie* (1654–60), both by Mlle de Scudéry, are set in Persia and Rome, respectively. Such novels reflect the society of the time. They also show how the readers and playgoers of the Classical age were formed: the minute analysis of the passions, when divorced from the superficial romanesque, looks forward to the psychological subtlety of Racine.

Other writers of the period make a more individual use of the novel form. Cyrano de Bergerac returned to the Renaissance tradition of fictional travel as a vehicle for social and political satire and may be seen as an early exponent of science fiction. So provocative were the ideas expressed in his *Histoire comique des états et empires de la lune* (1656) and *Histoire comique des états et empires du soleil* (1661; *A Voyage to the Moon: With Some Account of the Solar World*) that neither work was published until after 1655, the year of his death. Paul Scarron was more down-to-earth in purpose and manner: in *Le Roman comique* (1651–57) he set out to parody the heroic novels. His novel follows the fortunes of an itinerant troupe of actors and has some value as documentary, but in his portrayal of provincial society Scarron yields to his penchant for good-humoured burlesque, also illustrated in his mock-epic *Virgile travesti* (1648–52).

The *Maximes* of La Rochefoucauld

The honnête homme. Partly because of the influence of the salons and partly as a result of disillusionment at the failure of the Fronde, the heroic ideal was gradually replaced in the 1650s by the concept of *honnêteté*. The word literally means "honesty" but figuratively refers to a sincere refinement of tastes and manners. Unlike the aspirant after *gloire* ("glory"), the *honnête homme* ("gentleman") cultivated the social graces and valued the pleasures of social intercourse. A cultured amateur, modest and self-effacing, he took as his model the Renaissance *uomo universale* ("universal man"), the complete all-rounder. François de La Rochefoucauld provides an interesting illustration of the transition between the two ages. An aristocrat who played a leading part in the Fronde, he was motivated in his early life by ambition and family pride but retired to begin a new career as man of letters. The *Maximes* (1665), his principal achievement, is a collection of 500 epigrammatic reflections on human behaviour, expressed in the most universal terms: the general tone is cynical, self-interest being seen as the source of all actions. If a more positive message is to be seen, it is the recognition of *honnêteté* as a code of behaviour that holds society together. However, even this is touched with cynicism. La Rochefoucauld's view of *honnêteté* is a pragmatic one, falling as far short of the ideal defined by Antoine Gombaud, chevalier de Méré, in his *Discours de la vraie honnêteté* (1701; "Discourse on True Honnêteté") and other essays, where it is presented as a true *art de vivre,* as it does of the example set by Charles de Saint-Denis, sieur de Saint-Évremond, who, in the opinion of contemporaries, most nearly lived up to such an ideal. Few *honnêtes gens* had the culture, the taste, and the temperament to practice the art of living in such an exemplary way, but the ideal of tolerant, cultured Epicureanism for a while set the tone of social life in Paris.

This period also saw the fullest development of the feminine cult of *préciosité,* a style of thought and expression exhibiting delicacy of taste and sentiment. Inasmuch as *honnêteté* stands for moderation in all things, and *préciosité,* in the extreme, for affectation and extravagance, the two phenomena may seem to be opposites. The sentiments and manners satirized by Molière in *Les précieuses ridicules* (1659) do not represent the whole picture, however, and, although the natural desire of these early feminists to assert themselves meant that their ideas were often taken to extremes, *précieuses* like Mlle de Scudéry were responsible for introducing a new subtlety into the language, establishing new standards of delicacy in matters of taste, and propagating advanced ideas about the equality of the sexes in marriage. Their aims thus ran parallel to those of the *honnêtes gens*, and the ideal of the educated, emancipated woman was the female counterpart of the masculine ideal defined above.

The fullest representation of the *honnête homme* in imaginative literature is to be found in the theatre of Jean-Baptiste Poquelin, known as Molière. A bourgeois by birth, a courtier, and an *honnête homme,* Molière was also an actor-manager and an entertainer. He toured the provinces with his theatre troupe from about 1645 until 1658, when they returned to Paris. Molière soon succeeded in imposing on audiences a completely new type of comedy. While his early plays may be divided conventionally into *comédies littéraires* and popular farces, from *L'École des femmes* (1662) onward these two strains are fused, creating a formula that combined the Classical structure, the linguistic refinement, and the portrayal of manners expected of comedy with the caricatural characterization proper to farce. Even in stylized verse plays such as *L'École des femmes, Le Misanthrope* (1666), *Le Tartuffe* (1664), or *Les Femmes savantes* (1672), the comedy of manners merely provides a framework for the comic portrait of a central character, in which exaggeration and fantasy play a considerable part. However topical the subject and however prominent the satirical content of Molière's plays, his characters always possess a common denominator of universal humanity. Most plays contain, alongside the comic character, one or more examples of the *honnête homme;* and the social norm against which his comic characters offend is that of a tolerant, humane *honnêteté.* In *Le Tartuffe,* and in *Dom Juan* (1665), topical references and satirical implications were so provocative, because both plays dealt with the delicate subject of religious belief, that there were strong reactions from churchmen. However, from the start of his Paris career Molière could count on the active support of the king, Louis XIV. A number of his plays were written for performance at Versailles or other courts; and Molière also wrote several *comédies-ballets* and collaborated in other divertissements that brought together the arts of poetry, music, and dance.

The biggest box-office success of the century, judged by length of first run, was the *Timocrate* (1656) of Pierre Corneille's younger brother Thomas, a prolific playwright adept at gauging the public taste. *Timocrate* was exactly contemporary with the *précieux* novels of Mlle de Scudéry, and, like Philippe Quinault in his *tragédies galantes,* the author reproduced the disguises and amorous intrigues so much admired by habitués of the salons. However, the 1660s were to see the rivalry between two acknowledged masters of serious drama. Pierre Corneille, returning to the theatre in 1659 after a hiatus, wrote several more plays; but though *Sertorius* (1662) or his last play, *Suréna* (1674), bear comparison with earlier masterpieces, the heroic idealism had lost conviction. While Corneille retained his partisans among older playgoers, it was Jean Racine who appealed to newer audiences, less idealistic in their attitude to psychology: the new realism was in tune with La Rochefoucauld's *Maximes* rather than with Descartes's *Traité des passions.*

Racine's fatalism. Whether Racine's Jansenist upbringing determined his view of a human nature controlled by perverse and willful passions, or whether his knowledge of Greek tragedy explains the fatalism of his own plays, the imaginary world inhabited by his heroes could not be more different from that of Corneille's. Tragedy for Racine is an inexorable series of events leading to a foreseeable catastrophe. Plot is of the simplest; the play opens with the action at crisis point; and once the first step is taken, tension mounts between incompatible protagonists until one or more is destroyed. Racine's career began in 1664 with *La Thébaïde,* a grim account of the mutual hatred of Oedipus' sons; this was followed by *Alexandre le grand* (1665), his only attempt at the manner of Quinault. The masterpieces date from the highly successful *Andromaque* (1667), another subject from Greek legend, after which, for *Britannicus* (1669) and *Bérénice* (1670), Racine turned to topics from Roman history. *Bajazet* (1672) is based on modern Turkish history; *Mithridate* (1673) has as its hero the famous enemy of Rome; and finally there followed two plays with Greek mythological subjects: *Iphigénie* (1674) and *Phèdre* (1677).

Writings of Boileau

Nondramatic verse. Nondramatic verse still enjoyed a special prestige, as shown in *L'Art poétique* (1674) of Nicolas Boileau-Despréaux, where the genres most highly esteemed are the epic (of which no distinguished example was written during the century), the ode (a medium for official commemorative verse), and the satire. Boileau himself, in his satires (from 1660) and epistles (from 1674), as well as in *L'Art poétique,* established himself as the foremost critic of his day; but despite a flair for judging contemporaries, his criteria were limited by current aesthetic doctrines. In *Le Lutrin* (1674–83), a model for Alexander Pope's *The Rape of the Lock*, he produced a masterpiece of comic writing in the Classical manner. Jean de La Fontaine's *Fables* (1668; 1678–79; 1692–94) succeed in transcending the limitations of the genre; and although readers formerly concentrated excessively on the moral teaching they offer, it is possible to appreciate beneath their apparent naïveté the mature skills of a highly imaginative writer, who displays great originality in adapting to his needs the linguistic and metrical resources of the Classical age.

THE CLASSICAL MANNER

Though the novel was still considered to be a secondary genre, it produced one masterpiece that embodied the Classical manner to perfection. In *La Princesse de Clèves* (1678) by Mme de La Fayette, the narrative forsakes the fanciful settings of its pastoral and heroic predecessors and explores the relationship between the individual and society in a sober, realistic context. The language achieves its effects by understatement and subtle nuance rather than by rhetorical flourish; and it is appropriate that a woman writer should have created this lasting tribute to the feminine influence, which, in the salons, helped to form such an expressive medium for psychological analysis. The other great woman writer of her age, Mme de Sévigné, was (like La Fontaine) too idiosyncratic to be truly representative. Her intimate, informal correspondence—totally unlike that of Jean-Louis Guez de Balzac half a century earlier—was nevertheless composed with a careful eye to literary effect. Mme de Sévigné not only was an admirable example of the cultured reader for whom the *grands classiques* wrote but was herself one of the most skillful prose writers of her day.

The *Pensées* of Pascal

The most distinguished prose writer of the age, however, was a man who, if he does reflect the society he lived in, does so in a highly critical light. The *Pensées* of Blaise Pascal present an uncompromising reminder of the spiritual values of the Christian faith. The work remains incomplete, so that in place of the dialectical cogency of *Les Provinciales* (1656–57), his masterly satire of Jesuit casuistry, it possesses an enigmatic, incoherent quality in spite of the aphoristic brilliance of many fragments. The central theme is clear enough: Pascal's view of human nature has much in common with that of La Rochefoucauld or Mme de La Fayette, but in his case the misery of godless man is contrasted with the potential greatness man can attain through divine grace. Pascal is the first master of a really modern prose style. Whereas Descartes's prose is full of awkward Latinisms, Pascal uses a short sentence and is sparing with subordinate clauses. The clarity and precision he achieves are equally appropriate to the penetrating analysis of human nature in the *Pensées* and to the irony and comic force of the *Provinciales*.

Religious authors. A new intellectual climate can be recognized from 1680 onward. An increased spiritual awareness resulting from Jansenist teaching, the preaching of Jacques-Bénigne Bossuet and others, and the influence of Mme de Maintenon at court, marked French cultural life with a new moral earnestness and devotion. The position of Bossuet is an ambivalent one. In spite of his outspoken criticism of king and court, his view of kingship and of the relationship between church and state made him one of the principal pillars of the regime of the Sun King, carrying Richelieu's policies to their logical conclusion. His ultraorthodox views are expressed in writings such as the *Discours sur l'histoire universelle* (1681); but he also exerted a considerable moral influence in his sermons and funeral orations, which took the art of pulpit oratory to a new high level. François de La Mothe-Fénelon was a much less orthodox churchman, and the influence he wielded was of a more liberal nature. Like Bossuet, he was a tutor in the royal household, and he was also author of a classical novel, *Les Aventures de Télémaque* (1699).

Just as Fénelon chose a Classical model—his novel purports to be the continuation of Book Four of the *Odyssey*—so Jean de La Bruyère chose to write his *Caractères de Théophraste traduits du grec, avec les caractères ou les moeurs de ce siècle* (1688) in the style of the Greek moralist Theophrastus. However, his work, appended to his translation of Theophrastus, was from the beginning more specific in its reference to his own times; and successive editions, up to 1694, made of it a powerful indictment of the vanity and pretensions of a status-conscious society, and even of the extravagance and warmongering of the King himself. At best, La Bruyère writes as an ironic commentator on the social comedy around him.

An equally satirical picture of the age is left by a number of Molière's successors writing for the comic theatre (which, from the founding of the Théâtre Français in 1680, was organized on a monopoly basis). Comedy, at the hands of such writers as Jean-François Regnard, Florent Carton Dancourt, and Alain-René Lesage, continued to be lively and inventive; but the writing of tragedy, by contrast, already had become a much more derivative exercise. Exception must be made for Racine's last two plays, *Esther* (1689) and *Athalie* (1691), written not for the professional theatre but for the girls' school at Saint-Cyr. The latter in particular is as powerful as any of the secular plays.

The Ancients and the Moderns. Finally, the end of Louis XIV's reign witnessed the critical debate known as the *querelle des anciens et des modernes* (Quarrel of the Ancients and the Moderns), a long-standing controversy that came to a head in the Académie and in various published works. Whereas Boileau and others saw imitation of the literature of antiquity as the only possible guarantee of excellence, moderns such as Charles Perrault in his *Parallèle des anciens et des modernes* (1688–97) and Bernard Le Bovier, sieur de Fontenelle, in his *Digression sur les anciens et les modernes* (1688) claimed that the best contemporary works were inevitably superior, because of the greater maturity of the human mind. It was a sterile and inconclusive debate, but the underlying issue was most important, for the moderns indirectly, if not explicitly, anticipated those 18th-century thinkers whose rejection of a single universal aesthetic in favour of a relativist approach was to hasten the end of the Neoclassical age. (W.D.H.)

The 18th century: from Louis XIV to the Revolution

THE ENLIGHTENMENT

The death of Louis XIV on September 1, 1715, closed an epoch; the date of 1715 is a useful starting point for the Enlightenment. But the beginnings of critical thought go back much further, to about 1680, where one can begin to discern a new intellectual climate of independent inquiry and the questioning of received ideas and traditions.

The earlier date permits the inclusion of two important precursors. Pierre Bayle, a Protestant forced into exile by the repressive policies of Louis XIV against the Huguenots, paved the way for later attacks upon the established church by his own onslaught upon Roman Catholic dogma and, beyond that, upon rationalist ideologies of all kinds. His skepticism was constructive, however, underlying a fervent advocacy of toleration based on respect for freedom of conscience. In particular, his *Dictionnaire historique et critique* (1697; 2nd ed., 1702) became an arsenal of knowledge and critical ideas alike for the 18th century.

Bayle and Fontenelle

Bayle's contemporary Fontenelle continued in Descartes's wake to make knowledge, especially of science, more accessible to the educated layman. His *Entretiens sur la pluralité des mondes* (1686; *A Plurality of Worlds*) explains the Copernican universe in simple terms, the author expounding his lessons with characteristic gallantry to an attractive marquise on six moonlit evenings in the park of her château. The *Histoire des oracles* (1687) complements this popular erudition by a rationalist critique of erroneous legends. Fontenelle helped to lay the basis for empirical observation as the proper approach to scientific truth.

Both Bayle and Fontenelle promoted the Enlightenment principle that the pursuit of verifiable knowledge was a central human activity. Bayle was concerned with the problem of evil, which seemed to him a mystery in which philosophical speculation was gratuitous and understandable by faith alone. But such unknowable matters did not at all invalidate the search for hard fact, as the *Dictionnaire* abundantly shows. Fontenelle, for his part, saw that the furtherance of truth depended upon the elimination of error, arising as it did from human laziness in unquestioningly accepting received ideas or from human love of mystery. Though both thinkers shared a pessimistic view of human nature, they also saw ways in which the human condition could be improved.

Montesquieu

The Baron de Montesquieu, the first of the great Enlightenment authors, demonstrated a liberal approach to the world fitting in with a pluralist view of society. His *Lettres persanes* (1721; *Persian Letters*) were at once successful and established his reputation. Purporting to be letters written to and by two Persians visiting France, they depict a contemporary Paris full of vitality and movement but precariously vulnerable to possible despotism.

His interest in social mechanisms and causation is pursued further in the *Considérations sur les causes de la grandeur des Romains et de leur décadence* (1734; *Reflections on the Causes of the Grandeur and Decline of the Romans*). To explain Rome's greatness and decline, Montesquieu invokes the notion of an *esprit général* ("general spirit"), a set of secondary causes underlying each society and determining its developments. Herein are the seeds of *De l'esprit des lois* (1748; *The Spirit of Laws*), the preparation of which took 14 years. This great work brought political discussion into the public arena in France by its insistence upon the need, in whatever form of society, to maintain liberty as prime object of concern.

Voltaire (François-Marie Arouet), on any count, bestrides the Enlightenment. Whether as dramatist, historian, reformer, poet, philosopher, or correspondent, for 60 years he remained an intellectual leader in France. A stay in England (1726–28) led to the *Lettres philosophiques* (1734), which, taking England as a polemical model of philosophical freedom, experimental use of reason, and respectful patronage of arts and science, offered a program for a whole civilization. In later years Voltaire's onslaught upon the power of the Roman Catholic Church became more direct, as he denounced its doctrines and practices in countless pamphlets and the *Dictionnaire philosophique* (1764; *The Philosophical Dictionary*), the vade mecum of Voltairean attitudes. He laboured on historical works all his life, producing most notably *Le Siècle de Louis XIV* (1751; *The Age of Louis XIV*) and the *Essai sur les moeurs* (1756; "Essay on Customs"), the latter a world history of a half-million words. Above all, it was the growth of civilizations and cultures that particularly commanded his attention and formidable energy. He is best remembered for the tale *Candide* (1759), a savage denunciation of metaphysical optimism ("all is for the best in the best of all possible worlds") that reveals a world of horrors and folly. In *Candide*'s characters the instinct of survival remains uppermost, however, and provides a ray of hope in an otherwise sombre scene. Candide at last renounces absolute truths as futile and settles for the simple life of "cultivating his garden." The *conte* ("tale") called *L'Ingénu* (1767) continued this lesson; Voltaire turned from metaphysics to social satire upon the corrupt French government (set with prudence retrospectively in Louis XIV's reign). Reformist appeals to justice were the main focus of Voltaire's writings in his last 20 years, as he protested against such outrages as the executions, religiously motivated, of Jean Calas and the Chevalier de La Barre.

Diderot

Another universal genius of the age was Denis Diderot. He occupied a somewhat less exalted place, however, essentially because most of his greatest works were published only posthumously. But his encylopaedic range is undeniable. Theorist of the bourgeois drama, author of the greatest French antinovel of the century (*Jacques le fataliste,* 1796), and the first great French art critic (*Salons*), Diderot seized on the vision of a world materialistic and godless yet pulsating with energy and the unexpected. *Jacques le fataliste* captures the fluidity of a disconcerting universe where nothing is ever quite clear-cut or totally under control. Jacques represents it suitably by believing in fatalism yet acting with decisiveness when he wishes, just as if he possessed free will.

Diderot's interest in the plasticity of matter, where categories such as animal, vegetable, and mineral never seemed as distinct as conventional thought suggested, combined with an interest in biology, nowhere better exemplified than in *Le Rêve de d'Alembert* (written 1769, published 1830; *The Dream of d'Alembert*). This work is written in the characteristic form of a dialogue, allowing Diderot to range free with speculative questions rather than attempt firm answers.

In his own day Diderot was best known as editor of the *Encyclopédie,* a vast work in 17 folio volumes of text and 11 of illustrations. He and Jean Le Rond d'Alembert inaugurated the undertaking in 1751, and Diderot edited alone from 1758 until the final volume of plates appeared in 1772. A summation of knowledge rather than a radically polemical enterprise, the *Encyclopédie* is, however, the epitome of the Enlightenment, disseminating information to improve the human lot, reduce theological superstition, and, in Diderot's words from his key article "Encyclopédie," "change the common way of thinking."

DRAMA

Tragedy and the survival of Classical form. Classical tragedy survived into the 18th century, most notably in the theatre of Voltaire, which dominated the Comédie-Française from the premiere of *Oedipe* (1718) to that of *Agathocle* (1779). But even in Voltaire a profound change in sensibility is apparent as pity reigns supreme, to the exclusion of terror. Tragedy, in the view of Fontenelle or the Abbé Dubos, should teach men virtue and humanity. Voltaire's *Zaïre* (1732) does just that, through the spectacle of Christian intolerance overwhelming the eponymous heroine, torn as she is between the religion of her French Catholic forefathers and the Muslim faith of her future husband, a Turk. No fatality of character destroys her, but simply the failings of Christians unworthy of their creed, allied to gratuitous and avoidable chance. Such pathos, often touching, is not the stuff of great tragedy.

Theatre of Voltaire

Marivaux and Beaumarchais. The best of 18th-century drama takes a different course. Pierre Marivaux wrote more than 30 comedies, mostly between 1720 and 1740, bearing for the most part upon the psychology of love. Typically, the Marivaudian protagonist is a refined young lady who finds herself, to her bewilderment or even despair, falling in love despite herself, thereby losing her autonomy of judgment and action. *La Surprise de l'amour,* a title Marivaux used twice (1722, 1727), becomes a regular motif, the interest of each play resting in the delicate changes of attitude and circumstance rung by the dramatist. His sympathy for the generally likable heroes and heroines stops short, however, of indulgence. The action is dramatic essentially because the characters' stubborn pride, central to their being, has to succumb to the demands of their instincts. Vanity, in Marivaux's view, is endemic to human nature. In *Le Jeu de l'amour et du hasard* (1730; *The Game of Love and Chance*), the plot of which is based on masters disguised as servants and vice versa, a heroine named Silvia experiences profound consternation at the quite unacceptable prospect of falling for a valet. When she learns the happy truth, her relief immediately gives way to a determination to force her lover Dorante into surrender while he still thinks her a servant. As her father puts it, "What an insatiable vanity of amour propre!" Many plays deal more explicitly with social barriers created by rank or money, like *La Double Inconstance* (1723) and *Les Fausses Confidences* (1737). As the subtlety of Marivaux's perceptions has become better understood, he has come to be regarded as the fourth great classic (after Corneille, Racine, and Molière) of the French theatre.

Pierre-Augustin Caron de Beaumarchais is best remembered for two comic masterpieces, *Le Barbier de Séville* (1775; *The Barber of Seville*) and *Le Mariage de Figaro* (1784; *The Marriage of Figaro*). Both are dominated by Figaro, a scheming dynamo of wit and generosity. He is a wholly free man in the first play, plotting his master Almaviva's conquest of Rosine, but he is obliged in the second play to defend his fiancée, Suzanne, against Almaviva's irresponsible meddling. (Some critics have detected a prerevolutionary quality to *Le Mariage,* but the evidence is too insubstantial to sustain this thesis.) As much as the sharpness of wit and character, the brilliance of structure wins admiration. All is movement and vicissitude, *Le Mariage* in particular with its 92 scenes (about thrice the average number in a Classical play) and profusion of theatrical "business" rising to the magisterial imbroglio of the final act.

Bourgeois drama. Yet Beaumarchais himself espoused the *drame bourgeois* ("bourgeois drama," or "middle-class tragedy") in his *Essai sur le genre dramatique sérieux* (1767). He wrote several *drames,* among them the sequel to *Le Mariage* in *L'Autre Tartuffe, ou La Mère coupable* (1792). The growing importance of sentiment on the stage had proved as inimical to Classical comedy as to Classical tragedy. More popular was a type of comedy both serious and moralistic, like *Le Glorieux* (1732; *The Conceited Count*) by Philippe Néricault Destouches, who claimed in the preface that he wanted to "purify society," or the *comédies larmoyantes* ("tearful comedies") of Pierre-Claude Nivelle de La Chaussée, which enjoyed great popularity when they appeared in the 1730s and '40s. Diderot's *Entretiens sur le fils naturel* (1757) gave a theoretical underpinning to the new mood. The author called for a "tragédie domestique et bourgeoise," realistic and affecting, able to inspire strong emotions and incline audiences to more elevated states of mind. This "genre sérieux" ("serious genre"), reacting against the articulate tirades of Classical tragedy, would draw on pantomime and tableaux or inarticulate speech rather than on eloquent discursiveness. Beaumarchais's own prescriptions run on similar lines. Though Diderot's plays did not live up to his theories, the emphasis upon middle-class virtuousness was to be made dramatically effective in Michel-Jean Sedaine's *Le Philosophe sans le savoir* (1765; "The Unwitting Philosopher"; Eng. trans., *The Duel*). Louis-Sébastien Mercier transposed the same formula a class downward into the artisan world in *La Brouette du vinaigrier* (1775; "The Barrel-load of the Vinegar Merchant"). Both achieved greater fidelity of representation on the stage. But the success of the *drame bourgeois* was short-lived, perhaps because it attempted the incompatible aims of being true to life and inculcating idealistic attitudes.

POETRY

The emphasis upon reason, science, and philosophy may explain the absence of great poetry in the 18th century. The best verse is that of Voltaire, whose chief claim to renown during most of his lifetime was as a poet. In epic, mock-epic, philosophical poems, or witty society pieces he was preeminent; but to the modern critic the lyrical effusion or linguistic intensity that might indicate genius seem to be missing.

THE NOVEL

The success of the novel is a more positive story. Despite official opposition and occasional censorship, the new genre developed apace. The first great 18th-century exemplar is now seen to be Robert Challes, whose *Illustres françaises* (1713), a collection of seven tales intertwined, commands ever greater attention for its serious realism and disabused candour anticipating Stendhal. As the bourgeois spirit acquired a more prominent place in society, the *roman de moeurs* became important, most notably in the novels of Alain-René Lesage: *Le Diable boiteux* (1707; *The Devil upon Two Sticks*) and more especially *L'Histoire de Gil Blas de Santillane* (1715–35; *The Adventures of Gil Blas of Santillane*). The latter, a loose-knit picaresque novel, recounts its hero's rise in society and concomitant moral education, set against a comprehensive picture of the surrounding world. Characterization and sensibility receive greater attention in the novels of the Abbé Prévost, whose reputation has become more broadly based with the publication (beginning in 1969) of his complete works. He is best known, however, as the author of the *Histoire du chevalier des Grieux et de Manon Lescaut* (1731), an ambiguous mixture of disinterested passion and shabby criminality in which des Grieux, a young scapegrace but also a man of the most exquisite sentiments, sacrifices himself to the amoral, delicate, and forever enigmatic Manon. In this tragic tale love conquers all, but it constantly needs vulgar money to sustain it. Tears and swoonings abound, as do precise notations of financial costs. This blend of traditional romance and sordid realism, never quite one or the other, combines with the ambivalent characterization of the chevalier to create a masterpiece.

By contrast, Marivaux as novelist devoted his main energies to psychological analysis and the moral life of his characters. His two great narratives, *La Vie de Marianne* (1731–41) and *Le Paysan parvenu* (1734–35; "The Fortunate Peasant"), follow one single character recounting, as in *Manon Lescaut,* his past experience. But unlike the tone of *Manon Lescaut,* the comic note prevails in Marivaux's novels as Marianne and Jacob make their way upward in society. Reflection upon conduct becomes more important than conduct itself; the narrator, now of mature years, comments and endlessly interprets his actions when young and still in transit socially. The result provides a rich density of feelings, meticulously analyzed or finely suggested. Both protagonists are morally equivocal, born survivors with an eye for the main chance, yet they also are attractive because they reveal themselves so disarmingly and because they are capable of disinterested and honourable actions. What abides, however, is the portrait of one particular consciousness, unceasingly informative on the mysteries of the human mind and heart.

Rousseau

The preeminent name associated with the sensibility of the age is that of Jean-Jacques Rousseau. He promoted the cult of nature, lakes, mountains, and gardens, in contrast to the false glitter of cultured society. He called for a new way of life attentive above all to man's innate sense of pity rather than dependent upon meretricious reasoning; espoused untutored simplicity and the true equality of all because all men share a capacity for feeling; and aimed at total sincerity in his confessional writings and thereby gave birth to the modern autobiography. Thus he stands as one of the greatest thinkers of his time, alongside, and generally in opposition to, Voltaire. He established the modern novel of sensibility with the resounding success of his *Julie: ou La Nouvelle Héloïse* (1761), a novel about an impossible, doomed love. He composed an indispensable classic of educational theory with *Émile: ou De l'éducation* (1762), which traces the program of an ideal education from birth to marriage. The hero, brought up away from corrupting society, becomes a truly moral person, in keeping with the principles of natural man. Rousseau stresses the importance of feeling and spontaneity of action over purely theoretical doctrine; religious sensibility is an essential element of Émile's makeup.

The sharp hostility toward contemporary society already evident in his *Discours sur les sciences et les arts* (1750) is more profoundly elaborated in the *Discours sur l'origine et les fondements de l'inégalité parmi les hommes,* sometimes called the *Second Discours* (1755). Social inequality has come about because men have allowed their God-given right of freedom to be usurped. Our elegant, civilized society is a sham, whose reality is endless posturing, hostility, injustice, enslavement, and alienation. The possibly revolutionary implications are to some extent spelled out in the *Contrat social* (1762; *A Treatise on the Social Contract*). Liberty and equality can be reestablished, according to Rousseau, by a new social pact of all with all, willingly accepted, obeying the *volonté générale* ("general will"), which alone has total sovereignty. In this way passive subjects of the state will be turned into active citizens zealous for the public good. But this act will require a moral transmutation, whereby men use their reason properly, in the exercise of selfless virtue; this emphasis on reason is underlined by the highly abstract character of the work. Commentators have differed widely in their readings of the *Contrat social* as a liberal or totalitarian document, but Rousseau at least saw himself as unambiguously defending freedom.

The *Confessions*

Rousseau's struggle toward a morality based on transparent honesty is continued in the *Confessions* (written 1765–70), where he seeks self-knowledge through awareness of the unconscious, the importance of childhood in shaping the man, and the role of sexuality; in so doing he anticipates modern psychoanalysis. This original exploration of the self is developed further in the *Rêveries du promeneur solitaire* (written 1776–78; *Reveries of a Solitary Walker*), which has been seen as foreshadowing even more strongly the Romantic movement and the literature of introspection of the next century.

The later 18th-century novel is dominated by the figure of Pierre Choderlos de Laclos and his masterpiece *Les Liaisons dangereuses* (1782; *Dangerous Acquaintances*), which gives a skillful account of erotic psychology as the libertine Valmont and his accomplice Mme de Merteuil plot the downfall of their victims. The tragic development is set in a Parisian society illustrating Rousseau's strictures: naturalness has given way to conformist expediency and cynicism, and the opportunity for spontaneous love has been lost. Laclos's novel delineates the void left in this heartless world; yet he also praises intelligence, which the highly crafted construction of the work brilliantly exemplifies. The detachment afforded by the structure of this epistolary novel precludes an assured understanding of the authorial viewpoint, and it has proved possible to interpret the work variously as an appeal to sensibility or as an exercise in pure cynicism. The ambiguity abides, preserving the novel's place among the classics of the genre.

The Marquis de Sade

By contrast, Jacques-Henri Bernardin de Saint-Pierre's *Paul et Virginie* (1788) often seems over-sentimental to modern tastes. It remains nonetheless a rich evocation of exotic nature in the tropical setting of Mauritius. Nicolas-Edme Restif (called Restif de la Bretonne) wrote at great length about the Parisian society, often criminal and equivocal, in which he moved. Given to verbosity, he yet evoked vividly the low world around him. More disturbing is the Marquis de Sade, whose search for maximum intensity of physical sensation, particularly in deriving pleasure through the infliction of pain, gave rise to the word sadism. According to Sade, because nature is engaged in destruction as in procreation, murder is natural and morally acceptable. The true libertine must replace soft sentiment by an energy aspiring to total freedom. Sade's insistence upon experimental rationalism owes much to the Enlightenment, of which his antisocial egoism is, however, only a perverted expression. But in works like *Justine, ou les malheurs de la vertu* (1791; *Justine, or The Misfortunes of Virtue*) he made the reader aware as never before that the search for fulfillment via the enjoyment of cruelty forms part of the human psyche. (H.T.M.)

Entering the 19th century: from the Revolution to 1850

REVOLUTION AND EMPIRE

The French Revolution of 1789 provided no clean break with the literary traditions of the Enlightenment. Many ways of thinking and feeling and most literary forms persisted with little change from 1789 to 1815. Indeed, the Napoleonic regime encouraged a return to the Classical mode. The insistence on formal qualities, notions of good taste, rules, and appeals to authority implicitly underlined the regime's centralizing, authoritarian, and imperial aims. This Classicism, or, strictly speaking, Neoclassicism, represented the etiolated survival of the high style and literary forms that had dominated the "serious" literature—and drama in particular—in France for almost two centuries. It is the complex series of reactions against this dominance, the search for new forms, the expansion of the vocabulary of literature, and the development of new criteria of taste that, together with the profound impact of the social and political events of the times, provide the main thrust of French Romanticism.

The poetry of André Chénier. André Chénier was executed during the last days of the Terror. His work first appeared in volume in 1819 and is thus associated with the first generation of French Romantic poets, who saw in him a symbol of persecuted genius. Although deeply imbued with the Classical spirit, especially that of Greece, he nevertheless exploited Classical myths for modern purposes. He began work on what he planned to be a great epic poem, "Hermès," a history of the universe and human progress. The completed fragments reflect the Enlightenment spirit but also anticipate the episodic epic poems of the Romantics (such as Victor Hugo's *Légende des siècles,* 1859–83). Chénier, though a moderate in revolutionary terms, was deeply committed in his politics. This is evident in the scathing fierceness of his *Ïambes,* many of which were written from prison shortly before his execution. His best known poems, however, are elegies that sing of captivity, death, and dreams of youth and lost happiness.

Revolutionary oratory and polemic. The intensity of political debate in Paris during the Revolution, whether in clubs, in the National Assembly, or before tribunals, threw into prominence the arts of oratory. Speaking in the name of reason, virtue, and liberty, and using the Roman republic or the city-states of Greece as frame of reference, revolutionary leaders such as Honoré-Gabriel Riqueti, comte de Mirabeau, infused the intellectual preoccupations of the Enlightenment with a sense of drama and passion. This renewal of rhetoric is echoed in the enormously expanded political press. To some extent the proclamations and communiqués of Napoleon prolonged this revolutionary eloquence.

Atala and *René*

Chateaubriand. The French Revolution made an émigré of François-René, vicomte de Chateaubriand, and his first major work, the *Essai . . . sur les révolutions* (1797), is a complex and sometimes confused attempt to understand revolution in general, the French Revolution in particular, and the individual's relationship to these phenomena. Chateaubriand took as his model the stance of the 18th-century *philosophe,* but his *Génie du Christianisme* (1802; "The Genius of Christianity") caught a new mood of return to religious faith based on emotional appeals and underlines the aesthetic superiority of Christianity. The impact of this work was enormous. Within it were two short narratives, *Atala* and *René.*The latter quickly came to represent the *mal du siècle,* the essence of Romantic sensibility, presenting an insecure, solitary, and disorientated young hero not dissimilar to Goethe's Werther.

Behind all of Chateaubriand's works lies the sense of a break, caused by the French Revolution, in a stable, ordered existence. His *Mémoires d'outre-tombe* (1848–50; "Memoirs from Beyond the Tomb"), the masterpiece he worked on most of his adult life and intended for posthumous publication, uses the autobiographical format to meditate on the history of France, the passing of time, and the vanity of human desires. His lyrical and rhythmic prose, which earned him the title Enchanteur, left a deep impression on many Romantic writers.

Mme de Staël and the debate on literature. Mme de Staël (Anne-Louise-Germaine Necker, baronne de Staël-Holstein) was truly encyclopaedic in her interests. Her contribution to intellectual debate far exceeded any narrow definition of literature. Liberal and, after her offer of support was rebuffed, fiercely anti-Napoleon in politics, eclectic in philosophy, mixing rationalism and spiritualism, and determinedly internationalist in her feeling for literature, she moved most easily in a world of ideas, surrounding herself with the salon of intellectuals she founded at Coppet, Switzerland. Her two novels, *Delphine* (1802) and *Corinne* (1807; *Corinna*), focus on the woman of talent persecuted by society. Her two most influential works, *De la littérature* (1800; "On Literature") and *De l'Allemagne* (1810; *Germany*), expanded conceptions of literature, claiming, for example, that postrevolutionary society required a new literature. She explored the contrast, as she saw it, between the literature of the south (rational, Classical) and the literature of the north (emotional, Romantic), and she showed the interest of foreign writers like Shakespeare, Ossian, and above all the German Romantics.

Many of these ideas emerged from discussions with August Wilhelm von Schlegel, author of the widely read *Cours de littérature dramatique* (1809, 1814), and from meetings with and readings of the Germans Goethe and Schiller. The Genevan economist and writer Jean-Charles-Léonard Simonde de Sismondi reinforced many of Mme de Staël's points in his *De la littérature du midi de l'Europe* (1813). This cosmopolitan cultural relativism was an inflammatory attitude in the prevailing Neoclassical literary climate.

ROMANTICISM

The *mal du siècle*

French Romanticism cannot be reduced to a listing of themes. Although one can point to a remarkable number of works that concentrate on the isolated and misunderstood individual, evoke nature and natural forces, and emphasize a religious sensibility, these elements are not specific to the early 19th century. The writings of certain French authors, such as Jean-Jacques Rousseau, have been described as pre-Romantic, but in general Romanticism in France developed later than in Germany or Britain. Its particular flavour is a result of the impact of revolutionary turmoil and the Napoleonic odyssey on French writers' sensibilities. The terms *mal du siècle* (world weariness; literally "ills of the century") or *enfant du siècle* (literally "child of the century") symbolize their distress. The latter is picked up and exploited in Alfred de Musset's autobiographical *Confession d'un enfant du siècle* (1836). Most French Romantics, whether they adopted a liberal or conservative attitude or whether they wished to ignore the weight of history and politics, asserted that their century was sick, and all were acutely aware of being products of their time. There was thus a new preoccupation with time and change. Romantics often retained the encyclopaedic ambitions of their predecessors, but faith in any simple notion of progress was shaken. Some distinction can be made between the generation of 1820, whose members wrote, often from an aristocratic viewpoint, about exhaustion, emptiness, loss, and ennui, and the generation of 1830, whose members spoke of dynamism—though often in the form of frustrated dynamism.

Foreign influences. When the émigrés who had fled from the effects of the Revolution trickled back to France they brought with them some of the cultural colouring acquired abroad (mainly in Britain and Germany) and this partially explains the paradox of aristocratic and politically conservative writers fostering new approaches to literature. Mme de Staël, as a liberal exile under Napoleon, was an exception. Travel had broadened intellectual horizons and had opened up the European cultural hegemony of France to other worlds and other sensibilities. The influence of the British Lord Byron's poetry and of the Byronic legend was particularly strong. Byron provided a model of poetic sensibility, cynicism, and despair, and his death in the Greek war of independence reinforced the image of the noble and generous but doomed Romantic hero. Italy and Spain, too, exercised an influence, though, with the exception of Dante, it was not their literature that attracted so much as the models of violent and exotic emotions these countries offered, with a proliferation of gypsies, bandits, poisonings, and revenge tales. (C.Sm.)

The *cénacles*

The poetry of the Romantics. The new climate was especially evident in poetry. The salon of Charles Nodier became one of the first of the literary groups known as the *cénacles;* later groups were to centre on Charles-Augustin de Sainte-Beuve, who is remembered chiefly as a literary critic. In addition to the outstanding poets of the period were a host of minor talents, and the Romantic upheaval in literature opened the way for a variety of possible developments, from the gentle lyricism of Marceline Desbordes-Valmore to the frenetic extravagance of Petrus Borel. For a time, about 1830, there was a marked possibility that French Romantic poetry might veer toward radical politics and the socialism of utopian writers like Saint-Simon, rather than in the direction of *l'art pour l'art,* or art for art's sake. The popularity of the songs of Pierre-Jean de Béranger is a reminder of the existence of an alternative current, political and satirical, beside the intimate lyricism and aesthetic preoccupations of typical Romantic verse. (R.C.Bu.)

Lamartine. Alphonse de Lamartine made an enormous impact as a poet with his *Méditations poétiques* (1820; *Meditations*). Using a restricted Neoclassical vocabulary, and unadventurous in versification, he nevertheless succeeded in creating through the musicality of his verse and often through the evocation of vaporous landscapes a sense of great longings unfulfilled. This soft-centred elegiac tone is tempered by occasional deep despair and Byronic revolt. The *Harmonies poétiques et religieuses* (1830; "Poetic and Religious Harmonies"), with their religious emotion, reinforce the quest for serenity, which remains threatened by unease and disquiet. *Jocelyn* (1836; Eng. trans., *Jocelyn*) and *La Chute d'un ange* (1838; "The Fall of an Angel") are intermittently successful attempts at epic, which tempted many French Romantics. An undercurrent in Lamartine's poetry is the preoccupation with politics. His essential contribution to French poetry was made in the 1820s. His verse seemed to engage his whole being, in contrast to most 18th-century poets, who had seen their art as merely a polite accomplishment.

The early poetry of Hugo. It was also in the 1820s that the powerful and versatile genius of Victor Hugo emerged. In his first poems he was a supporter of the monarchy and the church. This conservative Roman Catholic legitimism is a common strand in the poetic generation of 1820, and the debt to Chateaubriand's *Génie du Christianisme* is evident. These early poems lack the mellifluous quality of Lamartine's *Méditations,* but by the time of the *Odes et ballades* (1826) there are already hints of the Hugoesque mixture of intimate poetry, speaking of family relationships and problems of the ego; a prophetic and visionary tone; and an eagerness to explore a wide range of poetic techniques. Hugo called *Les Orientales* (1829) a useless book of pure poetry. It can be linked with the *l'art pour l'art* movement (see below), concentrating on the exotic and the visual combined with verbal and formal inventiveness. Hugo published four important collections in the 1830s (*Les Feuilles d'automne,* 1831; *Les Chants du crépuscule,* 1835; *Les Voix intérieures,* 1837; *Les Rayons et les ombres,* 1840), in which poetry of nature and family life is interwoven with a sad, solitary, hesitant, but never quite despairing quest for true consciousness. The poetry moves from the personal to the visionary and the prophetic, prefiguring in the lyric mode the epic sweep of much of his later work.

Vigny's *Destinées*

Vigny. In contrast to Hugo's scope, the poetry of Alfred-Victor, comte de Vigny, was more limited and controlled. In common with Hugo and many other Romantic poets, however, he proposed the poet as prophet and seer. For Vigny the poet is essentially a dignified, moralizing philosopher, using the symbol as rational expression of his philosophy. Broadly pessimistic in tone, emphasizing suffering and noble stoicism, he multiplied victim figures in his work, with the poet-philosopher as quintessential victim. His *Destinées* (1864), composed between 1838 and his death in 1863, exemplify the high spiritual aspiration that represents one aspect of the Romantic ideal. The control and concentration of expression is in contrast to the verbal flood of much Romantic writing and foreshadows more modern attitudes to poetic composition.

Musset. The young, brilliantly gifted Alfred de Musset quickly established his reputation with his *Contes d'Espagne et d'Italie* (1830). His exuberant sense of humour, an uncommon trait among Romantic poets, led him to use extravagant Romantic effects and at the same time treat them ironically. Later, a trajectory from dandyism through debauchery to a sense of emptiness and futility, sustained only intermittently by the linking of suffering with love, resulted in a radical dislocation of the sense of self. The "Nuits" poems ("Nuit de mai," "Nuit de décembre," "Nuit d'août," "Nuit d'octobre," 1835–37) express this purifying power of suffering in verse of sustained sincerity, purged of all the early showiness.

Nerval. For a long while Gérard de Nerval was seen as the translator of German literature (notably his adaptation of Goethe's *Faust*) and as a charming minor Romantic. Later critics have seen as his real contribution to poetry the 12 sonnets of *Les Chimères,* composed between about 1844 and 1854, and the prose poems added to the spiritual odyssey *Aurélia* (1855). The dense symbolic allusiveness of these latter works is the poetic transcription of an anguished, mystical quest that draws on the most diverse religious myths and all manner of literary, historical, occult, and esoteric knowledge. They represent one of the peaks of achievement of that side of the Romantic movement that sought in the mystical a key to the spiritual reintegration of the divided postrevolutionary self. The prose poem and the use of symbol link up with the poetry of Charles Baudelaire and Stéphane Mallarmé.

Romantic theatre. Some critics have been tempted to call Romantic theatre in France a failure. Few plays from that time remain in the active repertory, though the theatre was perceived throughout the period to be the dominant literary form. Quarrels about the theatre provided some of the most celebrated battles of Romanticism against Classicism.

Hugo. The first performance of Hugo's *Hernani* (1830) was one such battle, and Romanticism won a symbolic victory. *Hernani* followed Stendhal's call in the pamphlets *Racine et Shakespeare* (1823, 1825) for theatre that would appeal to a contemporary public, Hugo's own major theoretical statement in the preface to his play *Cromwell* (1827), and the production in Paris of several Shakespearean and historical dramas. (In particular an English troupe playing Shakespeare had had a sustained and triumphal season in Paris in 1827.)

Hernani drew on popular melodrama for its effects, exploited the historical and geographical local colour of an imagined 16th-century Spain, and had a tragic hero with whom the young Romantics were able to identify. These elements are fused by Hugo's lyric poetry to produce a dramatic spectacle close to that of Romantic opera. *Ruy Blas* (1838), in similar vein, mixes poetry, comedy, and tragedy with strong antithetical effects to provide the mingling of dramatic genres, which Hugo saw as the essence of Romantic drama. The failure of *Les Burgraves* (1843) is commonly given as the beginning of the end of Romantic theatre. Its grandiose epic conception on stage seemed merely false, abstract, and melodramatic to its audiences.

Vigny. Where Hugo's verse dramas tended to the lyrical and the spectacular, Vigny's most famous play, *Chatterton* (1835), in its concentrated simplicity, has many analogies with Classical theatre. It is, however, a bourgeois drama of the sort called for by Diderot and focusses on the suicidal poet Thomas Chatterton as a symbolic figure of the idealistic poet misunderstood by a bourgeois society—a typical Romantic fate.

Musset. Musset did not have public performance primarily in mind when writing most of his plays, and yet, ironically, he is the one playwright of this period whose works have continued to be regularly performed. In the 1830s he wrote a series of short comedies and *proverbes*—almost charades—in which light-hearted fantasy and the delicate hesitations of young love, rather in the manner of Marivaux, are contrasted with ironic pieces expressing underlying disillusionment.

The larger scale *Lorenzaccio* (1834) is the one indisputable masterpiece of Romantic theatre. A drama set in Renaissance Florence but with clear links to post-1830 France is combined with a brilliant study of a once pure but now debauched hero almost paralyzed by doubt. The world of wasted youth and lost illusions is evoked in a prose that at times resembles lyric poetry. The showy historical colour and the bluster typical of Romantic melodrama are replaced here by a deep sense of tragic poetry that stands comparison with Shakespeare.

THE NOVEL FROM CONSTANT TO BALZAC

The novel was the most rapidly developing literary form in postrevolutionary France, its enormous range allowing authors to deal flexibly with the changing relationship of the individual to society. The Romantic undergrowth encouraged the flourishing of such subspecies as the Gothic novel and the terrifying or the fantastic tale—the latter influenced in many cases by the translation from German of the works of E.T.A. Hoffmann—works that, when they are not simply ridiculous, seem to be straining to provide a fictional equivalent for the subconscious or an intuition of the mystical. Balzac was greatly influenced by this "infra-literature" in his attempt to achieve a synthesis of the spiritual and the material.

Benjamin Constant's *Adolphe* (1816), presented as a fictional autobiography, belongs to an important strand in the tradition of the French novel, namely the novel of concentrated psychological analysis of an individual, which runs from the 17th century to the present day. In that sense *Adolphe* has about it a Classical intensity and simplicity of line. Its moral ambiguity, however, together with the hesitations of the hero and his weakness, is related to the contemporary sense of moral sickness. In spite of the difference of style, there is a clear link with the themes of Chateaubriand's *René* and Étienne Pivert de Senancour's *Oberman* (1804).

The historical novel. The acute consciousness of a changed world after the Revolution and hence of difference between historical periods led novelists to re-create the specificity of the past, with a distinct preference for the Middle Ages and the Renaissance. Until about 1820 the Middle Ages was often regarded as a period of barbarism between Classical antiquity and the Neoclassical 17th and 18th centuries. But Chateaubriand's lyrical evocation of Gothic ruins and young royalist writers' attraction to a certain vision of feudalism provided a different evaluation of the period. The vogue for historical novels was at its strongest in the 1820s and was given impetus by the immense influence of the French translations of Sir Walter Scott. The best example of the picturesque historical novel is Hugo's *Notre-Dame de Paris* (1831; *The Hunchback of Notre Dame*). In it Hugo re-created an atmosphere of vivid, colourful, and intense 15th-century life, associating with it a plea for the preservation of Gothic architecture.

Influence of Sir Walter Scott's novels

A deeper reading of Scott's novels is implicit in some of Honoré de Balzac's works. Balzac not only evoked the surface or the atmosphere of a precise period but also examined the processes of historical transformation. Scott's studies of the aftereffects of the Jacobite rising can be paralleled by Balzac's analysis of the Breton counterrevolution in *Les Chouans* (1829). The historical novel ultimately became the staple of the popular novel, as in *Les Trois Mousquetaires* (1844; *The Three Musketeers*) by Alexandre Dumas *père*.

Stendhal. The works of Stendhal (Henri Beyle) constantly pose the questions "who am I?" and "where lies true happiness?" and often represent an individual attempt to define an aesthetic. His autobiographical sketches, such as *Vie de Henry Brulard* and *Souvenirs d'égotisme* (published posthumously in 1890 and 1892, respectively) give a fascinating insight into a highly critical intelligence trying to organize his experience into a rational philosophy while remaining aware that the claims of emotion will often undermine whatever system he creates. In many ways he is an 18th-century rationalist with a 19th-century sensibility.

He came to the novel form relatively late in life. *Le Rouge et le noir* (1830; *The Red and the Black*) and *La Chartreuse de Parme* (1839; *The Charterhouse of Parma*) are his masterpieces. Both present a young hero grappling with a decidedly nonheroic social and political environment. *Le Rouge et le noir* focusses on France in the late 1820s, whereas *La Chartreuse de Parme*, situated in Stendhal's beloved Italy (where he lived for much of his adult life), often reflects a vision of the Italy of the Renaissance as much as that of the 19th century. In both works Stendhal is deeply concerned with happiness, the nature of the self, and the relationship of the individual to the social and the political. His quicksilver style is capable of embracing in rapid succession different emotions, ideas, and points of view, thereby creating a sense of spontaneity and making him one of the most individual of novelists.

George Sand. George Sand (Amandine-Aurore-Lucile Dudevant) was a dominant figure in the literary life of the 19th century. Her works are little concerned with the novel as an art form but are dominated by thematic or ideological considerations. For example, her semiautobiographical works study the iniquitous position of women in 19th-century society (*Indiana*, 1832; *Lélia*, 1833). From the later 1830s George Sand developed an interest in humanitarian socialism, an idealism tinged with mysticism, reflected in works like *Le Compagnon du tour de France* (1841) and *Consuelo* (1842). For a long while, however, her literary reputation rested on works such as *La Mare au diable* (1846), *François le Champi* (1848), and *La petite Fadette* (1849), sentimental stories of country life tinged with realistic elements. She is an excellent example of the sentimental socialists involved in the 1848 Revolution.

Nodier, Mérimée, and the conte. Charles Nodier and Prosper Mérimée both exploit the short story and the novella. Nodier specialized in the *conte fantastique* ("fantastic tale") to explore dream worlds or various forms of madness, as in *La Fée aux miettes* (1832), and succeeded thereby in suggesting the importance of the role of the unconscious in human beliefs and conduct. Mérimée also used inexplicable phenomena, as in *La Vénus d'Ille* (1837), to hint at repressed aspects of the psyche or the irrational power of passion. More commonly, combining a Classical analytical style with Romantic themes, he directed a cool, ironical look at violent emotions. Short stories like *Mateo Falcone* (1829) and *Carmen* (1845) are peaks of this art.

Balzac, too, was an excellent short-story writer, often continuing in the Romantic mode the philosophical *conte* of the 18th century.

Balzac. Honoré de Balzac is perhaps best known for his *Comédie humaine,* the general title of a vast series of more than 90 novels and short stories published between 1829 and 1847. In these works he concentrated mainly on an examination of French society from the Revolution of 1789 to the eve of the 1848 Revolution, organically linking realistic observation and visionary intuition, while at the same time seeking to analyze the underlying principles of this constantly developing world. He ranged back and forth, often within the same novel, from the philosophical to the social, the economic, the legal; from Paris to the provinces; and from the summit of society to the *petit-bourgeois,* studying the destructive power of what he called thought or passion or vital energy. The search for the absolute or the unifying principle corresponds to one of the highest aspirations of the Romantic period. By using techniques such as the recurrence of characters in several novels, Balzac gives a temporal density and dynamism to his works. The frustrated ambitions of his young heroes (Rastignac in *Le Père Goriot,* 1835; Lucien de Rubempré in *Illusions perdues,* 1837–43) and the subjection of women, particularly in marriage, are used as eloquent markers of the impasse into which bourgeois liberalism had led the French Revolution. He emphasized the dissolving power of money and the every-man-for-himself individualism unleashed by the Revolution. In spite of this pessimistic view of society, however, Balzac remained fascinated by the power and energy of life in all its manifestations.

19TH-CENTURY THOUGHT

Literary criticism and journalism. The passionate, even virulent, political journalism of the revolutionary period soon slowed to a trickle under Napoleon. Literary debate interwoven with political considerations was renewed after 1815, and a shifting spectrum of royalist Romantics and Classical liberals moved toward a Liberal-Romantic consensus about 1830. The young critic Sainte-Beuve, himself the author of poems, supported Romanticism about 1830, though progressively detaching himself from it as he elaborated his biographical critical method. Criticism in the major literary reviews tended to be from a modified Classical viewpoint throughout the 1830s and even the 1840s, the Romantics replying in inflammatory prefaces to their works. The surge in newspaper circulation after 1836 tended to create a more "popular" market for serialized novels with strong melodramatic effects, as in Eugène Sue's *Mystères de Paris* (1842–43; *Mysteries of Paris*).

Sainte-Beuve

Historical writing. Early 19th-century historians were committed to historical erudition, but their works often seem closer to the world of literature. Augustin Thierry's narratives present the histories of England and France in terms of race (Normans versus Saxons and Franks versus Gallo-Romans). This is essentially a poetic concept close to that of Sir Walter Scott's *Ivanhoe.* Similarly, the early volumes of Jules Michelet's *Histoire de France* (1833–44) are based on the poetic idea of intuitive sympathy leading to a total resurrection of the essence of a past period encapsulated in imaginative symbolic figures. Alexis de Tocqueville represents a turning away from Romantic historiography in his great analytical studies of social principles in *De la démocratie en Amérique* (1835–40; *Democracy in America*) and *L'Ancien Régime et la Révolution* (1856; *The Old Regime and the Revolution*).

The intellectual climate before 1848. The early 19th century saw the renewal of interest in religion, ranging from the sentimental religiosity of Chateaubriand to the traditionalist theology of Louis-Gabriel-Ambroise, vicomte de Bonald and Joseph de Maistre, but 18th-century sensualism continued and was developed by the Idéologues, proponents of the Idéologie movement. Claude-Henri de Rouvroy, comte de Saint-Simon, and his followers tried to evolve a synthesis, which proved unstable, between socialistic scientific analysis, particularly of economics, and Christian belief. Félicité Lamennais, a Roman Catholic priest, moved toward a Christian socialism that ultimately estranged him from the church. The whole of the first half of the century is marked by such idealistic attempts to reconcile the head and the heart in imaginative syntheses.

Renan, Taine, and the movement of ideas in the second half of the 19th century. After the failure of what was seen as the woolly idealism of the 1848 Revolution a consciously scientific spirit came to dominate the study of social and intellectual life. Auguste Comte's *Cours de philosophie positive* (1830–42) fathered this new school of thought, called Positivism. It became almost a new religion. Ernest Renan adapted this scientific approach to the study of religion itself, notoriously in his *Vie de Jésus* (1863; *Life of Jesus*). Hippolyte Taine continued this Positivist analysis and emphasized the importance of biological science so as to produce a form of biological determinism to explain human conduct. His impact on the Naturalist literary theories of Émile Zola was crucial. (C.Sm.)

Completing the 19th century: from 1850 to 1900

Literature in the second half of the 19th century continued a natural expansion of trends already established in the first half. Intellectuals and artists remained acutely aware of the same essential problems: the nature of man, his relationship with the universe, the guarantees of morality, the pursuit of beauty, and the duties of the artist. But as writers became progressively alienated from the official culture of the Second Empire (1852–70), the forms of their revolt became more and more disparate. While the principles of Positivism were easily assimilated to the materialist pragmatism of the developing capitalist society, even many rationalist thinkers were drawn to forms of Idealism that placed faith in progress through science; and the antirationalist and antiutilitarian writers diverged into various types of mysticism and aesthetic formalism.

NEW DIRECTIONS IN POETRY

Gautier and l'art pour l'art. The greatest changes occurred in poetry. By the end of the 1830s Romantic poetry had narrowed in range, becoming synonymous with the direct expression of personal feelings and ideals in alexandrine verse paragraphs. Turning his back on his own earlier attempts to treat grand themes in the grand manner, Théophile Gautier sought a new direction for lyric poetry by linking idealism with aesthetics. From the first edition of *Émaux et camées* (1852; "Enamels and Cameos") to the posthumously published *Derniers vers* (1872), he devoted himself to a form of literary miniature painting, attempting to make something aesthetically valid out of subjects for the most part deliberately chosen for their triviality. The fashion for linking poetry with the plastic arts had grown up during the 1840s. Gautier simply developed the implications of this trend to the ultimate, concentrating on the language of shape, colour, and texture and limiting form almost exclusively to the very restrictive octosyllabic quatrain. Even themes that in his prose fiction suggest a genuine spiritual unrest, such as the fluid nature of identity or the destructive power of love, become the occasion for virtuoso ornamental elaboration. Many of the poems are stylized, sometimes ironic, treatments of amatory themes; others play with images of everyday life; but the best are transpositions from one art form to another, particularly those based on music ("Symphonie en blanc majeur," "Variations sur le Carnaval de Venise," and "Contralto").

Leconte de Lisle and Parnassianism. Gautier's cult of form is also to be met in the work of Théodore de Banville, notably in *Les Stalactites* (1846) and *Les Odes* *funambulesques* (1857). But the reaction against the expression of personal emotion in rambling rhetorical verse was not confined to the formalism of the *l'art pour l'art* poets. Charles-Marie-René Leconte de Lisle, who came to be labelled the founder of Parnassianism, took a different approach in his *Poèmes antiques* (1852), *Poèmes barbares* (1862), and *Poèmes tragiques* (1884). Although his theoretical pronouncements about the supremacy of beauty suggest affinities with Gautier, Leconte de Lisle was far from believing that the subject matter of poetry was of no significance. He wanted his poetry to transmute knowledge into a higher form of truth, and he believed in the necessity of systematic research prior to composition. The highly material surface of his poems is used to disguise deeply felt nihilistic metaphysical beliefs. For Leconte de Lisle the history of mankind presented a long, slow decline from the golden age of antiquity, leading inevitably toward the cosmic annihilation that post-Darwinian biologists saw as the natural end of evolution. The stories recounted from European and Oriental mythology, and the portraits of exotic animals and landscapes, though superficially scientific in their blending of scholarly documentation and objective narrative manner, all distill the same sense of revolt against a destiny that binds mankind to expiate crimes it is fated to commit. The style of the poems is not in fact concerned with the transcription of surfaces: the physical details are used to create moods that form symbolic analogues for the philosophical ideas.

Leconte de Lisle's ostensible manner and matter were taken up with enthusiasm by younger contemporaries. But only *Les Trophées* (Eng. trans., *Les Trophées;* "The Trophies"), the exquisitely miniaturist sonnets of José Maria de Heredia, written over a quarter of a century but not published until 1893, are still read, and even these have an appeal more like that of Meissen china fruit than the emotional or intellectual force normally associated with poetry.

Baudelaire. It is significant that Gautier, Hugo, and Leconte de Lisle were the three contemporary French poets for whom Charles Baudelaire felt the greatest admiration, although he had no time for formalism, didacticism, or the cult of antiquity. Antithetical in all things, Baudelaire was torn between the desire to express a metaphysical anguish more urgent and subjective than that of the Romantics and an aesthetic conviction that the effectiveness of art depended on precision and control. It is as misguided to look for consistency in Baudelaire's critical works (*L'Art romantique, Curiosités esthétiques,* both published posthumously in 1868) as in his poetry, since his ideas evolved constantly and in some cases radically throughout his most creative period (1845–64). To two basic ideas, however, he remained constant: that only the artist can create meaning out of the raw material of life, and that the material world is irredeemably corrupted by original sin. The first of these is responsible for the importance which he assigns to intuition, imagination, synesthesia, and the necessity for the artist to plunge himself into the world about him. The second led him to an impasse: the artist could only rise above material corruption through the creative act, but the creative act could not occur without the stimulus of corrupt reality. Baudelaire was accordingly a poet deeply concerned with the relationship between morality and art, which he located in the effective transposition of the artist's special perceptions of the world, and he was genuinely distressed by the official condemnation of the first edition of *Les Fleurs du mal* (1857; *The Flowers of Evil*) on a charge of obscenity provoked by its supposed erotic realism.

Les Fleurs du mal

The tensions within Baudelaire reached their height in the second edition of *Les Fleurs du mal* (1861). The collection is loosely structured to present a "self" who struggles to transcend the limitations of the material world. The struggle is presented in a series of experiences that start with love (mostly physical), move out into the ugly urban environment of contemporary Paris, and gradually descend through increasingly vicious experiences until only death offers the possibility of new stimulus sufficient to keep the creative consciousness of the poet-hero alive. The stylistic antitheses mirror the content. Within individual poems Baudelaire shifts between the rhetorical, the impressionist, the abstract, and the intensely physical. He balances banality and originality, the prosaic and the melodic, to emphasize the eternal interdependence of opposites, which he sees as the essence of man's condition.

In the last years of his life Baudelaire tried to extend the literary means at his disposal by experimenting with prose poetry. The range of themes in the posthumously edited *Petits poèmes en prose* is similar to that of *Les Fleurs du mal,* though the balance is different: urban landscapes, the ambiguous relationship of artist and crowd, and the degradations of poverty are given more space than is love. The relative freedom of the prose form allowed more shifts of tone; the juxtaposition of the ironic and the lyrical; and the interweaving of anecdote, narrative, and reflection. The best poems, such as "La Chambre double," make a positive use of this new freedom.

The later poetry of Victor Hugo. It comes as a shock to realize that though the second half of the 19th century is habitually treated as a period of reaction against Romanticism, nearly all the major poetry of Hugo was, in fact, published after 1850. The three collections *Les Châtiments* (1853), *Les Contemplations* (1856), and *La Légende des siècles* (1859, 1877, 1883) are linked by their epic quality. Different as they are in content, intention, and tone (though less varied in style), each is loosely structured to create an overall unity. *Les Châtiments,* written from exile in the Channel Islands and published clandestinely, is a hymn of hate against the mediocrity, callousness, and greed of Louis-Napoleon and the society of the Second Empire, interspersed with outbursts of compassion for the poor and oppressed. The poems are arranged so as to emphasize the darkness of the present and the light of the future, as Hugo proclaims his optimistic belief in the eventual triumph of peace, liberty, and social justice. Though the most monotonous of the three great works in content, it is the most varied in style, as if to offset the repetitiousness of the invective. In contrast to this political saga, *Les Contemplations* embodies Hugo's philosophical attitudes. It presents the poet as seer, penetrating the mysteries of creation and recounting the metaphysical truths perceived. The first four books contain much nature poetry, elegy, and love lyrics. The portentous and obscure rhetorical enumerations of the later visionary sections have dated beyond recall. *La Légende des siècles* reveals the same urge to play the prophet. The poems are a series of historical and mythological narratives, borrowing some of the scientific spirit that informed Leconte de Lisle's work but with none of the same attention to preliminary scholarly research. Together they form an account of the history of human existence as Hugo saw it.

After the three epic cycles Hugo returned to writing short lyrics on personal themes (*Les Chansons des rues et des bois* [1865; "Songs of the Streets and the Forests"]; *L'Art d'être grand-père* [1877; "The Art of Being a Grandfather"]), although he never abandoned his role as didactic poet, as the collections churned out in the 1880s testify.

REALISM IN THE NOVEL

Diversity among the Realist school. The label Realism came to be applied to literature by way of painting as a result of the controversy surrounding the work of Gustave Courbet in the early 1850s. Courbet's realism consisted in the emotionally neutral presentation of a slice of life chosen for its ordinariness rather than for any intrinsic beauty. Literary realism, however, was a much less easily definable concept. Hence the loose use of the term in the late 1850s, when it was applied to works as various as Flaubert's *Madame Bovary,* Baudelaire's *Fleurs du mal,* and the social dramas of Alexandre Dumas *fils.* Even the members of the so-called Realist school were not entirely in agreement. Edmond Duranty, cofounder of the monthly journal *Réalisme* (1856), supported the view that novels should be written in a plain style about the ordinary lives of middle- or lower-class people, but he insisted that the Realists' main aim should be to serve a social purpose. Jules-François-Félix Husson (known as Champfleury), an art critic and novelist, stressed the need for careful research and documentation and rejected any element of moral

The brothers Goncourt

intention. The practice of those labelled Realists was even more diverse than their theory. The writers who most fully realized Champfleury's ideal of a documentary presentation of the day-to-day, Edmond and Jules Goncourt, were also the most concerned with that aesthetic perfection of style which Duranty and Champfleury rejected in practice as well as in principle. In the Goncourts' six jointly written novels that appeared in the 1860s, and in four further novels written by Edmond Goncourt after his brother's death, plot is reduced to a minimum and the interest of the novel is divided equally between stylistic bravura and the minutely documented portrayal of a milieu or a psychological state—the upbringing of a middle-class girl in *Renée Mauperin* (1864), or the degenerating life-style of a female servant in *Germinie Lacerteux* (1864; *Germinie*).

Gustave Flaubert. The problem with the Realists was that each had his own definition of reality and his own recipe for how to transcribe it. It is easy to see why Gustave Flaubert was so firm in dissociating himself from such writers as Champfleury and Duranty, given that his own work undermined all sense of stability in perceptions and values by emphasizing the idea that reality is relative to the person who perceives it. Furthermore, Flaubert rejected any idea of transposing a slice of life onto the page in everyday language. For him, only art could give meaning to the raw material provided by the external world, and only through art could language be lifted above the emptiness of its everyday function so as to record objectively the author's perception of the world.

Flaubert's juvenilia, of which the first version of *L'Éducation sentimentale* (1845) is the most important work, show the writer's struggle to control his own instinctive idealism and to find a way of reconciling his belief in the primacy of facts with his rejection of contemporary petty materialism. His fascination with escapism and Romantic excess was to reappear in *Salammbô* (1863; *Salambo*) and *La Tentation de Saint-Antoine* (1874; *The Temptation of Saint Anthony*), in which he portrayed exotic subjects in a heightened lyrical fashion. But his major novels, *Madame Bovary* (1857) and *L'Éducation sentimentale* (1870; *Sentimental Education*) show trivial lives frittered away in hopeless attempts to transcend the banality and dishonesty of the modern world. Emma Bovary destroys herself by taking empty abstractions—passion, happiness—as concrete absolutes, and by attempting to base her life on such concepts. In her efforts to make the world (and more specifically the men) around her fit her preconceived image, she ignores the nature of material reality itself, as symbolized by money, and is inexorably drawn onward to financial ruin and suicide. Emma's own mediocrity is matched by that of the provincial society in which she lives, and her illusory view is paralleled by the various illusions entertained by almost all the major characters. Most of these, however, like the apothecary Homais, realize that the way to succeed in life is to accept the official values promoted as absolute by the ruling bourgeoisie. *L'Éducation sentimentale* extends the study to cover the entire "generation of 1848," showing how all emotional, artistic, and social ideals are corroded by contact with reality. Its central character, Frédéric Moreau, is a passive version of Emma, and the symbolism of money gives way to that of prostitution—the sale of love, talent, and principle.

In his *Trois contes* (1877; *Three Tales*) Flaubert approached the same beliefs from the opposite angle, showing how the withdrawal from reality of the ascetic or saint, exemplified by Félicité, the simple servant in "Un Coeur simple," St. Julian in "La Légende de Saint-Julien l'Hospitalier," and John the Baptist in "Hérodias," when coupled with the metaphysical aspirations central to Christian belief, offers a form of supreme illusion that the material world cannot touch.

In all these works, and in his unfinished satirical novel, *Bouvard et Pécuchet* (published posthumously in 1881; *Bouvard and Pécuchet*), Flaubert returns consistently to the problem of communication. He was haunted by the way in which the conventional language of love, literature, journalism, politics, and science pretends to portray a fixed reality while in fact concealing the subjectivity of all perceptions. His obsessive reworking of every sentence that he wrote was motivated by the desire to create a style that would preserve the meaninglessness of "reality" while justifying by its own beauty the existence of the novels.

DRAMA AFTER 1850

Major writers of social drama

The society of the Second Empire, and indeed that of the early decades of the Third Republic, was not fond of seeing itself too accurately portrayed on the stage; yet at the same time, in reaction against the escapism and nonconformity of Romantic drama, its members wanted the stage to reflect contemporary values and preoccupations. Hence the predominance, from 1850 to 1890, of social drama on the one hand and light comedy, farce, and operetta on the other. Social drama, denied the use of political issues by censorship, confined itself to the tension between new money and old social position, the morality of financial speculation, and the threat to family life posed by extramarital sexual relationships—all themes touched upon previously in light comedy (*e.g.,* the plays of Eugène Scribe). The settings and character types related to the audience's milieu; hence the plays were considered to be realistic at the time, although their sentimentality, black-and-white morality, and melodramatic turns of plot make them seem highly artificial in modern terms. The major writers of social drama were Alexandre Dumas *fils* and Émile Augier, both of whom began by describing society and ended by prescribing for it. Dumas *fils* is best remembered for his romanticization of the courtesan in *La Dame aux camélias* (1848), the novel and play on which the libretto of Giuseppe Verdi's *La Traviata* was based, but the moralizing *Les Idées de Mme Aubray* (1867), with its plea for the social redemption of repentant fallen women, is more typical of his major works. Augier's morality was more solidly conservative than was Dumas's, as can be seen from one of his best known plays, *Le Mariage d'Olympe* (1855), which not only proposes that what makes a woman into a prostitute in the first place is an innate propensity to vice, but also suggests that if a fallen woman insinuates herself into a respectable family it is legitimate to shoot her. On the other hand, Augier's treatment of the venality of the press and the corruption of financiers in *Les Effrontés* (1861) is as trenchant and effective as comparable portraits in the Naturalist novelists.

Light comedy and farce similarly relied upon a thin layer of contemporary social relevance, with marriage, the *ménage à trois*, and the pretensions of the lower middle class as the main subjects. In farce, in particular, social criticism passed from being an end to a means. Although the characters found themselves in situations in which events followed a nightmare logic quite at odds with their own stereotyped realism and revealed the potential irrelevance of their vaunted rationality, the return to sanity at the end of the plays confirmed the audience's assumption that the world would ultimately always conform to expected and accepted standards. The classic examples of the genre are the plays of Eugène-Marin Labiche, notably *Le Chapeau de paille d'Italie* (1851; *The Italian Straw Hat*) and *Le Voyage de M. Perrichon* (1860).

The operetta

When their taste ventured into something more literary, Second Empire audiences were obliged to look to the fantastical comedies of Alfred de Musset, written 30 years earlier but not staged until the 1850s and '60s. In light comedy proper and costume drama the leading figure of the age was Bernard Shaw's bugbear, Victorien Sardou. But the most successful genre of all was undoubtedly operetta, in particular the absurd comedies of the collaborators Henri Meilhac and Ludovic Halévy. Main examples of their work, set to music by Offenbach, are *La Belle Hélène* (1865), *La Vie parisienne* (1866), and *La Grande-Duchesse de Gérolstein* (1867). It is a reflection on the society of the day that *La Belle Hélène,* in which a frivolous pastiche of classical legend is spiced by an acute satire on the manners, morals, and values of the court of Napoleon III, was the nearest thing to political satire that the French stage could boast for 20 years.

The Franco-German War and the consequent collapse of the empire had little perceptible effect on mainline theatre. Offenbach lost favour because of his German associations, but Augier, Dumas, and Sardou continued to flourish. Attempts by other writers (Flaubert, the Goncourts, Zola) to establish a more genuinely realistic form of theatre failed, partly because public taste and theatrical commercialism made experiment nearly impossible, and partly because the plays written were either theatrically unsatisfying or lost much of their realism in reworking novels for the stage. The only effective Naturalist dramatist was Henry-François Becque, whose *Les Corbeaux* (*The Vultures*), first performed in 1882, and *La Parisienne* (1885; *Parisienne*), without completely ridding themselves of the structural formulas of the well-made play, came nearer than any other drama of the period to portraying brief moments in ordinary lives. That Becque owed his success to André Antoine, the founder and director of the Théâtre Libre (1887–96), is symptomatic of the way in which literary theatre in the last decades of the century was largely dependent on small-scale directorial experimentation. Antoine aimed at creating a unity between the staging (decor and acting style) of a play and its content, in the interest of total realism. From 1891 Paul Fort, founder of the Théâtre d'Art, and his successor, Aurélian-François-Marie Lugné-Poe, who restyled the company as the Théâtre de l'Oeuvre, applied Antoine's principles to the creation of antinaturalistic theatre. It was these little experimental companies that principally staged Symbolist plays, notably the works of Maurice Maeterlinck, with their emphasis on the suggestion of forces beyond reality and of meaning which lies beyond the explicit surface of language. But the audiences for *L'Intruse, Les Aveugles,* and *Pelléas et Mélisande* were small and select, and the significance of such theatrical innovation only became felt more widely in the following century.

Experimental theatre

NATURALISM

The argument for the existence of a Naturalist school of writing depends on the joint publication, in 1880, of *Les Soirées de Médan,* a volume of short stories by Émile Zola, Guy de Maupassant, Joris-Karl Huysmans, Henry Céard, Léon Hennique, and Paul Alexis. But it is doubtful whether Naturalism can justifiably be regarded as more than an extension of the methods of interpreting reality already in vogue. The Naturalists purported to take a more scientifically analytical approach to the presentation of reality than had their predecessors, treating dissection as a prerequisite for description. Hence Zola's attachment to the term *naturalisme,* borrowed from Hippolyte Taine, the Positivist philosopher who claimed for literary criticism the status of a branch of psychology. Unfortunately, it is difficult to find a coherent exposé of the Naturalist theoretical position. Zola's work notes are understandably fragmentary, and his public statements about the novel are all distorted by their polemical purpose—particularly the notorious essay "Le Roman expérimental" (1880; "The Experimental Novel"), in which he developed the untenable parallel between the methods of the novelist and of the experimental scientist. An examination of the views held in common by Zola, Maupassant, and Huysmans indicates that the basis of Naturalism can best be defined as the careful study of a given environment, the application of a mechanistic theory of psychology, and the rejection of any sort of idealism or escapism. However, like Flaubert the Naturalists did not see reality as fixed: Zola and Maupassant accepted as inevitable the transposition of reality through the temperament of the individual writer.

Émile Zola. The common points of Naturalist practice are even more elusive than their theory. Zola's Naturalism depends on the extensive documentation that he undertook prior to the writing of each novel. This extensiveness is emphasized by the subtitle of his 20-novel cycle *Les Rougon-Macquart: Histoire naturelle et sociale d'une famille sous le second Empire* (*Natural and Social History of a Family Under the Second Empire*). The linking of so many novels through a single family and the emphasis on the deterministic effects of heredity and environment confirm the scientific purpose. Zola's canvas is broader than Flaubert's, or even Balzac's: he handles subjects as diverse as a miners' strike in *Germinal* (1885; Eng. trans., *Germinal*), working-class alcoholism in *L'Assommoir* (1877; Eng. trans., *L'Assommoir;* "The Drunkard"), the sexual decadence of the upper classes in *La Curée* (1872; *The Kill*) and *Nana* (1880; Eng. trans., *Nana*), and the ferocious attachment of the peasantry to their land in *La Terre* (1887; *Earth*). But there are countless examples of manipulation of facts, particularly in the chronology of the novels, which show that for Zola documentary accuracy was not paramount. Indeed, his work notes reveal that he saw the scientific principles underlying the novels as a literary device to hold them together and thus strengthen the personal vision of reality that they contained. The sense of period and family unity is soon submerged, as Zola becomes both poet and moralist in his portrayal of contemporary values. All the major novels are dominated by symbolically anthropomorphized forces that control and destroy both individual and mass. Thus the mine in *Germinal* is represented as a voracious beast devouring those who work in it. This tendency to symbolism can be seen in an even more extreme form in the reinterpretation of the Genesis story in *La Faute de l'abbé Mouret* (1875; "The Transgression of Abbé Mouret"; Eng. trans., *The Sinful Priest*). As the cycle progresses, the sense of a doomed society rushing toward the Apocalypse grows, and it is indeed confirmed in the penultimate novel, on the Franco-German War, *La Débâcle* (1892; *The Debacle*).

The trilogy *Les Trois Villes* ("The Three Cities") and the unfinished tetralogy *Les Quatres Évangiles* ("The Four Gospels"), which followed *Les Rougon-Macquart,* became progressively more didactic, laying bare the obsessions with scientific progress, socialist humanitarianism, and the rejection of Roman Catholicism, which had been present in a concealed form in the earlier novels. Zola's contribution to French life after *Les Rougon-Macquart* lay more in his spirited intervention in the Dreyfus Affair than in what Henry James justifiably called Zola's "nursery moralities."

Guy de Maupassant. Of the other Naturalists only Maupassant is widely read, though Céard's *Une Belle Journée* (1881) and the four early novels of Huysmans, particularly *A vau-l'eau* (1882; *Down Stream*), have been unjustly neglected. Maupassant had the advantage of being a protégé of Flaubert, but his style is markedly less detached than his master's. Many of his short stories, whether set in Normandy or Paris, rely on sharply reductive, satirical techniques directed against his favourite targets—women, the middle classes, the Prussians—and designed to bring out hypocrisy and dishonesty as the central forces in human life. His novels achieve a greater sense of detachment and are truer to the aim expressed in his essay "Le Roman" (1887; "The Novel") to "write the history of the heart, soul and mind in their normal state." There is a progression in manner and matter from *Une Vie* (1883; *A Woman's Life*), with its echoes of *Madame Bovary,* through the detached but destructive portrait of the worlds of journalism and finance in *Bel-Ami* (1885; Eng. trans., *Bel-Ami*) to powerful evocation of the crippling effects of jealousy in *Pierre et Jean* (1888; Eng. trans., *Pierre et Jean*). His mastery of the psychological novel is confirmed by his portrait of the effects of old age on a pair of lovers in *Fort comme la mort* (1889; *The Master Passion*), and his considerable skill in presenting broader social forces at work is evident in his analysis of a small spa in *Mont-Oriol* (1887), which is reminiscent of Zola's work.

Maupassant's novels

THE REACTION AGAINST REASON

In the last decades of the century, particularly from 1880 onward, the opposition intensified between those creative writers who built their ideals around the material world and those who rejected physical experience as meaningless in itself. Whereas Baudelaire and Flaubert incorporated elements of both attitudes into their writings, the poets and novelists who followed them tended to take one or the other line to an extreme: hence the emergence within a short time of movements as disparate as Naturalism, Decadence, Symbolism, and the Roman Catholic Revival.

The Decadents: Verlaine and Laforgue. Decadence was a movement primarily associated with poetry but whose psychological basis is well illustrated in Huysmans' novel *À rebours* (1884; *Against the Grain*) and the *Culte du moi* trilogy (1888–91) by Maurice Barrès. It derives from the same extreme deterministic philosophy as Naturalism and has much in common aesthetically with Impressionism in that it isolates subjectively perceived moments of meaningless physical experience. The impetus to decadent poetry came partly from the study of Baudelaire and partly from the work of Paul Verlaine. Though much of his early poetry imitated the work of Baudelaire and the Parnassians, in the *Fêtes galantes* (1869), a group of pastiches, and his major collection, *Romances sans paroles* (1974; "Songs Without Words"), Verlaine created the blend of musicality, physical atmospherics, and sense of psychological distortion that constituted his greatest poetic achievement. In so doing, he used *impair* (odd) metres, ambiguous syntax, and unusual collocations of abstract and concrete concepts in a way that radically advanced the technical range of French verse.

Features of Decadent poetry

In Verlaine's work two impressions predominate: that only the self is important, and that the function of poetry is to preserve moments of extreme sensation and unique impression. These were the features, together with the experiments in form, on which the younger generation of poets seized in the 1880s. Hence the founding of the review *Le Décadent* in 1886, whose title consecrated a label originally coined by hostile critics. The poetic movement found its best exponent in Jules Laforgue, who brought together a subjectivism and pessimism fed by his studies in contemporary German philosophy and a genius for harnessing effects of poetic contrast. His first two published collections, *Les Complaintes* (1885) and *L'Imitation de Notre-Dame la Lune* (1886), are a series of variations on the themes of the flight from life, woman, and ennui, each explored through a host of frequently recurring images (*e.g.,* the wind, Sundays, the stock comic figure Pierrot). The conscious intellectual antitheses of the first collection are reduced in the second and disappear entirely in the *Dernier vers* (1890), in which the orchestrated cycle of recurrent images embodies the meaninglessness of life rather than explains it. To match these tenuous thematic patterns Laforgue used a fluid verse form shaped by rhythmic patterns and assonance, the first important example of free verse in French poetry.

Symbolism: Rimbaud and Mallarmé. The distinction between Decadence and Symbolism is surprisingly slight, although it should ostensibly be a distinction between the acceptance of the idea that life is meaningless and a mystical belief in meanings that transcend reality. But the principal Symbolist poets were not in a conventional sense metaphysicians, and their search for transcendence derived from a subjectivity as intense as that of Verlaine and Laforgue.

The narrowness of the distinction is well illustrated by the case of Arthur Rimbaud. Rimbaud's poetic creed is generally taken to be contained in two letters of 1871, in which he prescribes for the poet the need to explore the inner self, reorder perceptions of existence, and thereby become a visionary. The fiercely ironic view of contemporary society that emerges from his early poems reveals in him an element of the political revolutionary. The dreamlike poem "Le Bateau ivre" ("The Drunken Boat") and the poems written during the period of his infatuation with Verlaine (the so-called "last poems") show a more far-reaching revolution in the interpretation of reality, using an atmospheric, dislocated style similar to that of Verlaine's *Romances sans paroles* but with images more surreal and formal experiments more radical. By 1872 Rimbaud had carried his aesthetic revolution still further in his prose poems *Illuminations* (probably written from 1872 onward, and published posthumously), in which moods of destruction, revolt, elation, liberation, and frustration are suggested through visions that have no logical coherence. Critics are divided as to whether or not Rimbaud's other cycle of prose poems, *Une Saison en enfer* (1873; *A Season in Hell*), predated the writing of the last *Illuminations.* In either case the work reveals Rimbaud's own doubts as to whether his poetic method could create a vision capable of affecting the world outside itself. His loss of confidence in the magical powers of language led to his abandoning literature completely, at or about the age of 19.

Stéphane Mallarmé brought a very different temperament and intellectual background to bear on the problem of the inadequacies of the material world. While both Rimbaud and Mallarmé believed in the special power of language, Rimbaud's vision was centred on life, Mallarmé's on death. His early poems, such as "L'Azur" ("Azure") and "Les Fenêtres" ("The Windows"), reveal a man haunted by the awareness of a transcendent reality that he cannot attain and that frightens him. An intellectual and spiritual crisis in 1867 led him to a final acceptance of death as the only inevitability in life. But while this fact negated his personal significance, he found in it a new value for the products of his mind. Only the world of literature, born of the writer's imagination and fixed in the creative medium of language, was unassailable by the forces of chance. A meaning for life could only be found, therefore, in art. Ironically, although until his death Mallarmé pursued the vision of writing his Grand Oeuvre, he in fact published very little: the *Poésies* (1887), a handful of prose poems and essays, an unfinished prose drama, and "Un Coup de dés jamais n'abolira le hasard" (1897; "A Throw of the Dice Will Never Abolish Chance").

Though Mallarmé's philosophical crisis is important as an explanation of why he came to write as he did, his place in the history of poetry depends more on the techniques he evolved in the pursuit of his ideals. In the effort to escape from the limitation of surface reality, he came more and more to depend on elaborate techniques of evocation and suggestion. And in his desire to assert a God-like creative role he exercised tight control over all the formal elements of his verse—the very opposite of Rimbaud's experiments in liberation. As early as *L'Après-midi d'un faune* (1876; "The Afternoon of a Faun"; later interpreted musically by Claude Debussy) he concentrated on multiplicity of meaning: even a reductive reading of the poem has to see it as simultaneously the dream evocation of the faun's erotic desires and a meditation upon the creative impulse at an abstract level. The later "Prose (pour des Esseintes)," "Plusieurs sonnets," and "Autres poëmes et sonnets" are studies in the possibilities of language, in which, as in music, recurrent images and antithetical patterns communicate on an emotive level. The curious "Un Coup de dés," with its use of the typography to reflect the theme of chance, suggests that ultimately Mallarmé, like Rimbaud, felt defeated. He realized that the poet in his pursuit of the absolute via literature could never possess complete mastery of expression, and therefore could never exclude the hazard of random inspiration. His art was thereby reduced to the status of totally subjective self-exploration. Perhaps Huysmans was right to present Mallarmé as the ultimate decadent writer in *À Rebours.*

By an irony of literary history Symbolism as a historical movement strictly postdates Mallarmé. It derived its name from an article by Jean Moréas, who produced the first manifesto of the movement in 1886. The 1880s and '90s continued to be a period of artistic ferment, which produced many charming poems but no major poets. Musicality, myth, mysticism, and melancholia are the hallmarks of nearly all the best verse of the period and of nearly all the worst. Among those whose works have deservedly survived in anthologies are Henri de Régnier and Francis Viélé-Griffin and the Belgian poets Georges Rodenbach and Émile Verhaeren.

THE NOVEL LATER IN THE CENTURY

The development of the novel in the 1880s reflected the same thirst for absolutes as the new movements in poetry. But neither Decadence (with the exception of *À Rebours*) nor Symbolism generated prose fiction of lasting significance. There was a recrudescence of the *conte fantastique,* which found its foremost exponent in Auguste, comte de Villiers de L'Isle-Adam, as in his *Contes cruels* (1883; *Cruel Tales*). But the major trends in the novel were connected with the revival of Roman Catholicism and the growth of nationalism in the aftermath of the Franco-German War. The religious spirit was sometimes aesthetic, as in Huysmans' *La Cathédrale* (1898), sometimes visionary, as in Léon Bloy's *Le Désespéré* (1886) and *La Femme pauvre* (1897; *The Woman Who Was Poor*), in which a hysterical attack on bourgeois society is combined with an equally hysterical espousal of the then-fashionable doctrine of vicarious suffering. But the combination of Roman Catholic teaching and right-wing politics in the novels of Paul Bourget, beginning with *Le Disciple* (1889; "The Disciple"), is more typical of the spirit of the times. The antidemocratic, antirepublican views of Bourget were similar to those found in nationalist writers, notably Maurice Barrès. Barrès moved from decadent self-absorption to an extreme form of historical determinism. He saw the meaning of the individual as defined by his part in a collective inherited unconscious, which itself was defined by race. His trilogy *Le Roman de l'énergie nationale,* particularly *Les Déracinés* (1897), is an important document for an understanding of the attitudes of the French right during the Dreyfus Affair and between the world wars.

Anatole France

The only novelist of note who stood outside all these trends, and yet was a typical offspring of the age that produced them, achieving the double distinction of winning the Nobel Prize for Literature for 1921 and being put on the Index, was Anatole France (pen name of Jacques-François-Anatole Thibault). France made his initial reputation as a literary critic and author of psychological novels, but he rapidly became the personification of the pessimism fashionable after Germany's victory over France in 1870, an attitude typically expressed in the detachedly ironic exposure of human weakness in *Les Opinions de M. Jérôme Coïgnard* and *La Rôtisserie de la Reine Pédauque* (both 1893). The same attitudes pervaded the first three volumes of his *Histoire contemporaine,* a novel sequence impartially mocking church, right-wing opposition, and corrupt political establishment. But in the fourth volume, *Monsieur Bergeret à Paris* (1901; *Monsieur Bergeret in Paris*), France's commitment to the pro-Dreyfus faction in the Dreyfus Affair introduced both a more bitter note to his satire and an unaccustomed commitment to positive humanitarian ideals. Like many other Dreyfusards he was to be disillusioned by the aftermath of the affair, a response typified by his extended satire of French society through the ages in *L'Île des Pingouins* (1908; *Penguin Islands*) and his condemnation of fanaticism in his novel on the French Revolution, *Les Dieux ont soif* (1912; *The Gods Are Athirst*). (C.Ro.)

Beginning the 20th century: from 1900 to 1940

THE LEGACY OF THE 19TH CENTURY

French writing of the first quarter of the 20th century reveals a dissatisfaction with the pessimism, skepticism, and narrow rationalism of the preceding age and displays a new confidence in man's possibilities, although this is undercut by World War I. There is a continuity with the poetry of the late 19th century but a rejection of the prose. Mallarmé and Rimbaud were models for Paul Valéry and Paul Claudel, but the Naturalist novel was considered by the new generation to be unduly deterministic and falsely objective. Charles-Louis Philippe, in *Bubu de Montparnasse* (1901; Eng. trans., *Bubu de Montparnasse*), used the material of Zola, namely the Paris slums, but depicted it through a narrator who could identify with the working-class protagonists.

In philosophy the rationalism of Taine and Renan exerted less influence than Henri Bergson's belief in man's creative ability and in intuition as an instrument to understand the universe. Among foreign thinkers Arthur Schopenhauer, so important to the preceding generation, gave way to Friedrich Nietzsche, whose books were read not for the superman theme but as a protest against the limitations of the mechanistic world.

Effect of the Dreyfus Affair

Literature continued to follow the political and social struggles of the Third Republic. The Dreyfus Affair unleashed a wave of "commitment," with Maurice Barrès and Charles Maurras on the anti-Dreyfus side (those opposed to a retrial for Dreyfus) and Charles Péguy on the other. The debate about the education system and about the separation of church and state form the backdrop to a Roman Catholic renaissance that begins with Claudel and Péguy and later finds expression in François Mauriac and Georges Bernanos. Although often politically conservative and theologically orthodox, this writing is audacious in depicting the individual's need for God and his personal quest for salvation. Meanwhile the anti-German sentiment, which stemmed from the 1870 defeat and was revived in the years immediately preceding World War I, helped create the Action Française, led by Maurras. The group sought to steer French culture toward integral nationalism, a policy that sought to restore the monarchy, even as the burgeoning Socialist movement also won adherents.

THE NOUVELLE REVUE FRANÇAISE AND ITS WRITERS

Although the Third Republic governments were weak, centrist coalitions that writers found difficult to admire, the hidden stability of French society made possible a literature that exalted individual experience. Some of the leading writers of the years before 1914 gathered around the *Nouvelle Revue Française,* which was founded by André Gide in 1908. The review, which became France's leading literary magazine while also spawning the Gallimard publishing house, shunned extremes, was distrustful of commitment, and sought a balance between modernity and tradition. Although its articles represented a network of dialogues rather than one fixed position, it nonetheless emphasized the authenticity of inner life.

Valery Larbaud's *A.O. Barnabooth: son journal intime* (1913; *A.O. Barnabooth: His Diary*) depicts the slow discovery of the self after an initial liberation. The enormously successful *Le Grand Meaulnes* (1913; *The Wanderer*) by Alain-Fournier (pseudonym of Henri-Alban Fournier) explored the new theme of adolescence; in poetry, Saint-John Perse (pseudonym of Alexis Léger) depicts the triumphant recovery of childhood in *Éloges* (1911; *Éloges, and Other Poems*); and Jacques Rivière's essays on painting, the Russian ballet, and contemporary writers show an excellent critical mind piecing together its age.

Novels of André Gide

The house of Gallimard published the four greatest writers of this period: Gide, Marcel Proust, Claudel, and Valéry. Gide's *Les Nourritures terrestres* (1897; *Fruits of the Earth*) and *L'Immoraliste* (1902; *The Immoralist*) encouraged a generation of French youth to question the values of family and tradition and to be guided by that part of themselves that typically was ignored or repressed by society. *Les Caves du Vatican* (1914; *The Vatican Swindle*) depicted the *acte gratuit,* which is undertaken not for gain or self-interest but because it expresses the deepest strain in one's character. Less influential was *La Porte étroite* (1909; *Strait Is the Gate*), which explains the concomitant themes of asceticism and sacrifice.

Pursuit of freedom also guided Gide's technical experiments from *Paludes* (1895; *Marshlands*), considered to be one of his most important books, to *Les Faux-Monnayeurs* (1926; *The Counerfeiters*). He rejected the closed world of the 19th-century novel and instead sought forms of narration that were both internal and multiple and that allowed the reader a greater range of interpretation. Although some authors continued to produce traditional novels and multivolume works (such as Romain Rolland's *Jean Christophe,* 1904–12) using a conventional plot and time sequence, the best writing of the period is consciously avant-garde.

Marcel Proust's *À la recherche du temps perdu* (1913–27; *Remembrance of Things Past*) subjects existence to a remorseless analysis that seems to be in the best tradition of the French psychological novel. In the best known episode, that of Swann's love affair with Odette, Proust shows how the object of love is an illusion created and defined by the lover. But if reason dissects, unconscious memory may create the totality of experience. In the last volumes of this work its structure, which is based on recurring motifs perceived by intuition, is laid bare.

Proust, Claudel, and Valéry

Unlike his great rival Gide, Paul Claudel believed that man's deepest self emerged in the dialogue with a God who is jealous and remote but never absent. Less pious and less of a preacher than he is sometimes considered to be, Claudel depicts in *L'Annonce faite à Marie* (1912; *Tidings Brought to Mary*) a heroine who restores the divine order by her suffering and isolation. Yet in *Partage de Midi* (1906; *Break of Noon*) sexual love, albeit purified and punished, is the image of God's love for man.

Claudel's masterpiece is *Le Soulier de satin* (1930; *The Satin Slipper*), in which divine grace haunts the characters who try in vain to escape it. This view of human character was well suited to the theatre, and Claudel's plays are full of buffoonery, ritual, and movement. They break with the realistic theatre of the 19th century, and they have also lasted better than the vaguely Symbolist plays of Maurice Maeterlinck, whose *Oiseau bleu* (1908; *The Blue Bird*) was more popular at the time.

Although he was also a great poet, Claudel may be less important than Paul Valéry, who inherited Mallarmé's sense that the language of poetry was separate from ordinary discourse. Valéry, however, pursued poetry not as an end in itself but as a form of self-knowledge. The act of writing and of reading poetry reveals various states of consciousness, and the process makes possible glimpses of totality. In his greatest poem, "Le Cimetière Marin" (1920; "The Graveyard by the Sea"), Valéry combines extraordinary self-awareness with sensuous enjoyment of the outside world. Earlier, in a prose work called "La Soirée avec Monsieur Teste" (1896; "An Evening with Monsieur Teste"), which offers parallels with *Paludes*, Valéry had parodied the ideal of complete self-awareness.

THE IMPACT OF WORLD WAR I

The confidence displayed in the pages of the *Nouvelle Revue Française* was sapped by the slaughter in the trenches in World War I. The influence of the Action Française was initially increased by the Allied victory, and antiwar novels, such as Henri Barbusse's *Le Feu* (1916; *Under Fire*), were relatively few in number. The early 1920s were a brilliant period, during which the cosmopolitanism of reviews like *Commerce*, directed by Valéry, Larbaud, and the poet Léon-Paul Fargue and including texts from many countries, was a conscious attempt to overcome the rifts created in Europe by the war. French writing was influenced by foreign artists like James Joyce, whose inner monologue was adapted into French by Larbaud in *Amants, heureux amants* (1923; "Lovers, Happy Lovers"); in turn, Paris drew writers like T.S. Eliot, Eugenio Montale, and William Carlos Williams. Cautiously Gide and Rivière began to defy the Action Française and to advocate more gentle treatment of the defeated Germany. A cult of travel writing was exemplified by Paul Morand, whose *Ouvert la nuit* (1922; *Open All Night*) and *Fermé la nuit* (1923; *Closed All Night*) were popular.

The Surrealists

A different note was struck by the Surrealists, who drew on and retrospectively exalted Guillaume Apollinaire. The poems of *Alcools* (1913; Eng. trans., *Alcools*) and Apollinaire's interest in Cubist painting were filtered through the imported slogans of Dadaism and turned into a movement that wished to break violently with existing French culture, including the masters of the *Nouvelle Revue Française*. By emphasizing the subconscious and by using devices such as automatic writing, the Surrealists sought to destroy both existing social structures and the ordered text. André Breton, Louis Aragon, and Paul Éluard led a movement that mocked the homeland, the army, the existing political parties, and ordinary methods of perception.

POLITICAL COMMITMENT

In their hatred of contemporary French society the Surrealists endorsed Communism, although only Louis Aragon played a significant role within the Communist Party. Political commitment became more important (even though Julien Benda had warned of its dangers in *La Trahison des clercs* [1927; *The Great Betrayal*]) in the early 1930s, both because Hitler's attainment of power in Germany increased the possibility of a Fascist Europe and because the stability of the Third Republic was undermined by economic depression. The political polarization that stemmed from events such as the Stavisky affair (1933–34), which led to charges of widespread corruption in the parliamentary regime, or the outbreak of the Spanish Civil War in 1936 caused writers to take political stances, whether on the right or the left. Meanwhile, discontent with both the paper revolutions of Surrealism and the individualism of the older *Nouvelle Revue Française* drove the next generation to discover itself through action.

On the political right, the best known protagonist was Pierre-Eugène Drieu la Rochelle, whose *Gilles* (1939) remains an important book because it depicts the evolution of a young man during the interwar years. The novel begins with Gilles's experience of the trenches and takes him through periods of despair until he decides that he must fight for General Franco in Spain. An avowed Fascist with anarchist tendencies, Drieu, who was to collaborate during the Nazi occupation of France, was followed by younger men such as Robert Brasillach, author of *Notre avant-guerre* (1941), and Lucien Rebatet, who, like Brasillach, contributed during the Occupation to the virulently anti-Semitic newspaper *Je Suis Partout*.

On the political left, Joseph Stalin's decision to end the policy of hostility toward the Socialist Party and instead to form Popular Fronts brought many writers into or close to the Communist Party. Newspapers like *Commune* and *Monde*, which advocated that literature should serve the cause of working-class liberation, were influential. Meanwhile Gide's adherence to and defection from Communism, depicted in *Retour de l'U.R.S.S.* (1936; *Return from the U.S.S.R.*), were widely discussed.

The books of Paul Nizan, who had joined the party earlier, exemplify this trend. *La Conspiration* (1938) is a satire on both the middle-class family and immature revolutionaries, while *Le Cheval de Troie* (1935; *Trojan Horse*) depicts a group of Communists engaged in the political struggle.

The issue of colonialism

An odd but important book is Henry de Montherlant's *La Rose de sable* (written in 1932 although not published until 1967). Montherlant offers a critique of French colonialism, using as his vehicle the figure of a nationalist officer who loses his belief in French rule over Morocco. The issue of colonialism had been posed by Gide in his *Voyage au Congo* (1927; *Travels in the Congo*), and it was to recur in the work of Albert Camus, who for a time was active in the Algiers cultural agency set up under the Popular Front by the newspaper *Commune*.

THE PAMPHLET

The bitter ideological clashes and the growing emotional tension brought a rush of political pamphlets. In France authors typically used the genre as a forum for personal opinion: an author would select a target and, in his pamphlet, pour out a diatribe of hatred against it. One example of "leftist" pamphleteering is Nizan's *Les Chiens de garde* (1932), in which the author excoriates Sorbonne philosophy, and another is Bernanos' *Les Grands Cimetières sous la lune* (1938; *A Diary of My Times*), which denounces Franco's Falangists. Authors on the political right were more prolific. An example is Henri Béraud's *Faut-il reduire l'Angleterre en esclavage?* (1935; "Must England Be Reduced to Slavery?"), which vituperates against perfidious Albion. But the dubious distinction of being the greatest pamphleteer falls to Louis-Ferdinand Céline (Louis-Ferdinand Destouches), whose *Bagatelles pour un massacre* (1937; "Trifles for a Massacre") and *L'Ecole des cadavres* (1938; "School for Corpses") are a frenzy of anti-Semitism and of pacifism at all costs.

THE NOVEL BETWEEN THE WARS

With a few notable exceptions, novels were less technically innovative in the second quarter of the century. The Surrealists made their contribution with André Breton's *Nadja* (1928; Eng. trans., *Nadja*) and Louis Aragon's *Le Paysan de Paris* (1926; *The Night-Walker*), and they influenced the works of Raymond Queneau. The tradition of the family novel was continued by Roger Martin du Gard's *Les Thibault* (1922–40), while Jules Romains delved into the history of the Third Republic for *Les Hommes de bonne volonté* (1932–47; *Men of Goodwill*). A popular adventure novel was Antoine de Saint-Exupéry's *Vol de nuit* (1931; *Night Flight*). More important are the novels of François Mauriac, whose *Noeud de vipères* (1932; *Vipers' Tangle*) and *Thérèse Desqueyroux* (1927; Eng. trans., *Thérèse Desqueyroux*) deploy the traditional form of the French psychological novel in order to depict characters who are deprived of God's grace and stranded in the desert of provincial middle-class society. Mauriac does not have the triumphant tone of earlier Roman Catholic writing and he analyzes the problems of guilt, spiritual loneliness, and confession.

The current of working-class writing, inaugurated by Philippe, was continued by Louis Guilloux. His *Maison du peuple* (1927) depicts a child's view of the oppressed but rebellious community in which he grows up, and his *Sang noir* (1935; *Bitter Victory*) is a bleaker depiction of provincial life. The regional novel, in fact, is well represented between the wars. Marcel Aymé gave it a satirical twist in *La Jument verte* (1933; *The Green Mare*), while Jean Giono advocated a return to the traditional values of peasant life in *Regain* (1930; *Harvest*). Realism also reasserted itself in the 1930s, and a popular success was Eugène Dabit's *Hôtel du nord* (1929; *Hotel du Nord*), which depicts the grim streets of northern Paris.

The novels of Malraux

Young French readers turned more avidly to the novels of André Malraux, whose novels depict the themes of adventure, Bolshevism, and revolutionary fraternity. *La Condition humaine* (1933; *Man's Fate*), which depicts the Communist uprising in Shanghai in 1927, shows a group of comrades who overcome their obsession with death by taking revolutionary action. *L'Espoir* (1937; *Man's Hope*) is a complex work that combines journalistic techniques, outbursts of lyricism, and switches in the narrative structure in order to depict the Spanish Civil War. If the book is in part an epic whose collective hero is the Republican fighters, it is also a debate about moral values versus efficiency and about the psychology of the Communist militant.

The best novelist of the 1930s, however, was Céline. *Voyage au bout de la nuit* (1932; *Journey to the End of the Night*) is a journey of discovery that moves from World War I, via Africa and America, to the drab suburbs of northern Paris. Intent on confronting the bleakest aspects of the human condition, Céline also wished to render them in a more immediate and brutal manner, so *Mort à credit* (1936; *Death on the Installment Plan*) is written in a tide of slang and obscenity that also possesses its own lyricism. By dismembering the sentences, scrapping plot, and moving without transition from reality to dream, Céline made the most original contribution of the interwar years to the art of novel writing.

POETRY

Valéry, Claudel, and Léon-Paul Fargue continued writing throughout this period and Saint-John Perse produced a great work, *Anabase* (1924; *Anabasis*). The influence of the Surrealists was strongest in poetry. Breton, whose work is rhetorical and only superficially chaotic, Aragon, and Paul Éluard (pseudonym of Eugène Grindel) all produced poetry that is still read. On the fringes of the movement were two better poets: Henri Michaux, whose prose poems *La Nuit remue* (1934; *The Night Moves*) are a striking example of that difficult genre, and René Char. Char's work exalts the mythical forces that reside in the countryside of southern France, with its bare hills and its twisted vegetation; of all Surrealists he has had the greatest influence on younger French poets. A simpler vein was tapped lyrically by Robert Desnos and satirically by Jacques Prévert, whose doggerel ballads reveal an anarchist's temperament.

THEATRE

Although the Surrealists retrospectively exalted Alfred Jarry's *Ubu roi* (1896; Eng. trans., *Ubu roi:* "King Ubu"), which exploded all theatrical conventions, they did not themselves produce plays of lasting value. In general the period between the wars was not a great era for the French theatre. The dominant playwrights were men like Édouard Bourdet, whose highly successful works were witty and clever but slight. A similar but better dramatist was Marcel Pagnol, whose *Marius* (1929; Eng. trans., *Marius*) is set in the Marseille docks. Cocteau and Jean Giraudoux were more serious figures, and Giraudoux's *La Guerre de Troie n'aura pas lieu* (1935; adapted in English as *Tiger at the Gates*) is characteristic of his fanciful manner.

The popular comedies of the day were anathematized by Antonin Artaud, but his theatre of cruelty was not to exert much influence until after World War II. Similarly the next generation would admire such directors as Jacques Copeau, whose Vieux-Colombier theatre had grown out of the *Nouvelle Revue Française;* Charles Dullin, who influenced the young Sartre; and Jean-Louis Barrault.

THE EVE OF WORLD WAR II

New influences were at work from the mid-1930s onward: the novels of the U.S. writers William Faulkner and John Dos Passos as well as the philosophy of Edmund Husserl and Martin Heidegger found an audience in France. Albert Camus published *L'Envers et l'endroit* (1937; *Betwixt and Between*) and *Noces* (1939; *Nuptials*), the two volumes of essays that reveal his sense of the beauty and the emptiness of life near the Mediterranean. Jean-Paul Sartre unravelled the French psychological novel and the traditional diary form in *La Nausée* (1938; *Nausea*), while in *Le Mur* (1939; *The Wall*) he depicted the aberrations that can occur in any person's character. His interest in Phenomenology, his sense of consciousness as a perpetual flight, and his insistence on the priority of existence over essence led him to set out the philosophy of Existentialism, which dominated the 1940s. (P.McC.)

Continuing the 20th century: from 1940

Writers continued to enjoy a leading place in cultural life, but the outstanding names were not mainly connected with imaginative literature. Their work was philosophical and critical and the movements with which they were associated extended beyond the field of literature as narrowly defined. Even within this field the *nouveau roman* (New Novel) was to challenge established conventions, and fiction no longer appeared to have a privileged place in literary culture. But, paradoxically, by asserting the primacy of the text as an object in itself, critics severed the last remaining links between its reality and the one it purported to describe, to conclude that all writing was essentially an exercise in the creation of a fictional "textual world."

THE GERMAN OCCUPATION AND POSTWAR FRANCE

France's defeat by German troops in 1940, and the resultant division of the country, was experienced as a national humiliation, and all Frenchmen and Frenchwomen were confronted with an unavoidable choice. Some writers escaped the country to spend the remaining years of the war in exile or with the Free French Forces. Others, because of political options made during the previous decade, moved directly into collaboration. And still others, because of pacifism or a belief that art could remain aloof from politics, tried to carry on as individuals and as writers, ignoring the taint of passive collaboration with the occupying forces or the Vichy government. Jean Cocteau and Jean Giono were among those and later were criticized for their conduct. Giono in fact was briefly imprisoned, as was Louis-Ferdinand Céline, whose reputation was seriously damaged by his anti-Semitism.

Several writers joined the military, as well as the intellectual, resistance. André Malraux served on many fronts and commanded a group of underground resistance fighters in World War II in France, confirming the image of the writer as a man of action; he was to serve as a minister under Charles de Gaulle in the postwar government and the Fifth Republic.

The German attack on the Soviet Union in 1941 was decisive for the French Communist Party, which was to gain considerably through its organized opposition to Fascism. The events of the 1930s and '40s strengthened the conviction that intellectuals could not remain politically uncommitted; the war clarified choices and made them seem crucial for the individual. After 1945, Existentialism, depicting mankind alone in a godless universe, rationalized this view of individuals as free to determine themselves through such choices.

Poetry of resistance

Meanwhile, the occupation brought prestige and an attentive audience to writers who upheld the honour of their defeated country. The poetry of resistance reached a wide public, notably in the works of Paul Éluard and Louis Aragon. Both were Communists (Aragon was to become the country's "cultural commissar" after 1945) and had been associated with the Surrealist movement from the 1920s. They turned in the war years to writing poems in direct language, and their poems were often transmitted orally through the occupied zone. A flourishing clandestine press was able to issue some publications, including the newspaper *Combat* and the Editions de Minuit, which brought out as its first book the story *Le Silence de la mer* (1942) by Vercors (Jean-Marcel Bruller). With the additional stories later added to a collection under the same title, this is probably the literary work that most accurately evokes the atmosphere and the dilemmas of the time. Camus's fable *La Peste* (1947; *The Plague*), an allegory set in a city visited by the plague, gave a universal dimension to the treatment of these dilemmas.

The war transformed the literary scene, eclipsing some writers and lending prestige to those who had made the fortunate political choices. During the occupation Sartre further elaborated his Existentialist philosophy in plays, such as *Les Mouches* (1943; "The Flies") and *Huis-Clos* (1944; *No Exit*, or *In Camera*) and expounded it in the treatise *L'Être et le néant* (1943; *Being and Nothingness*). After the liberation, the writer and his ideas set the tone for a postwar generation that congregated in the cafés and cellar clubs of Saint-Germain-des-Prés. The myth of this disillusioned youth, its district of Paris, its innocence, its jazz clubs, and its worship of Sartre were captured in Boris Vian's *L'Écume des jours* (1947).

Influence of Sartre

Sartre's reputation fluctuated widely during the 30 years from 1950 until his death: at times he was compared to Voltaire, and at other times he was dismissed as a senile fellow traveller. Until 1952 his name was linked with that of Camus, whose novel *L'Étranger* (1945; *The Stranger*, or *The Outsider*) expressed a vision similar to that of the early Sartre. But after their highly publicized break, Sartre moved toward the Existentialist Marxism of his *Critique de la raison dialectique* (1960; *Search for a Method*), and Camus toward a stoical humanism, his later fiction (*La Chute*, 1956; *The Fall*) showing evidence of his isolation, his creative unease, and his distress over France's war with Algeria.

The conflicts submerged in the euphoria of liberation surfaced during the Cold War period and were intensified by the colonial wars of the 1950s. Sartre's lifelong companion, Simone de Beauvoir, vividly depicted the contrary attractions of Communism and the United States for French intellectuals in her novel *Les Mandarins* (1954; *The Mandarins*). However, her analysis of the feminine condition, *Le Deuxième Sexe* (1949; *The Second Sex*), although reviled on its first appearance, was to be a more influential achievement, its themes being substantiated by her later autobiographical works. After Sartre's death she gave a moving account of his later years in *La Cérémonie des adieux* (1981; *Adieux, A Farewell to Sartre*), which was acknowledged as confirmation of their crucial role in intellectual life.

THE NOUVEAU ROMAN

The literary event of 1954 was *Bonjour tristesse*. Published when its author, Françoise Sagan (pseudonym of Françoise Quoirez), was only 19, this novel of adolescent love was written with "classical" restraint and a tone of cynical disillusionment and showed the persistence of traditional form in fiction. The previous generation, caught up in politics, had experimented with Socialist Realism (for example, the novels of Roger Vailland), yet, while the 1950s seem in retrospect to have been dominated by concern with form, the novel-reading public remained largely untouched by those experiments. The Naturalist novel survived in the work of Henri Troyat and others, while its assumptions about the role of the author and the nature of fictional "reality" continued to be taken for granted by a host of novelists and their readers.

On the other hand, these assumptions had long been challenged before the emergence of the *nouveau roman* (New Novel) in the work of Alain Robbe-Grillet, Claude Simon, Nathalie Sarraute, Michel Butor, and Marguerite Duras (pseudonym of Marguerite Donnadieu). What was new about these novelists, apart from the label applied to them, was their systematic rejection of the traditional framework of fiction—chronology, plot, character—and of the omniscient author. In place of these reassuring conventions, they offer texts that demand more of the reader, who is presented with compressed, repetitive, or only partially explained events from which to derive a meaning that will not, in any case, be definitive. In Robbe-Grillet's *La Jalousie* (1957; *Jealousy*), for example, the narrator's suspicions of his wife's infidelity are never confirmed or denied, but their obsessive quality is conveyed by the replacement of a chronological narrative with the insistent repetition of details or events. In *Le Libéra* (1968) by Robert Pinget there is no single narrator, while in the later novels of Jean Cayrol the narrative emanates from the sea, a field, the desert.

The *nouveau roman* was open to influence from works being written abroad (notably the work of William Faulkner) and from the cinema (Robbe-Grillet and Duras contributed to the *nouvelle vague*, or New Wave, style of filmmaking). But, by the time Robbe-Grillet's *Pour un nouveau roman* (*Toward a New Novel*) appeared in 1963, it was clear that the term covered a variety of approaches. In the same year, the Prix Théophraste Renaudot was awarded to Jean-Marie Le Clézio for *Le Procès-verbal* (*The Interrogation*), a novel welcomed partly because it was both "modern" and accessible. It was also heralded (prematurely) as offering an escape from the *nouveau roman*'s overintellectuality.

EXPERIMENTS IN THEATRE

During the 1940s the theatre provided a forum for the veiled expression of political dilemmas through the dramatization of individual crises of conscience. The plays of Montherlant, Jean Anouilh, Giraudoux, and Sartre made this, surprisingly, an outstanding moment for the Parisian stage. A government policy to provide state financial aid after the war led to the encouragement of great drama in the provinces (the Avignon Festival started in 1947) and the establishment of remarkable and innovative theatre companies, such as the Théâtre National Populaire and the Compagnie Jean-Louis Barrault–Madeleine Renaud. But, while the works they performed were inventive and intellectually stimulating, there was little change in the concept of theatre itself; this was a writer's theatre, the genre and the rules of stagecraft seemingly fixed within an agreed perception of what constituted "reality."

Jarry, Cocteau, and others had attempted to extend this perception long before in works that had opened drama to the irrational, the surreal, and the influence of circus and music hall. Artaud's *Le Théâtre et son double* (1938; *The Theatre and Its Double*) called for theatre that would shock its spectators into seeing the baseness of the real world. But it was only after the war, starting with plays staged in the Parisian fringe theatre, that the accepted notion of theatre and the primacy of the text were seriously challenged.

While the plays of Anouilh and Sartre conveyed their intentions effectively from the printed page, those of Jean Genet, Eugène Ionesco, Authur Adamov, and Samuel Beckett only revealed their full meaning in actual performance, the text often seeming flat, repetitive, or banal until brought to life on the stage. Though Genet's *Les Bonnes* (*The Maids*) appeared in 1947 and Ionesco's *La Cantatrice chauve* (*The Bald Soprano*) in 1949, public recognition of the new theatre did not come until 1953, with Roger Blin's production of Beckett's *En attendant Godot* (1952; *Waiting for Godot*). Originating in the fool of Shakespearean drama and the tramp of silent comedy, the characters of Vladimir and Estragon convey the absurdity and the tragedy of existence in an artistic context that resembles musical composition more than the classical "imitation of nature."

POSTWAR POETRY

Developments in the novel and the theatre were easier to define than those in poetry, where the lack of a broad readership was, in itself, an encouragement to fragmentation. The works of Jacques Prévert and the songs of Georges Brassens and Jacques Brel did achieve the status of popular poetry; but, apart from Saint-John Perse, there was no major figure in the tradition of Claudel and Valéry, and the poetry of the post-Surrealist generation appeared to have no clear formal or ideological direction. The mainstream of French poetry was represented by René Char, Pierre Emmanuel (pseudonym of Noël Mathieu), and Yves Bonnefoy. In contrast to the tendency to abstract and symbolic language that characterized their poetry, however, Francis Ponge in *Le Parti pris des choses* (1942) and later works used wordplay and devices to emphasize the act of writing, in prose poems centred on the impersonal description of objects.

On the whole, the intellectual bourgeoisie that might have provided the audience for poetry looked to the written word for the expression of ideas and found aesthetic stimulation in the visual arts, especially the cinema. A younger generation, from the late 1960s, was more open to fantasy and the imagination, but impatient of formal discipline. The "do-it-yourself" poetry that appealed to this group's egalitarian instincts was as ephemeral as the little magazines in which it appeared during the 1970s, and the "crisis of verse" that Jacques Roubaud described in *La Vieillesse d'Alexandre* (1978) remained unresolved.

Roubaud's own poetry, including *Trente et un au cube* (1973), looked to Japanese literature as the inspiration for work that was structured, yet free from the burden of European rhetoric. He was associated with the writers of OuLiPo (Ouvroir de Littérature Potentielle) who, inspired by Alfred Jarry and by Raymond Queneau, sought during the 1970s to escape from the vague "poeticism" of much contemporary free verse through the acceptance of rigorous formal constraints. Their fondness for wordplay and sometimes unbelievably demanding forms was illustrated in the works of Georges Perec. As well as poetry, Perec wrote novels, including *La Disparition* (1969), a text composed entirely without using the letter *e*, and *La Vie mode d'emploi* (1978), his most accessible work, built around the inhabitants of an apartment house.

Playful aspects of literary composition

This renewal of interest in the playful aspects of literary composition was consistent with contemporary critical theory and was accompanied by a reassessment of some earlier literature, such as the poetry of the *grands rhétoriqueurs*. Queneau, most widely known as the author of *Zazie dans le métro* (1959; *Zazie*), was the most immediate predecessor with his stylistic demonstrations in *Exercices de style* (1947) and the 10 sonnets of *Cent mille milliards de poèmes* (1961), which the reader was invited to rearrange in the hundred-thousand-billion ways indicated by the title. This unsolemn reaction to formlessness was clearly healthy, and the success of series devoted to the work of the more established poets showed that there was a readership even for quite demanding work, though that readership's social composition was less precisely defined and less coherent than it had been in earlier periods.

THE 1960S

In the early 1960s, free of colonial entanglements, France enjoyed increasing stability and affluence while, despite *le fast-food le marketing,* and *le rock,* French culture preserved an individual character and was defended against such transatlantic imports by René Etiemble in his polemic *Parlez-vous franglais?* (1964). The technocratic middle class, which benefitted most from the country's prosperity, was open to new ideas in science, and its materialist outlook found expression in *Le Hasard et la nécessité* (1970; *Chance and Necessity*) by Jacques Monod.

Monod, who won the Nobel Prize for Physiology or Medicine for 1965, rejected earlier ideologies, including religion, and drew on science for a view of the human place in the universe. The new technology seemed to promise endless growth and the erosion of class divisions. Perec, in *Les Choses* (1965), warned of the emptiness of this consumer society, while a bitter novel by Christiane Rochefort, *Les Petits Enfants du siècle* (1961), satirized the welfare state and revealed the drabness of life in a working-class housing complex. *La Dentellière* (1974), by Pascal Lainé, showed that the technocratic society had not abolished class differences and announced the next decade's concern for the position of women.

The most significant developments seemed to be outside the field of imaginative literature: in the structural anthropology of Claude Lévi-Strauss, the semiology of Roland Barthes, the neo-Freudian psychology of Jacques Lacan, and the philosophy of Michel Foucault or Jacques Derrida. Despite *Time* magazine's disparagement in 1969 of French culture, it can be argued that French writers, more than those of any other country, were making original contributions to almost every field of social science and the humanities.

Structuralism

Their work transcended academic boundaries. Structuralism, reacting against the Phenomenology of Sartre, asserted the crucial importance of relationships between phenomena, while semiology analyzed systems of signs, notably language, through which one attributes meaning to the raw data of reality. The journal *Tel Quel*, edited by Philippe Sollers, was the focus for a theory of writing as a concept to be extended beyond the realm of literature.

The New Criticism demanded more of the reader, who was to become an active participant in decoding the text, not a passive recipient. Critics emphasized context and variant readings, none of which was to be exclusively "correct." The text itself became the object of closer and closer scrutiny: a single line from a poem by Laforgue could give rise to five pages of exegesis in a critical journal.

The New Critics despised the university establishment and met with opposition from it about the time of Barthes's *Sur Racine* (1963; "On Racine"). The educational system was rigid and outdated. A liberal university admissions policy was combined with a teaching method based largely on formal lectures, and the vast student body found itself with no say in the running of a system that seemed to be largely irrelevant to its needs.

THE EVENTS OF 1968

During the student revolt in May 1968, streets, factories, schools, and universities became the stage for a spontaneous performance, the decor provided by posters and graffiti elevated to a popular art form. The theatre itself in the late 1960s and the 1970s moved still further away from the "writer's theatre" of earlier times, experimenting with audience participation and improvisation. Rock music and comic books flourished, and television, closely controlled by the government under de Gaulle, began to play an increasing role in cultural life; discussion programs and spin-offs from serials or adaptations were taking over from the press in guiding taste.

The events of 1968 led to no conclusions, and the community's reaction emphasized continuity and conservatism. The academies, the literary prizes, the dominant publishing houses, and the university elite survived more or less intact. The most evident long-term benefit of the upheaval was the encouragement it gave to the feminist movement. The analysis begun by Simone de Beauvoir was taken up in a host of works, and the novels of Claire Etcherelli, Marie Cardinal, Chantal Chawaf, and Hélène Cixous were among many that, in different ways, affirmed the value of feminine experience. Historians of both sexes were stimulated to reassess past roles of women, the family, and sexuality. The gains, by the 1980s, were enormous, though Marguerite Duras, whose novels had long emphasized the freeing of their women characters from a life-destroying social and domestic background, dissociated herself from some aspirations of the feminist movement, which she also found restricting.

LITERATURE AFTER 1970

With no movement obviously set to replace the *nouveau roman* in fiction, there were dire predictions about the future of literary culture. Only Michel Tournier was generally agreed to be outstanding. *Le Roi des Aulnes* (1971) was an extraordinary combination of myth and parable, and Tournier's imagination, as well as his skillful narrative technique, were confirmed in *Les Météores* (1975) and *Gilles et Jeanne* (1983). But critical acclaim for Tournier's work did not encourage imitation, and the most one could say of the novel up to the mid-1980s was that it exhibited a variety of tendencies, from post-*nouveau roman* experiments to traditional survivals.

The frustrations of the times may have added to the attraction of the historical novel. Marguerite Yourcenar (pseudonym of Marguerite de Crayencour), who in 1980 became the first woman elected to the Académie Française, had shown that the genre could appeal to more than escapism. *Mémoires d'Hadrien* (1951; *Memoirs of Hadrian*) and *L'Oeuvre au noir* (1968; *The Abyss*) were portraits of men who overcame the limitations of their time, as well as rich evocations of the past. History proved able to accommodate a vast range of fiction, from popular romance (Jeanne Bourin's best-selling *La Chambre des dames,* 1979) and fictionalized biography to the linguistic and narrative experiments of Claude Simon (*Les Géorgiques,* 1981) and Pierre Guyotat (*Le Livre,* 1984) or the sensitive prose of Florence Delay (*L'Insuccès de la fête,* 1980) and Christiane Singer (*La Mort viennoise,* 1978). It was sustained by the prestige of historiography: Michel Foucault's studies of sexuality and attitudes toward death, and the social history associated with the journal *Annales,* edited by Emmanuel Le Roy Ladurie, whose *Montaillou* (1975) was an international best-seller.

There was a corresponding interest in biography, autobiography, and memoirs. The novelists Julien Green and Julien Gracq (pseudonym of Louis Poirier) were among several figures of an earlier generation who began to publish journals and memoirs rather than fiction. The public delighted in the stories of Marcel Pagnol's Provençal childhood, but also in Nathalie Sarraute's *Enfance* (1983; *Childhood*), and seemed increasingly prepared to come to terms with some technical innovations. Georges Perec's *W: ou, le souvenir d'enfance* (1975; *W; or, The Memory of Childhood*) is an autobiography formed of the alternating chapters of two seemingly unconnected texts, which eventually find their resolution in the concentration camp.

Detective fiction, a genre sometimes exploited by the *nouveau roman,* had an outstanding practitioner in Georges Simenon, who, during the 1970s, also turned to autobiography. The gangster novels of Albert Simonin made imaginative use of Parisian slang, but the chief attraction of the thriller for more "literary" writers was its form, which they, like a number of filmmakers, adopted as a framework for the investigation of questions of identity or moral and political dilemmas (for example, in Michel del Castillo's *La Nuit du décret,* 1981).

The period after 1968 was one of adjustment to political, economic, and social changes, exemplified by the development of the feminist movement. The analysis begun by Simone de Beauvoir in *The Second Sex* was taken up in the novels of Claire Etcherelli, Marie Cardinal, Chantal Chawaf, and Hélène Cixous. Cixous developed the idea of *écriture féminine*, which emphasized such "feminine" intellectual traits as openness and play, and expressed this theory in various prose fictions. Monique Wittig sought to model women's struggle for self-designation in such novels as *Le Corps lesbien* (1973; *The Lesbian Body*). In the theatre Marguerite Duras's *India Song* (1972; Eng. trans. *India Song*) found new configurations to express the protean nature of desire.

Approaching the 21st century: the 1980s and beyond

POSTCOLONIAL LITERATURE

Contributions by immigrants and their descendants

Pierre Nora, writing the closing essay to his great project of national cultural commemoration, *Les Lieux de mémoire* (1984–92; *Realms of Memory*), commented on the multiplicity of meanings and connotations that since the mid-1970s had become invested in the once-monolithic concepts of identity, memory, and patrimony: "the three key words of contemporary consciousness." An important contribution was being made to French cultural life not only by Francophone writers from North Africa, sub-Saharan Africa, and the Caribbean but by descendants of immigrants in France itself. Works produced by the children of North African immigrants began to be published in the early 1980s; their insights into cross-cultural identity and the patterns of life in underprivileged working-class suburbs enriched the literature in works such as Leïla Houari's *Zeida de nulle part* (1985; "Zeida from Nowhere") or her *Poème-fleuve pour noyer le temps présent* (1995; "Stream-of-Consciousness Poetry to Drown the Present In"). The French also began to come to terms with the Algerian conflict, as evidenced by the success in France of Albert Camus's posthumously published *Le Premier Homme* (1994; *The First Man*), an autobiographical novel based on his father's childhood in Algeria in a colonist milieu. Having established—in novels such as *L'Amour, la fantasia* (1985; *Fantasia: An Algerian Cavalcade*)—her reputation as both ardent defender and critic of her native Algeria, the acclaimed novelist Assia Djebar began to produce fictions that look to Algeria but are also alert to the hierarchies of power in Europe, as in *Les Nuits de Strasbourg* (1997; "Strasbourg Nights").

POSTMODERNISM AND MAINSTREAM PROSE FICTION

Thought and sensibility at the end of the century were governed by postmodernism. Jean-François Lyotard's *La Condition postmoderne* (1979; *The Postmodern Condition*) declared the end of the modes and concepts that had fueled 18th-century scientific rationalism and the industrial and capitalist society to which it gave birth: the "grand narratives" of historical progress and concepts of universal moral value and absolute worth. Societies were to be seen instead as collections of games or performances, played within arbitrary sets of rules. History, it seemed, had no more use, and value judgments were at an end.

Mingling art forms

The constructs of postmodernism, which encouraged the mingling of different art forms and genres, heavily affected the novel of this period. Jean Echenoz's comic pastiches of adventure, detective, and spy stories pleased both critics and the reading public. Photography and writing joined to produce the *photo-roman*, concerned with exploring the relationship between the image and the narrative work that goes into its construction and interpretation. Good examples of the *photo-roman* are Roland Barthes's *La Chambre Claire* (1980; *Camera Lucida*) and Hervé Guibert's *Vice* (1991). Gay writing found an important collective focus in the AIDS crisis, most notably in Guibert's best-selling *À l'ami qui ne m'a pas sauvé la vie* (1990; *To the Friend Who Did Not Save My Life*). Social issues were addressed in the autobiographical fiction of Annie Ernaux, who, in *La Place* (1983; *Positions*; also published as *A Man's Place*) and *Une femme* (1988; "A Woman"; Eng. trans. *A Woman's Story*), looked at the stresses between generations created by social change and changes of class allegiance. Christiane Rochefort's novel of child abuse, *La Porte au fond* ("The Door at the Back of the Room"), appeared in 1988. Hélène Cixous's feminist classic, *Le Livre de Prométhéa* (1983; *The Book of Promethea*), learned, funny, sparkling, and innovative, achieved its writer's ambition to make a distinctive model of the desiring feminine subject. Marguerite Duras's autobiographical novel *L'Amant de la Chine du Nord* (1991; *The North China Lover*) voiced its author's own version of the feminine erotic. Monique Wittig stylized lesbian sadomasochism in her parodic *Virgile, non* (1985; "Virgil, No"; Eng. trans. *Across the Acheron*). Another generation began publishing in the 1980s. Marie Redonnet's prose fiction sits at the edge of popular culture, in a bizarre blend of realism and fantasy. Chantal Chawaf's sensually charged prose offers a highly original version of the blood rhythms of the body in *Rédemption* (1989; Eng. trans. *Redemption*), a new kind of vampire novel.

Radically diverse accounts of life in the contemporary world emerged. Sylvie Germain's magic realism works on landscapes steeped in history. Her novel *La Pleurante des rues de Prague* (1992; *The Weeping Woman on the Streets of Prague*) is a dreamlike, surreal evocation of a city haunted by its sorrowful history. Her *Tobie des marais* (1998; *The Book of Tobias*) reworks the Apocryphal tale in a France that is simultaneously, and pleasingly, both medieval and modern. The narrative personae of Michel Houellebecq's highly successful novels *Extension du domaine de la lutte* (1994; *Whatever*) and *Les Particules élémentaires* (1998; *The Elementary Particles,* also published as *Atomised*) are computer-age Baudelaires, narcissistic and world-weary. Marie Darrieussecq's *Truismes* (1996; *Pig Tales: A Novel of Lust and Transformation*) is an imaginative political and moral satire depicting the blackly comic world of a young working woman with a highly materialistic lifestyle who begins to turn into a pig.

POETRY

Christian Prigent asked in an essay of 1996 what poets were good for in the modern world. His work and that of such well-established figures as Philippe Jaccottet (*La Seconde Semaison* [1996; "The Second Sowing"]) still reached audiences at the turn of the century, and Michel Houellebecq published his collected poems (*Poésies*) in 2000. Martin Sorrell's bilingual anthology, *Elles* (1995; "They [the women]"), showed the flourishing state of women's poetry. In it, poets such as Marie-Claire Bancquart, Andrée Chedid, and Jeanne Hyvrard offer their own insights into the problematic of gender roles and the challenge of finding a female poetic voice.

DRAMA

Theatre scripts revived

Most interesting of all, perhaps, was the revival of scripted drama at the end of the 20th century. The directors' theatre that held sway in the 1970s and early 1980s (inspiring spectacular and innovative staging developments and giving great scope to actors) had marginalized new writing. Ministry of Culture subsidies supported the work of Michel Vinaver and Bernard-Marie Koltès, whose plays are concerned with individuals struggling with the institutional discourses—family, law, politics—of which contemporary consumer society and their own identities are woven. The quick exchanges of Vinaver's play *L'Émission de télévision* (1990; "The Television Program") express the anxieties of a world in which realities are constantly shifting. Koltès's work is especially concerned with the fast-expanding numbers of the marginalized in a postcolonial world. His *Dans la solitude des champs de coton* (1986; "In the Solitude of Cotton Fields"), written two years before his death from AIDS and now translated and performed across the world, brilliantly embodies his central belief that modern life is focused on the deal; that is, the struggle for power between unequal individuals, client and dealer, seller and buyer. What is acted out on the Koltèsian stage are the rhetorical performances by which people live—on the edge of darkness, at the frontiers of disorder.

It is perhaps in the theatre that the value of current insights into the ludic and performative nature of the human condition can most easily be tested. At the close of the century, the most modern of creative writers in this respect remained Irish-born Samuel Beckett, who died in 1989 but whose importance, influence, and presence continued to grow. Exploiting and offsetting the rhythms of language, vision, and movement in order to explore the limits and the potential of form, Beckett's drama enshrines the serious nature of play. In so doing, it brings into focus what have always been the best parts of the French contribution to the Western cultural tradition: the analytical vision that penetrates the patterns and structures of the historical moment, the synthetic imagination that clarifies those patterns for others to see, in all their force and intensity—and the driving desire to see them otherwise. (1992–94).

Middle Ages: Histories include JOHN FOX, *The Middle Ages* (1974), vol. 1 in the series *A Literary History of France*, ed. by P.E. CHARVET. Among the better anthologies are C.W. ASPLAND (ed.), *A Medieval French Reader* (1979); and BRIAN WOLEDGE (ed.), *The Penguin Book of French Verse*, vol. 1 (1961). Studies on the epics and the romances are JESSIE CROSLAND, *The Old French Epic* (1951, reprinted 1971); PIERRE LE GENTIL, *The Chanson de Roland* (1969; originally published in French, 1955); JOSEPH J. DUGGAN, *A Guide to Studies on the* Chanson de Roland (1976); ROGER SHERMAN LOOMIS (ed.), *Arthurian Literature in the Middle Ages* (1959, reprinted 1979); L.T. TOPSFIELD, *Chrétien de Troyes: A Study of the Arthurian Romances* (1981); DOUGLAS KELLY, *Chrétien de Troyes: An Analytic Bibliography* (1976); and DAVID J. SHIRT, *The Old French Tristan Poems* (1980). Useful works on the lyric include L.T. TOPSFIELD, *Troubadours and Love* (1975, reprinted 1978); and FREDERICK GOLDIN (comp.), *Lyrics of the Troubadours and Trouvères* (1973, reprinted 1983). Among the volumes on prose literature are JANET M. FERRIER, *French Prose Writers of the Fourteenth and Fifteenth Centuries* (1966). GRACE FRANK, *The Medieval French Drama* (1954, reprinted 1972), is helpful.

The 16th century: A brief overview is given in A.J. KRAILSHEIMER (ed.), *The Continental Renaissance* (1971, reissued 1978). Among studies of the Pléiade is GRAHAME CASTOR, *Pléiade Poetics: A Study in Sixteenth-Century Thought and Terminology* (1964). Other works on the poetry of the time are TERENCE C. CAVE, *The Cornucopian Text: Problems of Writing in the French Renaissance* (1979, reissued 1985), and *Devotional Poetry in France c. 1570–1613* (1969).

The 17th century: Important works include P.J. YARROW, "The Seventeenth Century, 1715–1789," in P.E. CHARVET (ed.), *A Literary History of France*, vol. 2 (1967); JOHN CRUICKSHANK (ed.), *French Literature and Its Background*, vol. 2: *The Seventeenth Century* (1969); JOHN LOUGH, *An Introduction to Seventeenth-Century France* (1954, reissued 1969); W.D. HOWARTH, *The Seventeenth Century* (1965), vol. 1 in *Life and Letters of France*; and A.J. KRAILSHEIMER (ed.), *Studies in Self-Interest: From Descartes to La Bruyère* (1962). Among works on the drama are C.J. GOSSIP, *Introduction to French Classical Tragedy* (1981); GORDON POCOCK, *Corneille and Racine: Problems of Tragic Form* (1973); and H.T. BARNWELL, *The Tragic Drama of Corneille and Racine: An Old Parallel Revisited* (1982).

The 18th century: A standard work on the period is provided by ROBERT NIKLAUS, "The Eighteenth Century, 1715–1789," in P.E. CHARVET (ed.), *A Literary History of France*, vol. 4 (1967). Works on the novel include PETER BROOKS, *The Novel of Worldliness: Crébillon, Marivaux, Laclos, Stendhal* (1969); JOAN HINDE STEWART, *Gynographs: French Novels by Women of the Late Eighteenth Century* (1993); and VIVIENNE MYLNE, *The Eighteenth-Century French Novel: Techniques of Illusion*, 2nd ed. (1981).

The 19th century: Excellent studies for 1800 to 1850 appear in D.G. CHARLTON (ed.), *The French Romantics*, 2 vol. (1984); and W.D. HOWARTH, *Sublime and Grotesque: A Study of French Romantic Drama* (1975). Among the better studies of the literature from 1850 to 1900 are CHRISTOPHER ROBINSON, *French Literature in the Nineteenth Century* (1978); F.W.J. HEMMINGS, *Culture and Society in France, 1848–1898: Dissidents and Philistines* (1971); G.M. CARSANIGA and F.W.J. HEMMINGS (ed.), *The Age of Realism* (1974, reissued 1978); A.G. LEHMANN, *The Symbolist Aesthetic in France, 1885–1895*, 2nd ed. (1968, reprinted 1977); ANNA BALAKIAN, *The Symbolist Movement: A Critical Appraisal* (1967, reissued 1977); MARVIN CARLSON, *The French Stage in the Nineteenth Century* (1972); JENNIFER BIRKETT, *The Sins of the Fathers. Decadence in France 1870–1914* (1986); and RICHARD GRIFFITHS, *The Reactionary Revolution: The Catholic Revival in French Literature, 1870–1914* (1966).

The 20th century: An overview of the period to 1970 exists in the series *Littérature français* in PIERRE-OLIVIER WALZER, *Le XX*^{e} *siècle*, vol. 1: 1896–1920 (1975), and GERMAINE BRÉE, vol. 2: 1920–1970 (1978). The second volume has been translated into English: GERMAINE BRÉE, *Twentieth-Century French Literature*, trans. by LOUISE GUINEY, (1983). Works on the novel include HENRI PEYRE, *The Contemporary French Novel* (1955, reissued 1959); JOHN STURROCK, *The French New Novel: Claude Simon, Michel Butor, Alain Robbe-Grillet* (1969); CELIA BRITTON, *The Nouveau Roman: Fiction, Theory, Politics* (1992); EDMUND J. SMYTH (ed.), *Postmodernism and Contemporary Fiction* (1991); MARGARET ATACK and PHIL POWRIE (eds.), *Contemporary French Fiction by Women: Feminist Perspectives* (1990); EVA MARTIN SARTORI and DOROTHY WYNNE ZIMMERMAN (eds.), *French Women Writers. A Bio-Bibliographical Source Book* (1991). Among works on the theatre are MARTIN ESSLIN, *The Theatre of the Absurd*, 3rd ed., rev. and enlarged (1980, reissued 2001); and DAVID BRADBY, *Modern French Drama, 1940–1990*, 2nd ed. (1991). Poetry studies include MARCEL RAYMOND, *From Baudelaire to Surrealism* (1970; originally published in French, 1933); PETER BROOME and GRAHAM CHESTERS, *An Anthology of Modern French Poetry, 1850–1950* (1976); MICHAEL BISHOP, *The Contemporary Poetry of France: Eight Studies* (1985); MARTIN SORRELL (ed.), *Modern French Poetry: A Bilingual Anthology Covering Seventy Years* (1992) and *Elles: A Bilingual Anthology of Modern French Poetry by Women* (1995). CHRISTOPHER ROBINSON, *Scandal in the Ink: Male and Female Homosexuality in Twentieth-Century French Literature* (1995), is an excellent study.

Freud

Sigmund Freud may justly be called the most influential intellectual legislator of his age. He was the founder of psychoanalysis, at once a theory of the human psyche, a therapy for the relief of its ills, and an optic for the interpretation of culture and society. Despite repeated criticisms, attempted refutations, and qualifications of Freud's work, its spell remained powerful well after his death and in fields far removed from psychology as it is narrowly defined. If, as the American sociologist Philip Rieff once contended, "psychological man" replaced such earlier notions as political, religious, or economic man as the 20th century's dominant self-image, it is in no small measure due to the power of Freud's vision and the seeming inexhaustibility of the intellectual legacy he left behind.

Mary Evans/Sigmund Freud Copyrights (courtesy of W.E. Freud)

Freud, 1921.

Early life and training. Freud was born on May 6, 1856, in Freiberg, Moravia (now Příbor, Czech.), then part of the Habsburg empire. His father, Jakob Freud, was a Jewish wool merchant who had been married once before he wed Freud's mother, Amalie Nathansohn. The father, 40 years old at Freud's birth, seems to have been a relatively remote and authoritarian figure, while his mother appears to have been more nurturant and emotionally available. Although Freud had two older half-brothers, his strongest if also most ambivalent attachment seems to have been to a nephew, John, one year his senior, who provided the model of intimate friend and hated rival that Freud reproduced often at later stages of his life.

The shaping influence of Vienna

In 1859 the Freud family was compelled for economic reasons to move to Leipzig and then a year after to Vienna, where Freud remained until the Nazi annexation of Austria 78 years later. Despite Freud's dislike of the imperial city, in part because of its citizens' frequent anti-Semitism, psychoanalysis reflected in significant ways the cultural and political context out of which it emerged. For example, Freud's sensitivity to the vulnerability of paternal authority within the psyche may well have been stimulated by the decline in power suffered by his father's generation, often liberal rationalists, in the Habsburg empire. So too his interest in the theme of the seduction of daughters was rooted in complicated ways in the context of Viennese attitudes toward female sexuality.

In 1873 Freud was graduated from the Sperl Gymnasium and, apparently inspired by a public reading of an essay by Goethe on nature, turned to medicine as a career. At the University of Vienna he worked with one of the leading physiologists of his day, Ernst von Brücke, an exponent of the materialist, antivitalist science of Hermann von Helmholtz. In 1882 he entered the General Hospital in Vienna as a clinical assistant to train with the psychiatrist Theodor Meynert and the professor of internal medicine Hermann Nothnagel. In 1885 Freud was appointed lecturer in neuropathology, having concluded important research on the brain's medulla. At this time he also developed an interest in the pharmaceutical benefits of cocaine, which he pursued for several years. Although some beneficial results were found in eye surgery, which have been credited to Freud's friend Carl Koller, the general outcome was disastrous. Not only did Freud's advocacy lead to a mortal addiction in another close friend, Ernst Fleischl von Marxow, but it also tarnished his medical reputation for a time. Whether or not one interprets this episode in terms that call into question Freud's prudence as a scientist, it was of a piece with his lifelong willingness to attempt bold solutions to relieve human suffering.

Freud's scientific training remained of cardinal importance in his work, or at least in his own conception of it. In such writings as his "Entwurf einer Psychologie" (written 1895, published 1950; "Project for a Scientific Psychology") he affirmed his intention to find a physiological and materialist basis for his theories of the psyche. Here a mechanistic neurophysiological model vied with a more organismic, phylogenetic one in ways that demonstrate Freud's complicated debt to the science of his day.

Jean-Martin Charcot

In late 1885 Freud left Vienna to continue his studies of neuropathology at the Salpêtrière clinic in Paris, where he worked under the guidance of Jean-Martin Charcot. His 19 weeks in the French capital proved a turning point in his career, for Charcot's work with patients classified as "hysterics" introduced Freud to the possibility that psychological disorders might have their source in the mind rather than the brain. Charcot's demonstration of a link between hysterical symptoms, such as paralysis of a limb, and hypnotic suggestion implied the power of mental states rather than nerves in the etiology of disease. Although Freud was soon to abandon his faith in hypnosis, he returned to Vienna in February 1886 with the seed of his revolutionary psychological method implanted.

Several months after his return Freud married Martha Bernays, the daughter of a prominent Jewish family whose ancestors included a chief rabbi of Hamburg and Heinrich Heine. She was to bear six children, one of whom, Anna Freud, was to become a distinguished psychoanalyst in her own right. Although the glowing picture of their marriage painted by Ernest Jones in his biography of Freud has been nuanced by later scholars, it is clear that Martha Bernays Freud was a deeply sustaining presence during her husband's tumultuous career.

Friendship with Wilhelm Fliess

Shortly after his marriage Freud began his closest friendship, with the Berlin physician Wilhelm Fliess, whose role in the development of psychoanalysis has occasioned widespread debate. Throughout the 15 years of their intimacy Fliess provided Freud an invaluable interlocutor for his most daring ideas. Freud's belief in human bisexuality, his idea of erotogenic zones on the body, and perhaps even his imputation of sexuality to infants may well have been stimulated by their friendship.

A somewhat less controversial influence arose from the partnership Freud began with the physician Josef Breuer after his return from Paris. Freud turned to a clinical practice in neuropsychology, and the office he established at Berggasse 19 was to remain his consulting room for almost half a century. Before their collaboration began, during the early 1880s, Breuer had treated a patient named Bertha Pappenheim—or "Anna O.," as she became known in the literature—who was suffering from a variety of hysterical symptoms. Rather than using hypnotic suggestion, as had Charcot, Breuer allowed her to lapse into a state resembling autohypnosis, in which she would talk about the initial manifestations of her symptoms. To Breuer's surprise, the very act of verbalization seemed to provide some relief from their hold over her (although later scholarship has cast doubt on its permanence). "The talking cure" or "chimney sweeping," as Breuer and Anna O., respectively, called it, seemed to act cathartically to produce an abreaction, or discharge, of the pent-up emotional blockage at the root of the pathological behaviour.

Technique of free association

Psychoanalytic theory. Freud, still beholden to Charcot's hypnotic method, did not grasp the full implications of Breuer's experience until a decade later, when he developed the technique of free association. In part an extrapolation of the automatic writing promoted by the German Jewish writer Ludwig Börne a century before, in part a result of his own clinical experience with other hysterics, this revolutionary method was announced in the work Freud published jointly with Breuer in 1895, *Studien über Hysterie* (*Studies in Hysteria*). By encouraging the patient to express any random thoughts that came associatively to mind, the technique aimed at uncovering hitherto unarticulated material from the realm of the psyche that Freud, following a long tradition, called the unconscious. Because of its incompatibility with conscious thoughts or conflicts with other unconscious ones, this material was normally hidden, forgotten, or unavailable to conscious reflection. Difficulty in freely associating—sudden silences, stuttering, or the like—suggested to Freud the importance of the material struggling to be expressed, as well as the power of what he called the patient's defenses against that expression. Such blockages Freud dubbed resistance, which had to be broken down in order to reveal hidden conflicts. Unlike Charcot and Breuer, Freud came to the conclusion, based on his clinical experience with female hysterics, that the most insistent source of resisted material was sexual in nature. And even more momentously, he linked the etiology of neurotic symptoms to the same struggle between a sexual feeling or urge and the psychic defenses against it. Being able to bring that conflict to consciousness through free association and then probing its implications was thus a crucial step, he reasoned, on the road to relieving the symptom, which was best understood as an unwitting compromise formation between the wish and the defense.

At first, however, Freud was uncertain about the precise status of the sexual component in this dynamic conception of the psyche. His patients seemed to recall actual experiences of early seductions, often incestuous in nature. Freud's initial impulse was to accept these as having happened. But then, as he disclosed in a now famous letter to Fliess of Sept. 2, 1897, he concluded that, rather than being memories of actual events, these shocking recollections were the residues of infantile impulses and desires to be seduced by an adult. What was recalled was not a genuine memory but what he would later call a screen memory, or fantasy, hiding a primitive wish. That is, rather than stressing the corrupting initiative of adults in the etiology of neuroses, Freud concluded that the fantasies and yearnings of the child were at the root of later conflict.

The absolute centrality of his change of heart in the subsequent development of psychoanalysis cannot be doubted. For in attributing sexuality to children, emphasizing the causal power of fantasies, and establishing the importance of repressed desires, Freud laid the groundwork for what many have called the epic journey into his own psyche, which followed soon after the dissolution of his partnership with Breuer.

Freud's work on hysteria had focused on female sexuality and its potential for neurotic expression. To be fully universal, psychoanalysis—a term Freud coined in 1896—would also have to examine the male psyche in a condition of what might be called normality. It would have to become more than a psychotherapy and develop into a complete theory of the mind. To this end Freud accepted the enormous risk of generalizing from the experience he knew best: his own. Significantly, his self-analysis was both the first and the last in the history of the movement he spawned; all future analysts would have to undergo a training analysis with someone whose own analysis was ultimately traceable to Freud's of his disciples.

Freud's self-exploration was apparently enabled by a disturbing event in his life. In October 1896, Jakob Freud died shortly before his 81st birthday. Emotions were released in his son that he understood as having been long repressed, emotions concerning his earliest familial experiences and feelings. Beginning in earnest in July 1897, Freud attempted to reveal their meaning by drawing on a technique that had been available for millennia: the deciphering of dreams. Freud's contribution to the tradition of dream analysis was path-breaking, for in insisting on them as "the royal road to a knowledge of the unconscious," he provided a remarkably elaborate account of why dreams originate and how they function.

The Interpretation of Dreams

In what many commentators consider his master work, *Die Traumdeutung* (published in 1899, but given the date of the dawning century to emphasize its epochal character; *The Interpretation of Dreams*), he presented his findings. Interspersing evidence from his own dreams with evidence from those recounted in his clinical practice, Freud contended that dreams played a fundamental role in the psychic economy. The mind's energy—which Freud called libido and identified principally, but not exclusively, with the sexual drive—was a fluid and malleable force capable of excessive and disturbing power. Needing to be discharged to ensure pleasure and prevent pain, it sought whatever outlet it might find. If denied the gratification provided by direct motor action, libidinal energy could seek its release through mental channels. Or, in the language of *The Interpretation of Dreams*, a wish can be satisfied by an imaginary wish fulfillment. All dreams, Freud claimed, even nightmares manifesting apparent anxiety, are the fulfillment of such wishes.

More precisely, dreams are the disguised expression of wish fulfillments. Like neurotic symptoms, they are the effects of compromises in the psyche between desires and prohibitions in conflict with their realization. Although sleep can relax the power of the mind's diurnal censorship of forbidden desires, such censorship, nonetheless, persists in part during nocturnal existence. Dreams, therefore, have to be decoded to be understood, and not merely because they are actually forbidden desires experienced in distorted fashion. For dreams undergo further revision in the process of being recounted to the analyst.

The Interpretation of Dreams provides a hermeneutic for the unmasking of the dream's disguise, or dreamwork, as Freud called it. The manifest content of the dream, that which is remembered and reported, must be understood as veiling a latent meaning. Dreams defy logical entailment and narrative coherence, for they intermingle the residues of immediate daily experience with the deepest, often most infantile wishes. Yet they can be ultimately decoded by attending to four basic activities of the dreamwork and reversing their mystifying effect.

The first of these activities, condensation, operates through the fusion of several different elements into one. As such, it exemplifies one of the key operations of psychic life, which Freud called overdetermination. No direct correspondence between a simple manifest content and its multidimensional latent counterpart can be assumed. The second activity of the dreamwork, displacement, refers to the decentring of dream thoughts, so that the most urgent wish is often obliquely or marginally represented on the manifest level. Displacement also means the associative substitution of one signifier in the dream for another, say, the king for one's father. The third activity Freud called representation, by which he meant the transformation of thoughts into images. Decoding a dream thus means translating such visual representations back into intersubjectively available language through free association. The final function of the dreamwork is secondary revision, which provides some order and intelligibility to the dream by supplementing its content with narrative coherence. The process of dream interpretation thus reverses the direction of the dreamwork, moving from the level of the conscious recounting of the dream through the preconscious back beyond censorship into the unconscious itself.

In 1904 Freud published *Zur Psychopathologie des All-*

tagslebens (*The Psychopathology of Everyday Life*), in which he explored such seemingly insignificant errors as slips of the tongue or pen (later colloquially called Freudian slips), misreadings, or forgetting of names. These errors Freud understood to have symptomatic and thus interpretable importance. But unlike dreams they need not betray a repressed infantile wish yet can arise from more immediate hostile, jealous, or egoistic causes.

In 1905 Freud extended the scope of this analysis by examining *Der Witz und seine Beziehung zum Unbewussten* (*Jokes and Their Relation to the Unconscious*). Invoking the idea of "joke-work" as a process comparable to dream-work, he also acknowledged the double-sided quality of jokes, at once consciously contrived and unconsciously revealing. Seemingly innocent phenomena like puns or jests are as open to interpretation as more obviously tendentious, obscene, or hostile jokes. The explosive response often produced by successful humour, Freud contended, owes its power to the orgasmic release of unconscious impulses, aggressive as well as sexual. But insofar as jokes are more deliberate than dreams or slips, they draw on the rational dimension of the psyche that Freud was to call the ego as much as on what he was to call the id.

Pioneering studies in sexology

In 1905 Freud also published the work that first thrust him into the limelight as the alleged champion of a pansexualist understanding of the mind: *Drei Abhandlungen zur Sexualtheorie* (*Three Contributions to the Sexual Theory,* later translated as *Three Essays on the Theory of Sexuality*), revised and expanded in subsequent editions. The work established Freud, along with Richard von Kraft-Ebing, Havelock Ellis, Albert Moll, and Iwan Bloch, as a pioneer in the serious study of sexology. Here he outlined in greater detail than before his reasons for emphasizing the sexual component in the development of both normal and pathological behaviour. Although not as reductionist as popularly assumed, Freud nonetheless extended the concept of sexuality beyond conventional usage to include a panoply of erotic impulses from the earliest childhood years on. Distinguishing between sexual aims (the act toward which instincts strive) and sexual objects (the person, organ, or physical entity eliciting attraction), he elaborated a repertoire of sexually generated behaviour of astonishing variety. Beginning very early in life, imperiously insistent on its gratification, remarkably plastic in its expression, and open to easy maldevelopment, sexuality, Freud concluded, is the prime mover in a great deal of human behaviour.

To spell out the formative development of the sexual drive, Freud focused on the progressive replacement of erotogenic zones in the body by others. An originally polymorphous sexuality first seeks gratification orally through sucking at the mother's breast, an object for which other surrogates can later be provided. Initially unable to distinguish between self and breast, the infant soon comes to appreciate its mother as the first external love object. Later Freud would contend that even before that moment, the child can treat its own body as such an object, going beyond undifferentiated autoeroticism to a narcissistic love for the self as such. After the oral phase, during the second year, the child's erotic focus shifts to its anus, stimulated by the struggle over toilet training. During the anal phase the child's pleasure in defecation is confronted with the demands of self-control. The third phase, lasting from about the fourth to the sixth year, he called the phallic. Because Freud relied on male sexuality as the norm of development, his analysis of this phase aroused considerable opposition, especially because he claimed its major concern is castration anxiety.

To grasp what Freud meant by this fear, it is necessary to understand one of his central contentions. As has been stated, the death of Freud's father was the trauma that permitted him to delve into his own psyche. Not only did Freud experience the expected grief, but he also expressed disappointment, resentment, and even hostility toward his father in the dreams he analyzed at the time. In the process of abandoning the seduction theory he recognized the source of the anger as his own psyche rather than anything objectively done by his father. Turning, as he often did, to evidence from literary and mythical texts as anticipations of his psychological insights, Freud interpreted that source in terms of Sophocles' tragedy *Oedipus Rex*. The universal applicability of its plot, he conjectured, lies in the desire of every male child to sleep with his mother and remove the obstacle to the realization of that wish, his father. What he later dubbed the Oedipus complex presents the child with a critical problem, for the unrealizable yearning at its root provokes an imagined response on the part of the father: the threat of castration.

Oedipus complex

The phallic stage can only be successfully surmounted if the Oedipus complex with its accompanying castration anxiety can be resolved. According to Freud, this resolution can occur if the boy finally suppresses his sexual desire for the mother, entering a period of so-called latency, and internalizes the reproachful prohibition of the father, making it his own with the construction of that part of the psyche Freud called the superego or the conscience.

The blatantly phallocentric bias of this account, which was supplemented by a highly controversial assumption of penis envy in the already castrated female child, proved troublesome for subsequent psychoanalytic theory. Not surprisingly, later analysts of female sexuality have paid more attention to the girl's relations with the pre-Oedipal mother than to the vicissitudes of the Oedipus complex. Anthropological challenges to the universality of the complex have also been damaging, although it has been possible to redescribe it in terms that lift it out of the specific familial dynamics of Freud's own day. If the creation of culture is understood as the institution of kinship structures based on exogamy, then the Oedipal drama reflects the deeper struggle between natural desire and cultural authority.

Freud, however, always maintained the intrapsychic importance of the Oedipus complex, whose successful resolution is the precondition for the transition through latency to the mature sexuality he called the genital phase. Here the parent of the opposite sex is conclusively abandoned in favour of a more suitable love object able to reciprocate reproductively useful passion. In the case of the girl, disappointment over the nonexistence of a penis is transcended by the rejection of her mother in favour of a father figure instead. In both cases, sexual maturity means heterosexual, procreatively inclined, genitally focused behaviour.

Sexual maladjustments

Sexual development, however, is prone to troubling maladjustments preventing this outcome if the various stages are unsuccessfully negotiated. Fixation of sexual aims or objects can occur at any particular moment, caused either by an actual trauma or the blockage of a powerful libidinal urge. If the fixation is allowed to express itself directly at a later age, the result is what was then generally called a perversion. If, however, some part of the psyche prohibits such overt expression, then, Freud contended, the repressed and censored impulse produces neurotic symptoms, neuroses being conceptualized as the negative of perversions. Neurotics repeat the desired act in repressed form, without conscious memory of its origin or the ability to confront and work it through in the present.

In addition to the neurosis of hysteria, with its conversion of affective conflicts into bodily symptoms, Freud developed complicated etiological explanations for other typical neurotic behaviour, such as obsessive-compulsions, paranoia, and narcissism. These he called psychoneuroses, because of their rootedness in childhood conflicts, as opposed to the actual neuroses such as hypochondria, neurasthenia, and anxiety neurosis, which are due to problems in the present (the last, for example, being caused by the physical suppression of sexual release).

Freud's elaboration of his therapeutic technique during these years focused on the implications of a specific element in the relationship between patient and analyst, an element whose power he first began to recognize in reflecting on Breuer's work with Anna O. Although later scholarship has cast doubt on its veracity, Freud's account of the episode was as follows. An intense rapport between Breuer and his patient had taken an alarming turn when Anna divulged her strong sexual desire for him. Breuer, who recognized the stirrings of reciprocal feelings, broke off his treatment out of an understandable confusion about the ethical implications of acting on these impulses.

Freud came to see in this troubling interaction the effects of a more pervasive phenomenon, which he called transference (or in the case of the analyst's desire for the patient, counter-transference). Produced by the projection of feelings, transference, he reasoned, is the reenactment of childhood urges cathected (invested) on a new object. As such, it is the essential tool in the analytic cure, for by bringing to the surface repressed emotions and allowing them to be examined in a clinical setting, transference can permit their being worked through in the present. That is, affective remembrance can be the antidote to neurotic repetition.

Transference

It was largely to facilitate transference that Freud developed his celebrated technique of having the patient lie on a couch, not looking directly at the analyst, and free to fantasize with as little intrusion of the analyst's real personality as possible. Restrained and neutral, the analyst functions as a screen for the displacement of early emotions, both erotic and aggressive. Transference onto the analyst is itself a kind of neurosis, but one in the service of an ultimate working through of the conflicting feelings it expresses. Only certain illnesses, however, are open to this treatment, for it demands the ability to redirect libidinal energy outward. The psychoses, Freud sadly concluded, are based on the redirection of libido back onto the patient's ego and cannot therefore be relieved by transference in the analytic situation. How successful psychoanalytic therapy has been in the treatment of psychoneuroses remains, however, a matter of considerable dispute.

Although Freud's theories were offensive to many in the Vienna of his day, they began to attract a cosmopolitan group of supporters in the early 1900s. In 1902 the Psychological Wednesday Circle began to gather in Freud's waiting room with a number of future luminaries in the psychoanalytic movements in attendance. Alfred Adler and Wilhelm Stekel were often joined by guests such as Sándor Ferenczi, Carl Gustav Jung, Otto Rank, Ernest Jones, Max Eitingon, and A.A. Brill. In 1908 the group was renamed the Vienna Psychoanalytic Society and held its first international congress in Salzburg. In the same year the first branch society was opened in Berlin. In 1909 Freud, along with Jung and Ferenczi, made a historic trip to Clark University in Worcester, Mass. The lectures he gave there were soon published as *Über Psychoanalyse* (1910; *The Origin and Development of Psychoanalysis*), the first of several introductions he wrote for a general audience. Along with a series of vivid case studies—the most famous known colloquially as "Dora" (1905), "Little Hans" (1909), "The Rat Man" (1909), "The Psychotic Dr. Schreber" (1911), and "The Wolf Man" (1918)—they made his ideas known to a wider public.

As might be expected of a movement whose treatment emphasized the power of transference and the ubiquity of Oedipal conflict, its early history is a tale rife with dissension, betrayal, apostasy, and excommunication. The most widely noted schisms occurred with Adler in 1911, Stekel in 1912, and Jung in 1913; these were followed by later breaks with Ferenczi, Rank, and Wilhelm Reich in the 1920s. Despite efforts by loyal disciples like Ernest Jones to exculpate Freud from blame, subsequent research concerning his relations with former disciples like Viktor Tausk have clouded the picture considerably. Critics of the hagiographic legend of Freud have, in fact, had a relatively easy time documenting the tension between Freud's aspirations to scientific objectivity and the extraordinarily fraught personal context in which his ideas were developed and disseminated. Even well after Freud's death, his archivists' insistence on limiting access to potentially embarrassing material in his papers has reinforced the impression that the psychoanalytic movement resembled more a sectarian church than a scientific community (at least as the latter is ideally understood).

If the troubled history of its institutionalization served to call psychoanalysis into question in certain quarters, so too did its founder's penchant for extrapolating his clinical findings into a more ambitious general theory. As he admitted to Fliess in 1900, "I am actually not a man of science at all. . . . I am nothing but a conquistador by temperament, an adventurer." Freud's so-called metapsychology soon became the basis for wide-ranging speculations about cultural, social, artistic, religious, and anthropological phenomena. Composed of a complicated and often revised mixture of economic, dynamic, and topographical elements, the metapsychology was developed in a series of 12 papers Freud composed during World War I, only some of which were published in his lifetime. Their general findings appeared in two books in the 1920s: *Jenseits des Lustprinzips* (1920; *Beyond the Pleasure Principle*) and *Das Ich und das Es* (1923; *The Ego and the Id*).

In these works, Freud attempted to clarify the relationship between his earlier topographical division of the psyche into the unconscious, preconscious, and conscious and his subsequent structural categorization into id, ego, and superego. The id was defined in terms of the most primitive urges for gratification in the infant, urges dominated by the desire for pleasure through the release of tension and the cathexis of energy. Ruled by no laws of logic, indifferent to the demands of expediency, unconstrained by the resistance of external reality, the id is ruled by what Freud called the primary process directly expressing somatically generated instincts. Through the inevitable experience of frustration the infant learns to adapt itself to the exigencies of reality. The secondary process that results leads to the growth of the ego, which follows what Freud called the reality principle in contradistinction to the pleasure principle dominating the id. Here the need to delay gratification in the service of self-preservation is slowly learned in an effort to thwart the anxiety produced by unfulfilled desires. What Freud termed defense mechanisms are developed by the ego to deal with such conflicts. Repression is the most fundamental, but Freud also posited an entire repertoire of others, including reaction formation, isolation, undoing, denial, displacement, and rationalization.

Id, ego, superego

The last component in Freud's trichotomy, the superego, develops from the internalization of society's moral commands through identification with parental dictates during the resolution of the Oedipus complex. Only partly conscious, the superego gains some of its punishing force by borrowing certain aggressive elements in the id, which are turned inward against the ego and produce feelings of guilt. But it is largely through the internalization of social norms that the superego is constituted, an acknowledgement that prevents psychoanalysis from conceptualizing the psyche in purely biologistic or individualistic terms.

Freud's understanding of the primary process underwent a crucial shift in the course of his career. Initially he counterposed a libidinal drive that seeks sexual pleasure to a self-preservation drive whose telos is survival. But in 1914, while examining the phenomenon of narcissism, he came to consider the latter instinct as merely a variant of the former. Unable to accept so monistic a drive theory, Freud sought a new dualistic alternative. He arrived at the speculative assertion that there exists in the psyche an innate, regressive drive for stasis that aims to end life's inevitable tension. This striving for rest he christened the Nirvana principle and the drive underlying it the death instinct, or Thanatos, which he could substitute for self-preservation as the contrary of the life instinct, or Eros.

Social and cultural studies. Freud's mature instinct theory is in many ways a metaphysical construct, comparable to Bergson's *élan vital* or Schopenhauer's Will. Emboldened by its formulation, Freud launched a series of audacious studies that took him well beyond his clinician's consulting room. These he had already commenced with investigations of Leonardo da Vinci (1910) and the novel *Gradiva* by Wilhelm Jensen (1907). Here Freud attempted to psychoanalyze works of art as symbolic expressions of their creator's psychodynamics.

The fundamental premise that permitted Freud to examine cultural phenomena was called sublimation in the *Three Essays*. The appreciation or creation of ideal beauty, Freud contended, is rooted in primitive sexual urges that are transfigured in culturally elevating ways. Unlike repression, which produces only neurotic symptoms whose meaning is unknown even to the sufferer, sublimation is a conflict-free resolution of repression, which leads to intersubjectively available cultural works. Although potentially reductive in its implications, the psychoanalytic

Sublimation and culture

interpretation of culture can be justly called one of the most powerful "hermeneutics of suspicion," to borrow the French philosopher Paul Ricoeur's phrase, because it debunks idealist notions of high culture as the alleged transcendence of baser concerns.

Freud extended the scope of his theories to include anthropological and social psychological speculation as well in *Totem und Tabu* (1913; *Totem and Taboo*). Drawing on Sir James Frazer's explorations of the Australian Aborigines, he interpreted the mixture of fear and reverence for the totemic animal in terms of the child's attitude toward the parent of the same sex. The Aborigines' insistence on exogamy was a complicated defense against the strong incestuous desires felt by the child for the parent of the opposite sex. Their religion was thus a phylogenetic anticipation of the ontogenetic Oedipal drama played out in modern man's psychic development. But whereas the latter was purely an intrapsychic phenomenon based on fantasies and fears, the former, Freud boldly suggested, was based on actual historical events. Freud speculated that the rebellion of sons against dominating fathers for control over women had culminated in actual parricide. Ultimately producing remorse, this violent act led to atonement through incest taboos and the prohibitions against harming the father-substitute, the totemic object or animal. When the fraternal clan replaced the patriarchal horde, true society emerged. For renunciation of individual aspirations to replace the slain father and a shared sense of guilt in the primal crime led to a contractual agreement to end internecine struggle and band together instead. The totemic ancestor then could evolve into the more impersonal God of the great religions.

A subsequent effort to explain social solidarity, *Massenpsychologie und Ich-analyse* (1921; *Group Psychology and the Analysis of the Ego*), drew on the antidemocratic crowd psychologists of the late 19th century, most notably Gustave Le Bon. Here the disillusionment with liberal, rational politics that some have seen as the seedbed of much of Freud's work was at its most explicit (the only competitor being the debunking psychobiography of Woodrow Wilson he wrote jointly with William Bullitt in 1930, which was not published until 1967). All mass phenomena, Freud suggested, are characterized by intensely regressive emotional ties stripping individuals of their self-control and independence. Rejecting possible alternative explanations such as hypnotic suggestion or imitation and unwilling to follow Jung in postulating a group mind, Freud emphasized instead individual libidinal ties to the group's leader. Group formation is like regression to a primal horde with the leader as the original father. Drawing on the army and the Roman Catholic Church as his examples, Freud never seriously considered less authoritarian modes of collective behaviour.

Freud's bleak appraisal of social and political solidarity was replicated, if in somewhat more nuanced form, in his attitude toward religion. Although many accounts of Freud's development have discerned debts to one or another aspect of his Jewish background, debts Freud himself partly acknowledged, his avowed position was deeply irreligious. As noted in the account of *Totem and Taboo,* he always attributed the belief in divinities ultimately to the displaced worship of human ancestors. One of the most potent sources of his break with former disciples like Jung was precisely this skepticism toward spirituality.

Skepticism toward religious beliefs

In his 1907 essay "Zwangshandlungen und Religionsübungen" ("Obsessive Acts and Religious Practices," later translated as "Obsessive Actions and Religious Practices") Freud had already contended that obsessional neuroses are private religious systems and religions themselves no more than the obsessional neuroses of mankind. Twenty years later, in *Die Zukunft einer Illusion* (1927; *The Future of an Illusion*), he elaborated this argument, adding that belief in God is a mythic reproduction of the universal state of infantile helplessness. Like an idealized father, God is the projection of childish wishes for an omnipotent protector. If children can outgrow their dependence, he concluded with cautious optimism, then humanity may also hope to leave behind its immature heteronomy.

The simple Enlightenment faith underlying this analysis quickly elicited critical comment, which led to its modification. In an exchange of letters with the French novelist Romain Rolland, Freud came to acknowledge a more intractable source of religious sentiment. The opening section of his next speculative tract, *Das Unbehagen in der Kultur* (1930; *Civilization and Its Discontents*), was devoted to what Rolland had dubbed the oceanic feeling. Freud described it as a sense of indissoluble oneness with the universe, which mystics in particular have celebrated as the fundamental religious experience. Its origin, Freud claimed, is nostalgia for the pre-Oedipal infant's sense of unity with its mother. Although still rooted in infantile helplessness, religion thus derives to some extent from the earliest stage of postnatal development. Regressive longings for its restoration are possibly stronger than those for a powerful father and thus cannot be worked through by way of a collective resolution of the Oedipus complex.

Civilization and Its Discontents

Civilization and Its Discontents, written after the onset of Freud's struggle with cancer of the jaw and in the midst of the rise of European Fascism, was a profoundly unconsoling book. Focusing on the prevalence of human guilt and the impossibility of achieving unalloyed happiness, Freud contended that no social solution of the discontents of mankind is possible. All civilizations, no matter how well planned, can provide only partial relief. For aggression among men is not due to unequal property relations or political injustice, which can be rectified by laws, but rather to the death instinct redirected outward.

Even Eros, Freud suggested, is not fully in harmony with civilization, for the libidinal ties creating collective solidarity are aim-inhibited and diffuse rather than directly sexual. Thus, there is likely to be tension between the urge for sexual gratification and the sublimated love for mankind. Furthermore, because Eros and Thanatos are themselves at odds, conflict and the guilt it engenders are virtually inevitable. The best to be hoped for is a life in which the repressive burdens of civilization are in rough balance with the realization of instinctual gratification and the sublimated love for mankind. But reconciliation of nature and culture is impossible, for the price of any civilization is the guilt produced by the necessary thwarting of man's instinctual drives. Although elsewhere Freud had postulated mature, heterosexual genitality and the capacity to work productively as the hallmarks of health and urged that "where id is, there shall ego be," it is clear that he held out no hope for any collective relief from the discontents of civilization. He only offered an ethic of resigned authenticity, which taught the wisdom of living without the possibility of redemption, either religious or secular.

Freud's final major work, *Der Mann Moses und die monotheistische Religion* (1938; *Moses and Monotheism*), was more than just the "historical novel" he had initially thought to subtitle it. Moses had long been a figure of capital importance for Freud; indeed Michelangelo's famous statue of Moses had been the subject of an essay written in 1914. The book itself sought to solve the mystery of Moses' origins by claiming that he was actually an aristocratic Egyptian by birth who had chosen the Jewish people to keep alive an earlier monotheistic religion. Too stern and demanding a taskmaster, Moses was slain in a Jewish revolt, and a second, more pliant leader, also called Moses, rose in his place. The guilt engendered by the parricidal act was, however, too much to endure, and the Jews ultimately returned to the religion given them by the original Moses as the two figures were merged into one in their memories. Here Freud's ambivalence about his religious roots and his father's authority was allowed to pervade a highly fanciful story that reveals more about its author than its ostensible subject.

Moses and Monotheism

Moses and Monotheism was published in the year Hitler invaded Austria. Freud was forced to flee to England. His books were among the first to be burned, as the fruits of a "Jewish science," when the Nazis took over Germany. Although psychotherapy was not banned in the Third Reich, where Field Marshall Hermann Göring's cousin headed an official institute, psychoanalysis essentially went into exile, most notably to North America and England. Freud himself died only a few weeks after World War II broke out, on Sept. 23, 1939, at a time when his worst fears about the irrationality lurking behind the facade of civilization were being realized. Freud's death did not, however, hinder the reception and dissemination of his ideas. A plethora of Freudian schools emerged to develop psychoanalysis in different directions. In fact, despite the relentless and often compelling challenges mounted against virtually all of his ideas, Freud has remained one of the most potent figures in the intellectual landscape of the 20th century.

(M.E.J.)

MAJOR WORKS. Several of these works appeared originally as journal articles; only the publication in book form is cited here. *Studien über Hysterie*, with Josef Breuer (1895; *Studies in Hysteria*, 1936); *Die Traumdeutung* (1899, dated 1900; *The Interpretation of Dreams*, 1913); *Zur Psychopathologie des Alltagslebens* (1904; *Psychopathology of Everyday Life*, 1914); *Drei Abhandlungen zur Sexualtheorie* (1905; *Three Contributions to the Sexual Theory*, 1910); *Über Psychoanalyse* (1910; *The Origin and Development of Psychoanalysis*, 1949); *Totem und Tabu: einige Übereinstimmungen im Seelenleben der Wilden und der Neurotiker* (1913; *Totem and Taboo: Resemblances Between the Psychic Lives of Savages and Neurotics*, 1918); *Zur Geschichte der psychoanalytischen Bewegung* (1924; *The History of the Psychoanalytic Movement*, 1917); *Vorlesungen zur Einführung in die Psychoanalyse* (1916–17; *A General Introduction to Psychoanalysis*, 1920); *Jenseits des Lustprinzips* (1920; *Beyond the Pleasure Principle*, 1922); *Das Ich und das Es* (1923; *The Ego and the Id*, 1927); *Hemmung, Symptom und Angst* (1926; *Inhibition, Symptoms and Anxiety*, 1927); *Die Frage der Laienanalyse* (1926; *The Problem of Lay-Analyses*, 1927); *Die Zukunft einer Illusion* (1927; *The Future of an Illusion*, 1928); *Das Unbehagen in der Kultur* (1930; *Civilization and Its Discontents*, 1930); *Neue Folge der Vorlesungen zur Einführung in die Psychoanalyse* (1933; *New Introductory Lectures on Psycho-Analysis*, 1933); *Der Mann Moses und die monotheistische Religion* (1939; *Moses and Monotheism*, 1939).

The standard German edition of Freud's works is *Gesammelte Werke: Chronologisch geordnet*, 18 vol. in 17 (1940–68). The English edition, with better annotations than the original, is *The Standard Edition of the Complete Psychological Works of Sigmund Freud*. trans. and ed. by JAMES STRACHEY, *et al.*, 24 vol. (1953–74, reprinted 1981); it is complemented by SAMUEL A. GUTTMAN, STEPHEN M. PARRISH, and RANDALL L. JONES (eds.), *The Concordance to The Standard Edition of the Complete Psychological Works of Sigmund Freud*, 6 vol., 2nd ed. (1984). Also helpful is ALEXANDER GRINSTEIN (comp.), *Sigmund Freud's Writings: A Comprehensive Bibliography* (1977), including listings of works not found in *The Standard Edition* and an index of English titles of Freud's works.

BIBLIOGRAPHY. Among biographical works are SIGMUND FREUD, *An Autobiographical Study*, 2nd ed. (1946, reissued 1963; originally published in German, 1925), his own brief account of his career and theories; ERNEST JONES, *The Life and Work of Sigmund Freud*, 3 vol. (1953–57, reissued 1981; also published as *Sigmund Freud: Life and Work*, 1953–57), also available in a one-volume condensed edition with the same title, edited and abridged by LIONEL TRILLING and STEVEN MARCUS (1961, reissued 1964); RICHARD WOLLHEIM, *Sigmund Freud* (1971, reissued 1981); PHILIP RIEFF, *Freud: The Mind of a Moralist*, 3rd ed. (1979); RONALD W. CLARK, *Freud. The Man and the Cause* (1980); and PETER GAY, *Freud: A Life for Our Time* (1980).

Selections from Freud's original writings and correspondence include JEFFREY MOUSSAIEFF MASSON (trans. and ed.), *The Complete Letters of Sigmund Freud to Wilhelm Fliess, 1877–1904* (1985); ERNST L. FREUD (ed.), *Letters of Sigmund Freud, 1873–1939* (1961, reprinted 1975; originally published in German, 1960); HILDA C. ABRAHAM and ERNST L. FREUD (eds.), *A Psycho-Analytic Dialogue: The Letters of Sigmund Freud and Karl Abraham, 1907–1926* (1965; originally published in German, 1965); ERNST L. FREUD (ed.), *The Letters of Sigmund Freud and Arnold Zweig* (1970, reprinted 1987; originally published in German, 1968); NATHAN G. HALE, JR. (ed.), *James Jackson Putnam and Psychoanalysis: Letters Between Putnam and Sigmund Freud, Ernest Jones, William James, Sandor Ferenczi, and Morton Prince, 1877–1917* (1971); ERNST PFEIFFER (ed.), *Sigmund Freud and Lou Andreas-Salomé: Letters* (1972, reissued 1985; originally published in German, 1966); WILLIAM MCGUIRE (ed.), *The Freud/Jung Letters*, trans. from German (1974, reprinted 1979); R. ANDREWS PASKAUSKAS (ed.), *The Complete Correspondence of Sigmund Freud and Ernest Jones, 1908–1939* (1993); and EVA BRABANT, ERNST FALZADER, and PATRIZIA GIAMPIERI-DEUTSCH (eds.), *The Correspondence of Sigmund Freud and Sándor Ferenczi* (1993–   ).

Views by Freud's family, friends, and colleagues include FRITZ WITTELS, *Sigmund Freud: His Personality, His Teaching, & His School* (1924, reprinted 1971; originally published in German, 1924); THEODOR REIK, *From Thirty Years with Freud*, trans. from German (1940, reissued 1975); HANNS SACHS, *Freud* (1944, reissued 1970); MARTIN FREUD, *Glory Reflected: Sigmund Freud, Man and Father* (1957; also published as *Sigmund Freud: Man and Father*, 1928, reissued 1983), by one of his children; ERICH FROMM, *Sigmund Freud's Mission: An Analysis of His Personality and Influence* (1959, reprinted 1978); MARY HIGGINS and CHESTER M. RAPHAEL (eds.), *Reich Speaks of Freud: Wilhelm Reich Discusses His Work and His Relationship with Sigmund Freud* (1967, reissued 1975); MAX SCHUR, *Freud* (1972); and ALDO CAROTENUTO, *A Secret Symmetry: Sabina Spielrein Between Jung and Freud* (1982; originally published in Italian, 1980).

Contemporaries and associates are described in VINCENT BROME, *Freud and His Early Circle: The Struggles of Psycho-Analysis* (1967); and PAUL ROAZEN, *Freud and His Followers* (1975, reissued 1984), and *Brother Animal: The Story of Freud and Tausk* (1969, reprinted 1986). Also of interest is K.R. EISSLER, *Talent and Genius: The Fictitious Case of Tausk Contra Freud* (1971).

Histories of psychoanalysis and psychoanalytic theory are offered in MARIE JAHODA, *Freud and the Dilemmas of Psychology* (1977, reissued 1981); SEYMOUR FISHER and ROGER P. GREENBERG, *The Scientific Credibility of Freud's Theories and Therapy* (1977, reprinted 1985), and *The Scientific Evaluation of Freud's Theories and Therapy: A Book of Readings* (1977); FRANK J. SULLOWAY, *Freud, Biologist of the Mind* (1979, reprinted 1983); ALEXANDER GRINSTEIN, *Sigmund Freud's Dreams*, 2nd ed. (1980); BRUNO BETTELHEIM, *Freud and Man's Soul* (1983); MARSHALL EDELSON, *Hypothesis and Evidence in Psychoanalysis* (1984); and WILLIAM J. MCGRATH, *Freud's Discovery of Psychoanalysis: The Politics of Hysteria* (1986).

Interpretive studies of Freud's work and views include HERBERT MARCUSE, *Eros and Civilisation: A Philosophical Inquiry into Freud* (1955, reissued 1974); J.A.C. BROWN, *Freud and the Post-Freudians* (1961, reprinted 1985); PHILIP RIEFF, *The Triumph of the Therapeutic: Uses of Faith After Freud* (1966, reissued 1987); PAUL ROAZEN, *Freud: Political and Social Thought* (1968, reissued 1986); PAUL RICOEUR, *Freud and Philosophy* (1970, originally published in French, 1961); and JULIET MITCHELL, *Psychoanalysis and Feminism* (1974).

Recent critiques of Freudian theory include ERICH FROMM, *Greatness and Limitations of Freud's Thought* (1980); JANET MALCOLM, *In the Freud Archives* (1984); JEFFREY MOUSSAIEFF MASSON, *The Assault on Truth: Freud's Suppression of the Seduction Theory* (1984, reissued 1994; also published as *Freud: The Assault on Truth*, 1984); ADOLF GRÜNBAUM, *The Foundations of Psychoanalysis* (1984); and ROBERT R. HOLT, *Freud Reappraised: A Fresh Look at Psychoanalytic Theory* (1989). PAUL ROBINSON, *Freud and His Critics* (1993), is a defense against several critics.

Freud's major case studies are reappraised in KARIN OBHOLZER, *The Wolf-Man: Conversations with Freud's Patient—Sixty Years Later* (1982; originally published in German, 1980); PATRICK J. MAHONY, *Freud and the Rat Man* (1986); FRANK J. SULLOWAY, "Reassessing Freud's Case Histories: The Social Construction of Psychoanalysis," *Isis*, 82:245–275 (1991, reprinted in TOBY GELFAND and JOHN KERR [eds.], *Freud and the History of Psychoanalysis*, 1992); HANNAH S. DECKER, *Freud, Dora, and Vienna 1900* (1991); and ROGIN TOLMACH LAKOFF and JAMES C. COYNE, *Father Knows Best: The Use and Abuse of Power in Freud's Case of Dora* (1993). (M.E.J./Ed.)

Fossil Fuels

Fossil fuels are combustible materials of organic origin, including oil, bitumen, natural gas, and coal. Such materials were formed by geochemical processes from the remains of organisms that were buried in the geologic past. Since the late 18th century, these mineral fuels have become the primary sources of energy for the industrial nations of the world. Together, the fossil fuels supply almost 90 percent of all the energy consumed today.

Recent scientific assessments place the world's total original endowment of recoverable conventional (*i.e.*, light and medium) oil at approximately 2,390,000,000,000 barrels. Thirty percent of this oil, however, has already been consumed, and only 23 percent is estimated as still undiscovered. Seventy-eight percent of the unconsumed conventional oil is thought to be located in the Eastern Hemisphere.

The world's total original endowment of recoverable natural gas has been assessed as the energy equivalent of about 2,576,000,000,000 barrels of oil. This includes an estimated 463,000,000,000 barrels of natural gas liquids (propane, butane, and natural gasoline), a figure based on average gas liquids production. Approximately 55 percent of the world's natural gas is thought to have been already discovered and about 14 percent consumed. Of the remaining existing gas, 84 percent is estimated to be located in the Eastern Hemisphere.

Major deposits of heavy oils are known to lie in the Western Hemisphere. The world's original endowment of recoverable heavy oil is believed to have been roughly 467,500,000,000 barrels, approximately 80 percent of which has been discovered and only about 14 percent of which has been consumed. Fifty-two percent of the unconsumed heavy oil is located in the Western Hemisphere.

Known bitumen deposits have been projected to contain about 354,000,000,000 barrels of recoverable crude oil. Seventy-six percent of the bitumen resource is in the Western Hemisphere. Known oil shale deposits have been estimated to contain about 1,067,000,000,000 barrels of recoverable shale oil. Eighty-eight percent of this resource is in the Western Hemisphere.

In summary, the world's total original endowment of recoverable petroleum, including natural gas, is assessed as equaling about 6,853,000,000,000 barrels of oil. The lighter, more desirable petroleum fuels occur primarily in the Eastern Hemisphere, while most of the heavier, less desirable varieties are found in the Western Hemisphere. The heavier fuels have not been exploited as extensively as the lighter fuels, because they are much more costly and difficult to extract and must be produced at considerably slower rates. Consequently, they remain available for development as the lighter fuels become depleted. Their cost, however, will be high and will be reflected in the world economy.

As for the other major fossil fuel, coal, scientific studies place the world's original endowment of minable coal deposits at more than 7,600,000,000,000 metric tons (approximately 6,900,000,000,000 short tons). Of this total, only about 2.5 percent has so far been exploited; therefore, coal reserves are projected to last from a few hundred to more than 1,000 years, depending on the assumed rate of consumption and technological developments. Almost 60 percent of the world's remaining recoverable coal is held by only three countries—the United States, Russia, and China.

This article describes the properties and origin of the fossil fuels and treats their occurrence, exploitation, and world distribution. For coverage of related topics in the *Macropædia* and *Micropædia*, see the *Propædia*, section 214, and the *Index*. For specific information about the methods of fossil fuel extraction and production, see the *Macropædia* article INDUSTRIES, EXTRACTION AND PROCESSING. (J.P.Ri./Ed.)

The article is divided into the following sections:

Oil

Liquid and gaseous hydrocarbons are so intimately associated in nature that it has become customary to shorten the expression "petroleum and natural gas" to "petroleum" when referring to both. The word petroleum (literally "rock oil" from the Latin *petra*, "rock" or "stone," and *oleum*, "oil") was first used in 1556 in a treatise published by the German mineralogist Georg Bauer, known as Georgius Agricola.

HISTORY OF USE

Exploitation of surface seeps. Small surface occurrences of petroleum in the form of natural gas and oil seeps have been known from early times. The ancient Sumerians, Assyrians, and Babylonians used crude oil and asphalt ("pitch") collected from large seeps at Tuttul (modern-day Hit) on the Euphrates for many purposes more than 5,000 years ago. Liquid oil was first used as a medicine by the ancient Egyptians, presumably as a wound dressing, liniment, and laxative.

Oil products were valued as weapons of war in the ancient world. The Persians used incendiary arrows wrapped in oil-soaked fibres at the siege of Athens in 480 BC. Early in the Christian era the Arabs and Persians distilled crude oil to obtain flammable products for military purposes. Probably as a result of the Arab invasion of Spain, the industrial art of distillation into illuminants became available in western Europe by the 12th century.

Early distillation

Several centuries later, Spanish explorers discovered oil seeps in present-day Cuba, Mexico, Bolivia, and Peru. In North America oil seeps were plentiful and were noted by early explorers in what are now New York and Pennsylvania, where the Indians were reported to have used the oil for medicinal purposes.

Extraction from underground reservoirs. Until the beginning of the 19th century, illumination in the United States and in many other countries was little improved over that known by the early Greeks and Romans. The need for better illumination that accompanied the increasing development of urban centres made it necessary to search for new sources of oil, especially since whales, which had long provided fuel for lamps, were becoming harder and harder to find. By the mid-19th century kerosene, or coal oil, derived from coal was in common use in both North America and Europe.

The Industrial Revolution brought on an ever-growing demand for a cheaper and more convenient source of lubricants as well as illuminating oil. It also required better sources of energy. Energy had previously been provided by human and animal muscle and later by the combustion of such solid fuels as wood, peat, and coal. These were collected with considerable effort and laboriously transported to the site where the energy source was needed. Liquid petroleum, on the other hand, was a more easily transportable source of energy. Oil was a much more concentrated and flexible form of fuel than anything previously available.

The stage was set for the first well specifically drilled for oil, a project undertaken by Edwin L. Drake in northwestern Pennsylvania. The completion of the well in August 1859 established the groundwork for the petroleum industry and ushered in the closely associated modern industrial age. Within a short time inexpensive oil from underground reservoirs was being processed at already existing coal-oil refineries, and by the end of the century oil fields had been discovered in 14 states from New York to California and from Wyoming to Texas. During the same period, oil fields were found in Europe and East Asia as well.

Significance of oil in modern times. At the beginning of the 20th century the Industrial Revolution had progressed to the extent that the use of refined oil for illuminants ceased to be of primary importance. The oil industry became the major supplier of energy largely because of the advent of the automobile. Although oil constitutes a major petrochemical feedstock, its primary importance is as an energy source on which the world economy depends.

The significance of oil as a world energy source is difficult to overdramatize. The growth in energy production during the 20th century is unprecedented, and increasing oil production has been by far the major contributor to that growth. Every day an immense and intricate system moves more than 60,000,000 barrels of oil from producers to consumers. The production and consumption of oil is of vital importance to international relations and has frequently been a decisive factor in the determination of foreign policy. The position of a country in this system depends on its production capacity as related to its consumption. The possession of oil deposits is sometimes the determining factor between a rich and a poor country. For any country, however, the presence or absence of oil has a major economic consequence.

Current daily consumption

On a time scale within the span of prospective human history, the utilization of oil as a major source of energy will be a transitory affair of about 100 years. Nonetheless, it will have been an affair of profound importance to world industrialization.

PROPERTIES

Chemical composition. *Hydrocarbon content.* Although oil consists basically of compounds of only two elements, carbon and hydrogen, these elements form a large variety of complex molecular structures. Regardless of physical or chemical variations, however, almost all crude oil ranges from 82 to 87 percent carbon by weight and 12 to 15 percent hydrogen. The more viscous bitumens generally vary from 80 to 85 percent carbon and from 8 to 11 percent hydrogen.

Crude oil can be grouped into three basic chemical series: paraffins, naphthenes, and aromatics. Most crude oils are mixtures of these three series in various and seemingly endless proportions. No two crude oils from different sources are completely identical.

The paraffin series of hydrocarbons, also called the methane (CH_4) series, comprises the most common hydrocarbons in crude oil. It is a saturated straight-chain series that has the general formula C_nH_{2n+2}, in which C is carbon, H is hydrogen, and n is an integer. The paraffins that are liquid at normal temperatures but boil between 40° and 200° C (approximately between 100° and 400° F) are the major constituents of gasoline. The residues obtained by refining lower-density paraffins are both plastic and solid paraffin waxes.

The naphthene series has the general formula C_nH_{2n} and is a saturated closed-ring series. This series is an important part of all liquid refinery products, but it also forms most of the complex residues from the higher boiling-point ranges. For this reason, the series is generally heavier. The residue of the refinery process is an asphalt, and the crude oils in which this series predominates are called asphalt-base crudes.

The aromatic series has the general formula C_nH_{2n-6} and is an unsaturated closed-ring series. Its most common member, benzene (C_6H_6), is present in all crude oils, but the aromatics as a series generally constitute only a small percentage of most crudes.

Nonhydrocarbon content. In addition to the practically infinite mixtures of hydrocarbon compounds that form crude oil, sulfur, nitrogen, and oxygen are usually present in small but often important quantities. Sulfur is the third most abundant atomic constituent of crude oils. It is present in the medium and heavy fractions of crude oils. In the low and medium molecular ranges, sulfur is associated only with carbon and hydrogen, while in the heavier fractions it is frequently incorporated in the large polycyclic molecules that also contain nitrogen and oxygen. The total sulfur in crude oil varies from below 0.05 percent (by weight), as in some Pennsylvania oils, to about 2 percent for average Middle Eastern crudes and up to 5 percent or more in heavy Mexican or Mississippi oils. Generally, the higher the specific gravity of the crude oil, the greater is its sulfur content. The excess sulfur is removed from crude oil during refining, because sulfur oxides released into the atmosphere during the combustion of oil would constitute a major pollutant.

Sulfur content

The oxygen content of crude oil is usually less than 2 percent by weight and is present as part of the heavier hydrocarbon compounds in most cases. For this reason, the heavier oils contain the most oxygen. Nitrogen is present in almost all crude oils, usually in quantities of less than 0.1 percent by weight. Sodium chloride also occurs in most crudes and is usually removed like sulfur.

Many metallic elements are found in crude oils, including most of those that occur in seawater. This is probably due to the close association between seawater and the organic forms from which oil is generated. Among the most common metallic elements in oil are vanadium and nickel, which apparently occur in organic combinations as they do in living plants and animals.

Crude oil also may contain a small amount of decay-resistant organic remains, such as siliceous skeletal fragments, wood, spores, resins, coal, and various other remnants of former life.

Physical properties. Oil consists of a closely related series of complex hydrocarbon compounds that range from gasoline to heavy solids. The various mixtures that constitute crude oil can be separated by distillation under increasing temperatures into such components as (from light to heavy) gasoline, kerosene, gas oil, lubricating oil, residual fuel oil, bitumen, and paraffin.

Crude oils vary greatly in their chemical composition. Because they consist of mixtures of thousands of hydrocarbon compounds, their physical properties such as colour, specific gravity, and viscosity also vary widely.

Specific gravity. Crude oil is immiscible with and lighter than water; hence it floats. Crude oils are generally classified as tar sands, heavy oils, and medium and light oils on the basis of specific gravity (*i.e.,* the ratio of the weight of equal volumes of the oil and pure water at standard conditions, with pure water considered to equal 1) and relative mobility. Tar sands contain immobile oil, which does not flow into a well bore (see below). Heavy crude oils have enough mobility that, given time, they can be obtained through a well bore in response to enhanced recovery methods. The more mobile medium and light oils are recoverable through production wells.

The API gravity scale

The widely used American Petroleum Institute (API) gravity scale is based on pure water, with an arbitrarily assigned API gravity of 10°. Liquids lighter than water, such as oil, have API gravities numerically greater than 10. Crude oils below 20° API gravity are usually considered heavy, whereas the conventional crudes with API gravities between 20° and 25° are regarded as medium, with light oils ranging above 25°.

Boiling and freezing points. Because oil is always at a temperature above the boiling point of some of its compounds, the more volatile constituents constantly escape into the atmosphere unless confined. It is impossible to refer to a common boiling point for crude oil because of the widely differing boiling points of its numerous compounds, some of which may boil at temperatures too high to be measured.

By the same token, it is impossible to refer to a common freezing point for a crude oil because the individual compounds solidify at different temperatures. However, the pour point—the temperature below which crude oil becomes plastic and will not flow—is important to recovery and transport and is always determined. Pour points range from 32° C to below −57° C.

Measurement systems. In the United States, crude oil is measured in barrels of 42 gallons each; the weight per barrel of API 30° light oil would be about 306 pounds. In many other countries, crude oil is measured in metric tons. For oil having the same gravity, a metric ton is equal to approximately 252 imperial gallons or about 7.2 U.S. barrels.

ORIGIN

Formation process. *From planktonic remains to kerogen.* Although it is recognized that the original source of carbon and hydrogen was in the materials that made up the primordial Earth, it is generally accepted that these two elements have had to pass through an organic phase to be combined into the varied complex molecules recognized as crude oil. The organic material that is the source of most oil has probably been derived from single-celled planktonic (free-floating) plants, such as diatoms and blue-green algae, and single-celled planktonic animals, such as foraminifera, which live in aquatic environments of marine, brackish, or fresh water. Such simple organisms are known to have been abundant long before the Paleozoic Era, which began some 540,000,000 years ago.

Rapid burial of the remains of the single-celled planktonic plants and animals within fine-grained sediments effectively preserved them. This provided the organic materials, the so-called protopetroleum, for later diagenesis (*i.e.,* the series of processes involving biological, chemical, and physical changes) into true petroleum.

The first, or immature, stage of petroleum formation is dominated by biological activity and chemical rearrangement, which convert organic matter to kerogen. This dark-coloured, insoluble product of bacterially altered plant and animal detritus is the source of most hydrocarbons generated in the later stages. During the first stage, biogenic methane is the only hydrocarbon generated in commercial quantities. The production of biogenic methane gas is part of the process of decomposition of organic matter carried out by anaerobic microorganisms (those capable of living in the absence of free oxygen).

From kerogen to petroleum. Deeper burial by continuing sedimentation, increasing temperatures, and advancing geologic age result in the mature stage of petroleum formation, during which the full range of petroleum compounds is produced from kerogen and other precursors by thermal degradation and cracking (the process by which heavy hydrocarbon molecules are broken up into lighter molecules). Depending on the amount and type of organic matter, oil generation occurs during the mature stage at depths of about 760 to 4,880 metres (2,500 to 16,000 feet) at temperatures between 65° and 150° C. This special environment is called the "oil window." In areas of higher than normal geothermal gradient (increase in temperature with depth), the oil window exists at shallower depths in younger sediments but is narrower. Maximum oil generation occurs from depths of 2,000 to 2,900 metres. Below 2,900 metres primarily wet gas, a type of gas containing liquid hydrocarbons known as natural gas liquids, is formed.

The "oil window"

Approximately 90 percent of the organic material in sedimentary source rocks is dispersed kerogen. Its composition varies, consisting as it does of a range of residual materials whose basic molecular structure takes the form of stacked sheets of aromatic hydrocarbon rings in which atoms of sulfur, oxygen, and nitrogen also occur. Attached to the ends of the rings are various hydrocarbon compounds, including normal paraffin chains. The mild heating of the kerogen in the oil window of a source rock over long periods of time results in the cracking of the kerogen molecules and the release of the attached paraffin chains. Further heating, perhaps assisted by the catalytic effect of clay minerals in the source rock matrix, may then produce soluble bitumen compounds, followed by the various saturated and unsaturated hydrocarbons, asphaltenes, and others of the thousands of hydrocarbon compounds that make up crude oil mixtures.

At the end of the mature stage, below about 4,880 metres, depending on the geothermal gradient, kerogen becomes condensed in structure and chemically stable. In this environment, crude oil is no longer stable and the main hydrocarbon product is dry thermal methane gas.

The geologic environment. *Origin in source beds.* Knowing the maximum temperature reached by a potential source rock during its geologic history helps in estimating the maturity of the organic material contained within it. Also, this information may indicate whether a region is gas-prone, oil-prone, both, or neither. The techniques employed to assess the maturity of potential source rocks in core samples include measuring the degree of darkening of fossil pollen grains and the colour changes in conodont fossils. In addition, geochemical evaluations can be made of mineralogical changes that were also induced by fluctuating paleotemperatures. In general, there appears to be a progressive evolution of crude oil characteristics from geologically younger, heavier, darker, more aromatic crudes to older, lighter, paler, more paraffinic types. There are, however, many exceptions to this rule, especially in regions with high geothermal gradients.

Accumulations of petroleum are usually found in relatively coarse-grained, permeable, and porous sedimentary reservoir rocks that contain little, if any, insoluble organic matter. It is unlikely that the vast quantities of oil now present in some reservoir rocks could have been generated from material of which no trace remains. Therefore, the site where commercial amounts of oil originated apparently is not always identical to the location at which they are ultimately discovered.

Primary migration

Oil is believed to have been generated in significant volumes only in fine-grained sedimentary rocks (usually clays, shales, or clastic carbonates) by geothermal action on kerogen, leaving an insoluble organic residue in the source rock. The release of oil from the solid particles of kerogen and its movement in the narrow pores and capillaries of the source rock is termed primary migration.

Accumulating sediments can provide energy to the migration system. Primary migration may be initiated during compaction as a result of the pressure of overlying sediments. Continued burial causes clay to become dehydrated by the removal of water molecules that were loosely combined with the clay minerals. With increasing temperature, the newly generated hydrocarbons may become sufficiently mobile to leave the source beds in solution, suspension, or emulsion with the water being expelled from the compacting molecular lattices of the clay minerals. The hydrocarbon molecules would compose only a very small part of the migrating fluids, a few hundred parts per million.

Migration through carrier beds. The hydrocarbons expelled from a source bed next move through the wider pores of carrier beds (*e.g.*, sandstones or carbonates) that are coarser-grained and more permeable. This movement is termed secondary migration. The distinction between primary and secondary migration is based on pore size and rock type. In some cases, oil may migrate through such permeable carrier beds until it is trapped by a permeability barrier and forms an oil accumulation (Figure 1). In others, the oil may continue its migration until it becomes a seep on the surface of the Earth, where it will be broken down chemically by oxidation and bacterial action.

Since nearly all pores in subsurface sedimentary formations are water-saturated, the migration of oil takes place in an aqueous environment. Secondary migration may result from active water movement or can occur independently, either by displacement or by diffusion. Because the specific gravity of the water in the sedimentary formation is considerably higher than that of oil, the oil will float to the surface of the water in the course of geologic time and accumulate in the highest portion of a trap.

Accumulation in reservoir beds. The porosity (volume of pore spaces) and permeability (capacity for transmitting fluids) of carrier and reservoir beds are important factors in the migration and accumulation of oil. Most petroleum accumulations have been found in clastic reservoirs (sandstones and siltstones). Next in number are the carbonate reservoirs (limestones and dolomites). Accumulations of petroleum also occur in shales and igneous and metamorphic rocks because of porosity resulting from fracturing, but such reservoirs are relatively rare. Porosities in reservoir rocks usually range from about 5 to 30 percent, but all available pore space is not occupied by petroleum. A certain amount of residual formation water cannot be displaced and is always present.

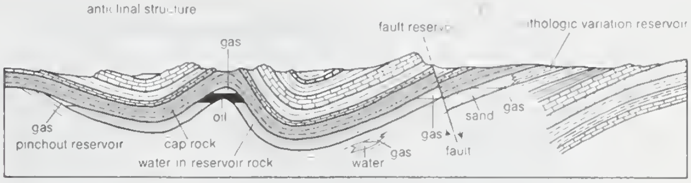

Figure 1: Principal types of traps.

Principal types of reservoir rocks

Reservoir rocks may be divided into two main types: (1) those in which the porosity and permeability is primary, or inherent, and (2) those in which they are secondary, or induced. Primary porosity and permeability are dependent on the size, shape, and grading and packing of the sediment grains (Figure 2) and also on the manner of their initial consolidation. Secondary porosity and permeability result from postdepositional factors, such as solution, recrystallization, fracturing, weathering during temporary exposure at the Earth's surface, and further cementation. These secondary factors may either enhance or diminish the inherent conditions.

Oil traps. After secondary migration in carrier beds, oil finally collects in a trap. The fundamental characteristic of a trap is an upward convex form of porous and permeable reservoir rock that is sealed above by a denser, relatively impermeable cap rock (*e.g.*, shale or evaporites). The trap may be of any shape, the critical factor being that it is a closed, inverted container. A rare exception is hydrodynamic trapping, in which high water saturation of low-permeability sediments reduces hydrocarbon permeability to near zero, resulting in a water block and an accumulation of petroleum down the structural dip of a sedimentary bed below the water in the sedimentary formation.

Anticlines

Structural traps. Traps can be formed in many ways (Figure 1). Those formed by tectonic events, such as folding or faulting of rock units, are called structural traps. The most common structural traps are anticlines, upfolds of strata that appear as ovals on the horizontal planes of geologic maps. About 80 percent of the world's petroleum has been found in anticlinal traps. Most anticlines were produced by lateral pressure, but some have resulted from the draping and subsequent compaction of accumulating sediments over topographic highs. The closure of an anticline is the vertical distance between its highest point and the spill plane, the level at which the petroleum can escape if the trap is filled beyond capacity. Some traps are filled with petroleum to their spill plane, but others contain considerably smaller amounts than they can accommodate on the basis of their size.

Another kind of structural trap is the fault trap. Here, rock fracture results in a relative displacement of strata

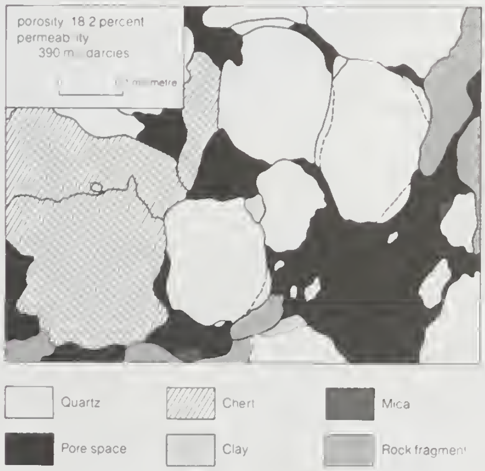

Figure 2: An example of primary porosity in a sandstone (graywacke) of an excellent reservoir rock.

Table 1: The Recoverable Oil Resources of the World*

region	cumulative production	reserves	undiscovered resources	total oil endowment†
North America	202	106	121	429
South America	74	93	44	211

†Percent of original reserves by average API gravity: 10°—20°: 5 percent; 20°—25°: 6 percent; 25°—35°: 57 percent; above 35°: 32 percent.

that forms a barrier to petroleum migration. A barrier can occur when an impermeable bed is brought into contact with a carrier bed. Sometimes the faults themselves provide a seal against "updip" migration when they contain impervious clay gouge material between their walls. Faults and folds often combine to produce traps, each providing a part of the container for the enclosed petroleum. Faults can, however, allow the escape of petroleum from a former trap if they breach the cap rock seal.

Other structural traps are associated with salt domes. Such traps are formed by the upward movement of salt masses from deeply buried evaporite beds, and they occur along the folded or faulted flanks of the salt plug or on top of the plug in the overlying folded or draped sediments.

Stratigraphic traps. A second major class of oil traps is the stratigraphic trap. It is related to sediment deposition or erosion and is bounded on one or more sides by zones of low permeability. Because tectonics ultimately control deposition and erosion, however, few stratigraphic traps are completely without structural influence. The geologic history of most sedimentary basins contains the prerequisites for the formation of stratigraphic traps. Typical examples are fossil carbonate reefs, marine sandstone bars, and deltaic distributary channel sandstones. When buried, each of these geomorphic features provides a potential reservoir, which is often surrounded by finer-grained sediments that may act as source or cap rocks.

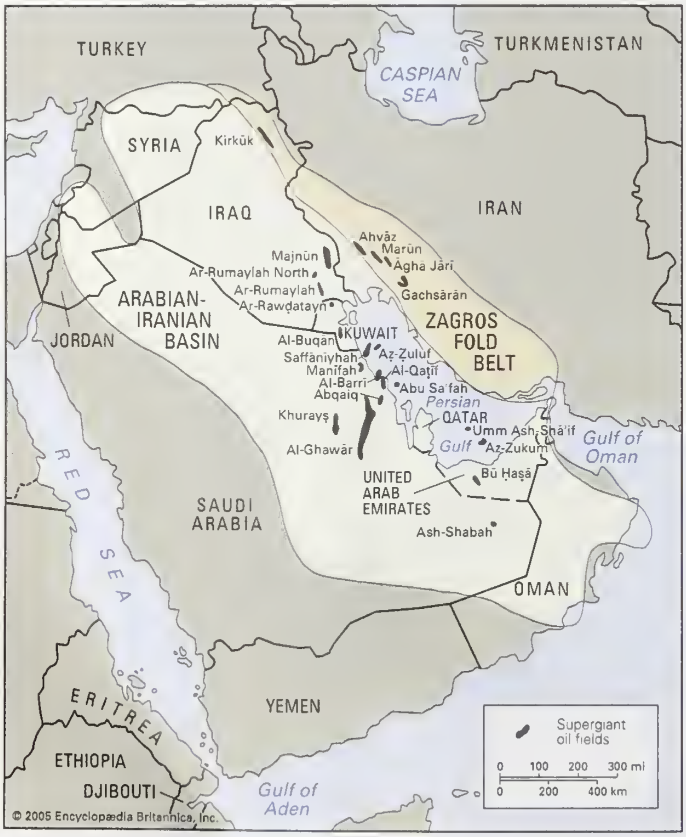

Figure 3: Major oil fields of the Arabian-Iranian basin region.

Sediments eroded from a landmass and deposited in an adjacent sea change from coarse- to fine-grained with increasing depth of water and distance from shore. Permeable sediments thus grade into impermeable sediments, forming a permeability barrier that eventually could trap migrating petroleum.

There are many other types of stratigraphic traps. Some are associated with the many transgressions and regressions of the sea that have occurred over geologic time and the resulting deposits of differing porosities. Others are caused by processes that increase secondary porosity, such as the dolomitization of limestones or the weathering of strata once located at the Earth's surface.

WORLD DISTRIBUTION

Location of reserves. *Oil fields.* Two overriding principles apply to world petroleum production. First, most petroleum is contained in a few large fields, but most fields are small. Second, as exploration progresses, the average size of the fields discovered decreases, as does the amount of petroleum found per unit of exploratory drilling. In any region, the large fields are usually discovered first.

Supergiant and world-class giant oil fields

Since exploration for oil began during the early 1860s, some 50,000 oil fields have been discovered. More than 90 percent of these fields are insignificant in their impact on world oil production. The two largest classes of fields are the supergiants, fields with 5,000,000,000 or more barrels of ultimately recoverable oil, and world-class giants, fields with 500,000,000 to 5,000,000,000 barrels of ultimately recoverable oil. Fewer than 40 supergiant oil fields have been found worldwide, yet these fields originally contained about one-half of all the oil so far discovered. The Arabian-Iranian sedimentary basin in the Persian Gulf region contains two-thirds of these supergiant fields. The remaining supergiants are distributed as follows: two in the United States, two in Russia, two in Mexico, one in Libya, one in Algeria, one in Venezuela, and two in China.

The nearly 280 world-class giant fields thus far discovered, plus the supergiants, account for about 80 percent of the world's known recoverable oil. There are, in addition, approximately 1,000 known large oil fields that initially contained between 50,000,000 and 500,000,000 barrels. These fields account for some 14 to 16 percent of the world's known oil. Less than 5 percent of the known fields originally contained roughly 95 percent of the world's known oil.

Sedimentary basins. Giant petroleum fields and significant petroleum-producing sedimentary basins are closely associated. In some basins, huge amounts of petroleum apparently have been generated because perhaps only about 10 percent of the generated petroleum is trapped and preserved. The Arabian-Iranian sedimentary basin is predominant because it contains more than 20 supergiant fields. No other basin has more than one such field. In 20 of the 26 most significant oil-containing basins, the 10 largest fields originally contained more than 50 percent of the known recoverable oil. Known world oil reserves are concentrated in a relatively small number of giant fields in a few sedimentary basins.

Worldwide, approximately 600 sedimentary basins are known to exist. About 160 of these have yielded oil, but only 26 are significant producers and 7 of these account for more than 65 percent of total known oil. Exploration has occurred in another 240 basins, but discoveries of commercial significance have not been made.

Geologic study and exploration. Current geologic understanding can usually distinguish between geologically favourable and unfavourable conditions for oil accumulation early in the exploration cycle. Thus, only a relatively few exploratory wells may be necessary to indicate whether a region is likely to contain significant amounts of oil. Modern petroleum exploration is an efficient process. If giant fields exist, it is likely that most of the oil in a region will be found by the first 50 to 250 exploratory wells. This number may be exceeded if there is a much greater than normal amount of major prospects or if exploration drilling patterns are dictated by either political or unusual technological considerations. Thus, while undiscovered commercial oil fields may exist in some of the 240 explored but seemingly barren basins, it is unlikely that they will be of major importance since the largest are normally found early in the exploration process.

The remaining 200 basins have had little or no exploration, but they have had sufficient geologic study to indicate their dimensions, amount and type of sediments, and general structural character. Most of the underexplored (or frontier) basins are located in difficult environments, such as polar regions or submerged continental margins. The larger sedimentary basins—those containing more than 833,000 cubic kilometres (200,000 cubic miles) of sediments—account for some 70 percent of known world petroleum. Future exploration will have to involve the smaller basins as well as the more expensive and difficult frontier basins.

Status of the world oil supply. The first 200,000,000,000 barrels of world oil were produced in 109 years from 1859 to 1968. Since that time world oil production rates have stabilized at a rate of about 22,000,000,000 barrels a year.

Table 1 shows the broad distribution of the world oil supply. Reserves are identified quantities of "in-place" petroleum that are considered recoverable under current economic and technological conditions. Estimated by petroleum engineers and geologists using drilling and production data along with other subsurface information, these figures are revised to include projected field growth as development progresses. Petroleum reserves are reported by oil companies and by some governments, and such data are compiled by the U.S. Department of Energy and the U.S. Geological Survey, as well as by oil industry trade journals. Undiscovered petroleum resources of the world have been estimated by the U.S. Geological Survey by the extrapolation of known production and reserve data into untested sediments of similar geology. A most likely consensus estimate was established, as was a range with upper and lower yield limits at 5 and 95 percent probabilities. The range for undiscovered oil resources assessed for the whole world is 275,000,000,000 to 1,469,000,000,000 barrels.

Table 2: Leading Oil Countries

country	cumulative production*	reserves*	undiscovered resources*	total oil endowment*
Saudi Arabia	71.5	261.2	41	373.7
United States	165.8	50.7	49	265.5
Russia	92.6	100.0	68	260.6

Duration of oil supply

Table 1 indicates that the most likely total world oil endowment is about 2,390,000,000,000 barrels. Of this amount, 77 percent has already been discovered and 30 percent has already been produced and consumed. If this estimate proves to be reasonably accurate, current relatively stabilized world oil-production volumes could be sustained to about the middle of the 21st century, at which time a shortage of conventional oil resources would force a production decline.

The Middle East is thought to have had an estimated 41 percent of the world's total oil endowment. North America is a distant second but has already produced almost half of

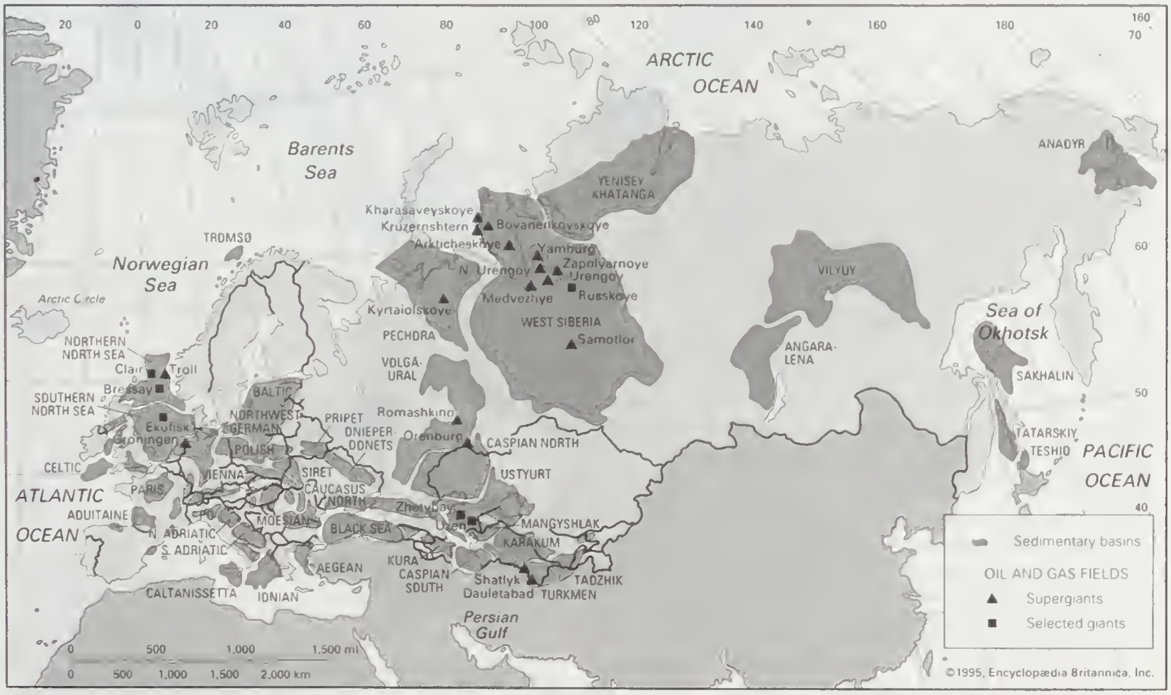

Figure 4: Sedimentary basins and major oil and gas fields of Europe, Russia, Transcaucasia, and Central Asia.

its total oil. Eastern Europe, because of the large deposits in Russia, is well endowed with oil. Western Europe is not, with most of its oil under the North Sea. Likewise, Africa, Asia, and South America are thought to have only relatively moderate amounts of oil. It is interesting to note that a large undiscovered oil resource is believed to exist in North America, which has many frontier basins. Both the Middle East and eastern Europe, however, are also thought to contain significant oil prospects.

Major producing countries. Table 2 lists the 18 countries believed to have had an original oil endowment exceeding 20,000,000,000 barrels. It also serves to show the concentration of world oil. These 18 countries have accounted for 86 percent of the world's oil production. They hold 94 percent of its reserves. Significantly, they are projected to have 82 percent of the world's remaining undiscovered oil resources. As can be seen, regions geologically favourable to the generation and deposition of oil are fairly rare. The 18 countries listed are estimated to have contained 89 percent of the world's original oil endowment.

Saudi Arabia. Saudi Arabia, shown in Figure 3, is thought to have had the largest original oil endowment of any country. The discovery that transformed Saudi Arabia into a leading oil country was the Al-Ghawār field. Discovered in 1948, this field has proved to be the world's largest, containing 82,000,000,000 barrels. Another important discovery was the Saffāniyah offshore field in the Persian Gulf. It is the third largest oil field in the world and the largest offshore. Saudi Arabia has eight other supergiant oil fields. Thus, it has the largest oil reserve in the world, not to mention significant potential for additional discoveries.

Russia. Russia is thought to possess the best potential for new discoveries. Also, it has significant reserves. Russian oil is derived from many sedimentary basins within the vast country, while Saudi Arabian fields, as well as many other Middle Eastern fields, are located in the great Arabian-Iranian basin (Figures 3 and 4). Russia has two supergiant oil fields, Samotlor and Romashkino. Production from these fields is on the decline, bringing total Russian oil output down with them. The best prospects for new Russian discoveries appear to exist in the difficult and expensive frontier areas.

United States, Mexico, and Canada. North America also has many sedimentary basins; they are shown in Figure 5. Basins in the United States have been intensively explored and their oil resources developed. More than 33,000 oil fields have been found, but only two are supergiants (Prudhoe Bay in the North Slope region of Alaska, shown in Figure 6, and East Texas). Cumulatively, the United States has produced more oil than any other country but is still considered to have a significant remaining undiscovered oil resource. Prudhoe Bay, which accounted for approximately 17 percent of U.S. oil production dur- Prudhoe Bay

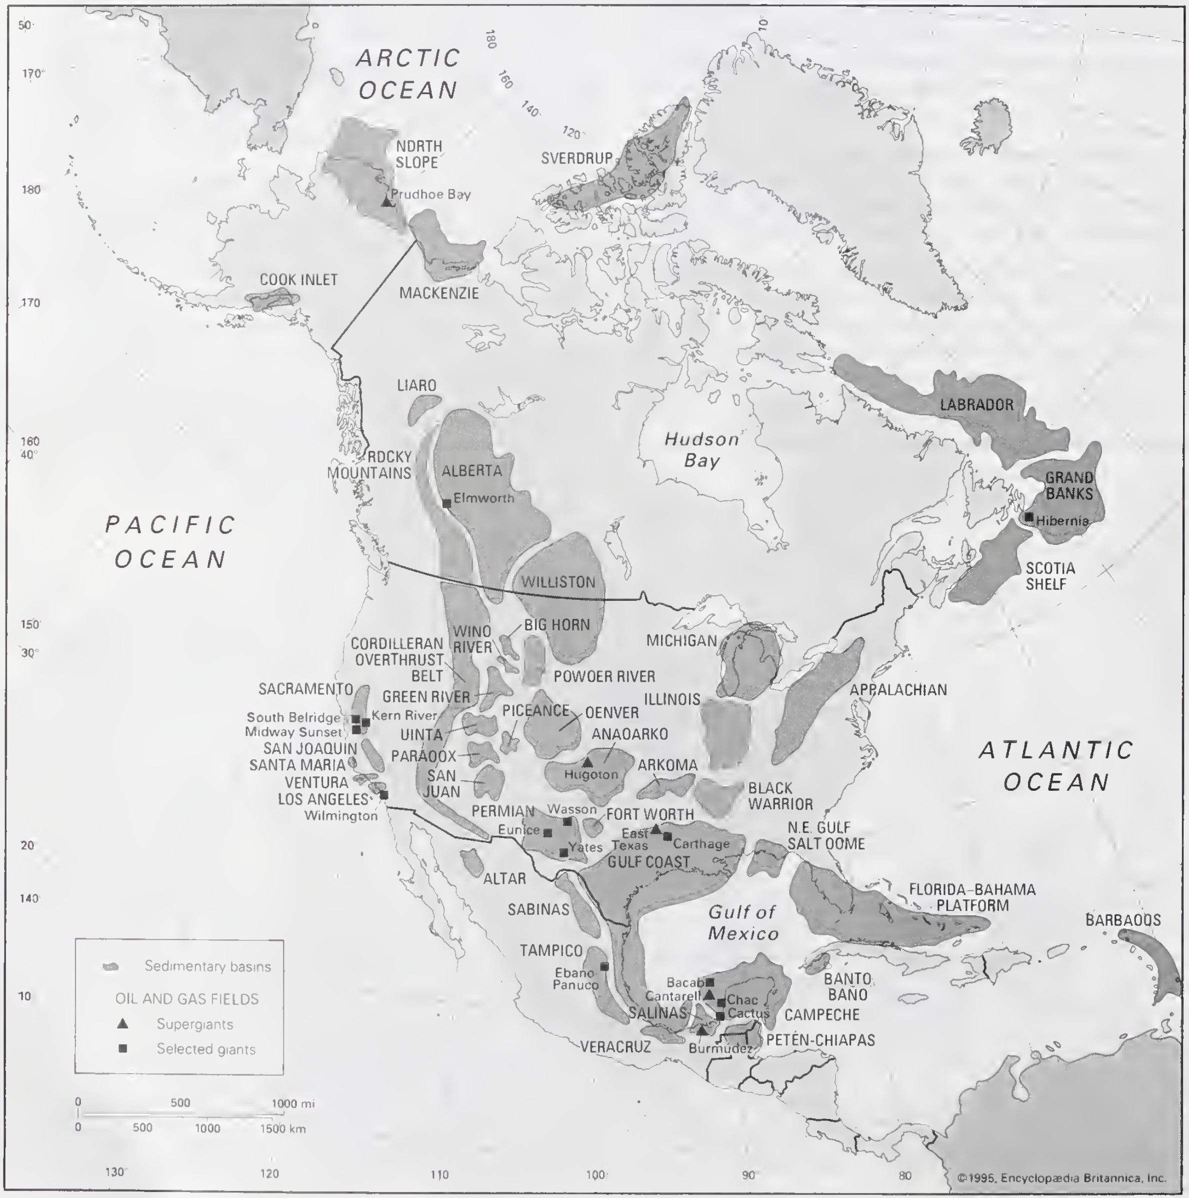

Figure 5: Sedimentary basins and major oil and gas fields of North America.

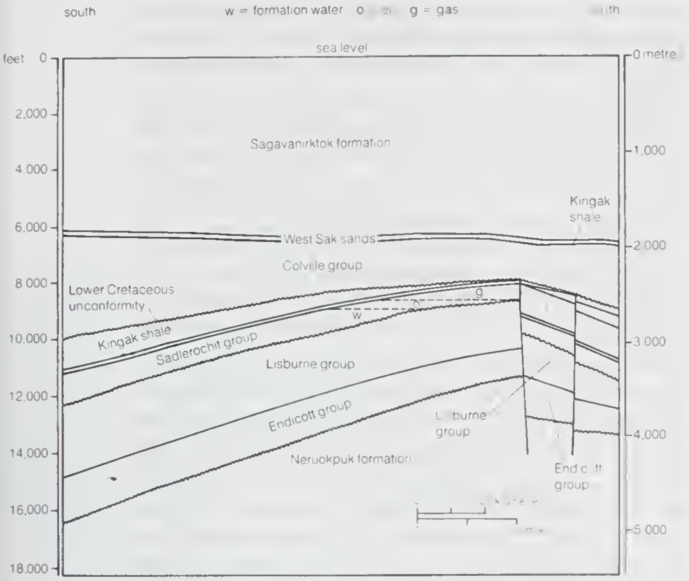

Figure 6: North-to-south cross section of the Prudhoe Bay complex.

From H C Jamison L D Brockett, and R A McIntosh, 'Prudhoe Bay—A 10-Year Perspective, in Michel T Halbouty ed , *Giant Oil and Gas Fields of the Decade 1968–1978*, The American Association of Petroleum Geologists, Tulsa Okla Memoir 30, 1980

ing the mid-1980s, is in decline. This situation, coupled with declining oil production in the conterminous United States, has contributed to a significant drop in domestic oil output. Mexico has produced only about one-fifth of its estimated total oil endowment. With two supergiant fields (Cantarell offshore of Campeche state and Bermudez in Tabasco state) and with substantial remaining reserves and resources, it will be able to sustain current production levels well into the 21st century. Conversely, Canada, with considerably smaller oil reserves and most of its undiscovered resource potential in remote regions, is unlikely to be able to sustain current production levels beyond the 1990s. Canada's largest oil field is Hibernia, discovered off Newfoundland in 1979. This giant field has yet to be developed.

Iraq, Kuwait, and Iran. The Middle Eastern countries of Iraq, Kuwait, and Iran are each estimated to have had an original oil endowment in excess of 100,000,000,000 barrels. These countries have a number of supergiant fields, all of which are located in the Arabian-Iranian basin, including Kuwait's Al-Burqān field (Figure 3). Al-Burqān is the world's second largest oil field, having originally contained 75,000,000,000 barrels of recoverable oil. Iraq possesses a significant potential for additional oil discoveries.

United Kingdom. The United Kingdom is an important North Sea exporter; however, as its undiscovered resource potential appears somewhat limited, it may require more of its oil output for internal use in the future.

Undiscovered resources. With an estimated 77 percent of the world's total recoverable oil endowment having already been discovered, the remaining 23 percent, mostly located in smaller fields or in more difficult environments, is expected to become ever more expensive to find and to recover. More than 11,000 man-years were required to construct the largest of the North Sea gravity platforms, making capital costs per daily oil production as much as 40 times the costs in the Middle East. A guyed tower constructed in more than 300 metres of water in the Gulf of Mexico has been estimated to produce oil at about 65 times the production cost in the Middle East. As oil exploitation moves into deeper waters or under Arctic ice, the cost will further escalate and will be reflected in the world economy. (J.P.Ri./G.I.A.)

Natural gas

Natural gas is often found dissolved in oil at the high pressures existing in a reservoir, and it also can be present as a gas cap above the oil. Such natural gas is known as associated gas. There are also reservoirs that contain gas and no oil. This gas is termed nonassociated gas.

Associated and non-associated gas

HISTORY OF USE

Discovery and early application. The first discoveries of natural gas seeps were made in Iran between 6000 and 2000 BC. Many early writers described the natural petroleum seeps in the Middle East, especially in the Baku region of what is now Azerbaijan. The gas seeps, probably first ignited by lightning, provided the fuel for the "eternal fires" of the fire-worshiping religion of the ancient Persians. The use of natural gas was mentioned in China about 900 BC. It was in China in 211 BC that the first known well was drilled for natural gas to reported depths of 150 metres (500 feet). The Chinese drilled their wells with bamboo poles and primitive percussion bits for the express purpose of searching for gas in Late Triassic limestones (more than 208,000,000 years old) in an anticline west of modern Chungking. The gas was burned to dry the rock salt found interbedded in the limestone. Eventually wells were drilled to depths approaching 1,000 metres, and more than 1,100 wells had been drilled into the anticline by 1900.

Natural gas was unknown in Europe until its discovery in England in 1659, and even then it did not come into wide use. Instead, gas obtained from carbonized coal (known as town gas) became the primary fuel for illuminating streets and houses throughout much of Europe from 1790 on. In North America the first commercial application of a petroleum product was the utilization of natural gas from a shallow well in Fredonia, N.Y., in 1821. The gas was distributed through a small-bore lead pipe to consumers for lighting and cooking.

Improvements in gas pipelines. Throughout the 19th century the use of natural gas remained localized because there was no way to transport large quantities of gas over long distances. Natural gas remained on the sidelines of industrial development, which was based primarily on coal and oil. An important breakthrough in gas-transportation technology occurred in 1890 with the invention of leakproof pipeline coupling. Nonetheless, materials and construction techniques remained so cumbersome that gas could not be used more than 160 kilometres (100 miles) from a source of supply. Thus, associated gas was mostly flared (*i.e.*, burned at the wellhead), and nonassociated gas was left in the ground, while town gas was manufactured for use in the cities.

Long-distance transmission of natural gas

Long-distance gas transmission became practical during the late 1920s because of further advances in pipeline technology. From 1927 to 1931 more than 10 major transmission systems were constructed in the United States. Each of these systems was equipped with pipes having diameters of approximately 51 centimetres (20 inches) and extended more than 320 kilometres. Following World War II, a large number of even longer pipelines of increasing diameter were constructed. The fabrication of pipes having a diameter of up to 142 centimetres became possible. Since the early 1970s the longest gas pipelines have had their origin in Russia. For example, the 5,470-kilometre-long Northern Lights pipeline crosses the Ural Mountains and some 700 rivers and streams, linking eastern Europe with the West Siberian gas fields on the Arctic Circle. As a result, gas from the Urengoy field, the world's largest, is transported to eastern Europe and then on to western Europe for consumption. Another gas pipeline, shorter but also of great engineering difficulty, is the 51-centimetre line that extends from Algeria across the Mediterranean Sea to Sicily. The sea is more than 600 metres deep along some parts of the route.

Natural gas as a premium fuel. As recently as 1960, associated gas was a nuisance by-product of oil production in many areas of the world. The gas was separated from the crude oil stream and eliminated as cheaply as possible, often by flaring. Only since the crude oil shortages of the late 1960s and early 1970s has natural gas become an important world energy source.

Even in the United States the home-heating market for natural gas was limited until the 1930s when town gas began to be replaced by abundant and cheaper supplies of natural gas, which contained twice the heating value of its synthetic predecessor. Also, when natural gas burns completely, carbon dioxide and water are normally formed. The combustion of gas is relatively free of soot, carbon monoxide, and the nitrogen oxides associated with the burning of other fossil fuels. In addition, sulfur dioxide emissions, another major air pollutant, are almost nonexistent. As a consequence, natural gas is often a preferred fuel for environmental reasons.

PROPERTIES

Chemical composition. *Hydrocarbon content.* Natural gas is a hydrocarbon mixture consisting primarily of methane and ethane, both of which are gaseous under atmospheric conditions. The mixture also may contain other hydrocarbons, such as propane, butane, pentane, and hexane. In natural gas reservoirs even the heavier hydrocarbons occur for the most part in gaseous form because of the higher pressures. They liquefy at the surface (at atmospheric pressure) and are referred to as natural gas liquids, gas condensate, natural gasoline, or liquefied petroleum gas. They may separate in some reservoirs through retrograde condensation or may be separated at the surface either in field separators or in gas processing plants by means of condensation, absorption, adsorption, or other modification. The average production of natural gas liquids in the United States is nearly 38 barrels per 1,000,000 cubic feet of produced gas.

Natural gas liquids

Nonhydrocarbon content. Other gases that commonly occur in association with the hydrocarbon gases are nitrogen, carbon dioxide, hydrogen, hydrogen sulfide, and such noble gases as helium and argon. Because natural gas and formation water occur together in the reservoir, gas recovered from a well contains water vapour, which is partially condensed during transmission to the processing plant.

Physical properties. The physical properties of natural gas include colour, odour, and flammability. The principal ingredient of gas is methane, which is colourless, odourless, and highly flammable. However, some of the associated gases in natural gas, especially hydrogen sulfide, have a distinct and penetrating odour, and a few parts per million is sufficient to impart a decided odour to natural gas.

Measurement systems. The amounts of gas accumulated in a reservoir, as well as produced from wells, are calculated in cubic metres at a pressure of 750 millimetres of mercury and a temperature of 15° C (or in cubic feet at an absolute pressure of 14.73 pounds per square inch and a temperature of 60° F). Since gas is compressed at high reservoir pressures, it expands upon reaching the surface and thus occupies more space. As its quantity is calculated in reference to standard conditions of temperature and pressure, however, the expansion does not constitute an increase in the amount of gas produced.

ORIGIN

Organic formation process. Natural gas is more ubiquitous than oil. It is derived from both land plants and aquatic organic matter and is generated above, throughout, and below the oil window. Thus, all source rocks have the potential for gas generation. Many of the source rocks for significant gas deposits appear to be associated with the worldwide occurrence of Carboniferous coal (roughly 286,000,000 to 360,000,000 years in age).

The biological stage. During the immature, or biological, stage of petroleum formation, biogenic methane (often called marsh gas) is produced as a result of the decomposition of organic material by the action of anaerobic microbes. These microorganisms cannot tolerate even traces of oxygen and are also inhibited by high concentrations of dissolved sulfate. Consequently, biogenic gas generation is confined to certain environments that include poorly drained swamps and bays, some lake bottoms, and marine environments beneath the zone of active sulfate reduction. Gas of predominantly biogenic origin is thought to constitute more than 20 percent of the world's gas reserves.

Biogenic methane

The mature stage of petroleum generation, which occurs at depths of about 760 to 4,880 metres, includes the full range of hydrocarbons that are produced within the oil window. Often significant amounts of thermal methane gas are generated along with the oil. Below 2,900 metres, primarily wet gas (gas containing liquid hydrocarbons) is formed.

The thermal stage. In the postmature stage, below about 4,880 metres, oil is no longer stable, and the main hydrocarbon product is thermal methane gas. The thermal gas is the product of the cracking of the existing liquid hydrocarbons. Those hydrocarbons with a larger chemical structure than that of methane are destroyed much more rapidly than they are formed. Thus, in the sedimentary basins of the world, comparatively little oil is found below 4,880 metres. The deep basins with thick sequences of sedimentary rocks, however, have the potential for deep gas production.

Inorganic formation. Some methane may have been produced by inorganic processes. The original source of the Earth's carbon was the cosmic debris from which the planet formed. If meteorites are representative of this debris, the carbon could have been supplied in comparatively high concentrations as hydrocarbons, such as are found in the carbonaceous chondrite type of meteorites. Continuous outgassing of these hydrocarbons may be taking place from within the Earth, and some may have accumulated as abiogenic gas deposits without having passed through an organic phase. In the event of widespread outgassing, however, it is likely that abiogenic gas would be too diffuse to be of commercial interest. Significant accumulations of inorganic methane have yet to be found.

The helium and some of the argon found in natural gas are products of natural radioactive disintegration. Helium derives from radioisotopes of thorium and the uranium family, and argon derives from potassium. It is probably coincidental that helium and argon sometimes occur with natural gas; in all likelihood, the unrelated gases simply became caught in the same trap. (J.P.Ri./Ed.)

The geologic environment. Like oil, natural gas migrates and accumulates in traps (Figure 1). Oil accumulations contain more recoverable energy than gas accumulations of similar size, even though the recovery of gas is a more efficient process than the recovery of oil. This is due to the differences in the physical and chemical properties of gas and oil. Gas displays initial low concentration and high dispersibility, making adequate cap rocks very important.

Natural gas can be the primary target of either deep or shallow drilling because large gas accumulations form above the oil window as a result of biogenic processes and thermal gas occurs throughout and below the oil window. In most sedimentary basins the vertical potential (and sediment volume) available for gas generation exceeds that of oil. About a quarter of the known major gas fields are related to a shallow biogenic origin, but most major gas fields are located at intermediate or deeper levels where higher temperatures and older reservoirs (often carbonates sealed by evaporites) exist.

Vertical extent of gas formations

Conventional gas reservoirs. Gas reservoirs differ greatly, with different physical variations affecting reservoir performance and recovery. In a natural gas (single-phase) reservoir it should be possible to recover nearly all of the in-place gas by dropping the pressure sufficiently. If the pressure is effectively maintained by the encroachment of water in the sedimentary rock formation, however, some of the gas will be lost to production by being trapped by capillarity behind the advancing water front. Therefore, in practice, only about 80 percent of the in-place gas can be recovered. On the other hand, if the pressure declines, there is an economic limit at which the cost of compression exceeds the value of the recovered gas. Depending on formation permeability, actual gas recovery can be as high as 75 to 80 percent of the original in-place gas in the reservoir. Associated gas is produced along with the oil and separated at the surface.

Unconventional gas reservoirs. Substantial amounts of gas have accumulated in geologic environments that differ from conventional petroleum traps. This gas is termed unconventional gas and occurs in "tight" (*i.e.,* relatively impermeable) sandstones, in joints and fractures or absorbed into the matrix of shales (often of the Devonian Period [about 360,000,000 to 408,000,000 years old]), dissolved or entrained in hot geopressured formation waters, and in coal seams. Unconventional gas sources are much more expensive to exploit and have to be produced at much slower rates than conventional gas fields. Moreover, recoveries are low. In all likelihood, unconventional gas will continue to complement conventional gas production but will not supplant it.

WORLD DISTRIBUTION

Location of major gas fields. The largest natural gas fields are the supergiants, which contain more than 850,000,000,000 cubic metres of gas, and the world-class giants, which have reserves of roughly 85,000,000,000 to 850,000,000,000 cubic metres. Supergiants and world-class giants represent less than 1 percent of the world's total known gas fields, but they originally contained, along with associated gas in giant oil fields (see above), approximately 80 percent of the world's reserves and produced gas.

Urengoy

Russia. Some of the world's largest gas fields occur in Russia in a region of West Siberia east of the Gulf of Ob on the Arctic Circle. The world's largest gas field is Urengoy, which was discovered in 1966. Its initial reserves have been estimated at 8,087,000,000,000 cubic metres. Nearly 6,230,000,000,000 cubic metres of this gas are in the shallowest reservoir, 1,100 to 1,250 metres deep, which is Upper Cretaceous in age (from about 66,400,000 to 97,500,000 years old). In all, Urengoy has 15 separate reservoirs, some in Lower Cretaceous rocks (those that are approximately 97,500,000 to 144,000,000 years old). The deepest is a gas condensate zone in Upper Jurassic strata (from about 144,000,000 to 163,000,000 years old). Urengoy began production in 1978. Its maximum output is expected to be as much as 250,000,000,000 cubic metres of gas per year, which would considerably exceed the production from any other gas field in the world.

Yamburg, Russia's second largest gas field, was discovered north of the Arctic Circle and north of Urengoy. Its original reserves were estimated at 4,700,000,000,000 cubic metres of gas, mostly from Upper Cretaceous reservoir rocks at depths of 1,000 to 1,210 metres. Development of Yamburg began in the early 1980s. Bovanenkovskoye, discovered in 1971 on the Yamal Peninsula in northwestern Siberia, is Russia's third largest field. It has reserves estimated at 4,102,000,000,000 cubic metres in Lower Cretaceous reservoir rock at depths of 1,190 to 1,475 metres. Bovanenkovskoye has not yet been developed. Some of the gas in these huge, shallow fields may be of biogenic origin and capped by permafrost.

Orenburg, discovered in the Volga-Urals region in 1967, is the largest Russian gas field outside of West Siberia. It had initial reserves of 1,778,300,000,000 cubic metres of gas and is now under production.

Europe. The largest natural gas field in Europe is Groningen, with original recoverable reserves of about 2,270,000,000,000 cubic metres. It was discovered in 1959 on the Dutch coast. The discovery well was drilled through evaporites of Permian age (about 245,000,000 to 286,000,000 years old) into a thick basal Permian sandstone that was gas-productive. Subsequent drilling outlined a broad anticline about 24 kilometres wide by 40 kilometres long, which has a continuous basal Permian sandstone reservoir capped by evaporites. The reservoir contains natural gas at depths between 2,440 and 3,050 metres. It overlies the truncated and strongly faulted coal-bearing Pennsylvanian sequence (the Pennsylvanian Period extended from about 286,000,000 to 320,000,000 years ago), which is considered to be the main source of the gas.

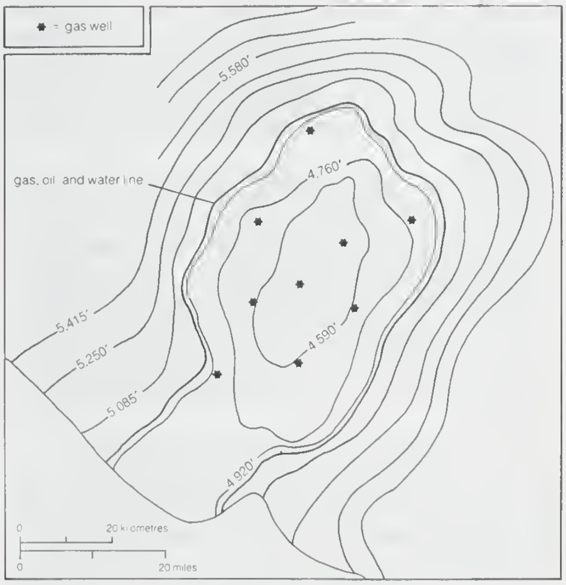

Figure 7: Reservoir of Hassi R'Mel gas field, Algeria.
From Philippe R. Magloire, "Triassic Gas Field of Hassi er R'Mel, Algeria," in Michel T. Halbouty ed., *Geology of Giant Petroleum Fields*, p. 496, The American Association of Petroleum Geologists, Tulsa Okla. Memoir 14, 1970

Hugoton

North America. In the United States, Hugoton, discovered in 1927 in Kansas and found to extend through the Oklahoma and Texas panhandles, is a gas field with an estimated ultimate recovery of 1,986,000,000,000 cubic metres. More than 7,000 wells have been drilled in this extensive field, which produces from a series of Permian limestones and dolomites. The gas accumulations are stratigraphically controlled by variations in lithology. The productive area extends along a 400-kilometre trend. Canada has a significant estimated endowment of natural gas, of which only about 17 percent has been produced. Its undiscovered resource potential is almost equal to that of the United States. The largest gas field is Elmworth. Discovered in Alberta in 1976, Elmworth contained some 560,000,000,000 cubic metres of gas in a Cretaceous sandstone reservoir. Mexico's largest gas accumulation is associated with the supergiant Bermudez oil field. Located in 1958 in the Chiapas-Tabasco region, Bermudez originally contained 490,000,000,000 cubic metres of associated gas in a Cretaceous dolomite reservoir. Although Mexico's estimated gas endowment is less than half that of Canada, natural gas is underutilized in Mexico, and only 11 percent of that country's estimated total recoverable gas has been produced.

North Africa. In North Africa the central basin of Algeria is the location of the Hassi R'Mel gas and condensate field (Figure 7). Discovered in 1956 in a large anti-

*In trillion cubic metres; figures adapted from *Oil & Gas Journal* and U.S. Geological Survey.

cline, the field is estimated to have originally contained about 2,520,000,000,000 cubic metres of recoverable gas in reservoirs of permeable Triassic sandstone (from about 208,000,000 to 245,000,000 years old) capped by salt beds. Hassi R'Mel is under development and is reported to have the capacity to produce 59,000,000,000 cubic metres of gas per year.

Middle East. There is an enormous gas potential in the Middle East associated with the major structures in the Arabian-Iranian basin. The Permian Khuff formation underlies most of the region and is an important gas-bearing horizon. It forms the reservoir of the supergiant North Field of offshore Qatar and also of other smaller nonassociated gas fields in the region. There also is great potential for nonassociated gas accumulations in Lower Cretaceous (as well as in the Permian) strata should the demand for Persian Gulf gas rise, either for domestic use or for export.

Asia. The largest gas field in Asia is Arun, which was discovered in 1971 in the North Sumatra basin of Indonesia. The gas reservoir is a reef limestone of middle Miocene age (from about 11,000,000 to 16,000,000 years old). Original reserves have been estimated at about 383,000,000,000 cubic metres. The gas is liquefied for export.

Status of world reserves. When the generation and migration of gas is considered, the extensive vertical gas-generation zone includes shallow biogenic gas, the intermediate dissolved gas of the oil window, and deeper thermal gas. This large vertical habitat for gas and the additional availability of source material indicate that considerable gas may have been formed and still remains undiscovered. Table 3, derived from an assessment of the U.S. Geological Survey and other estimates in the technical literature, shows the broad distribution of world natural gas. It is estimated that 45 percent of the world's recoverable gas remains undiscovered and that, on the basis of energy content, the world's ultimate recoverable resources of natural gas will approach those of oil. Because the utilization of gas in large volumes lags behind the use of oil, the world's stock of gas is expected to last longer than that of oil. However, if the consumption of gas approaches that of oil on an equivalent basis, it, too, will be short-lived as a major energy resource.

Duration of gas supply

About 14 percent of the world's estimated total gas endowment has been consumed or flared. The flaring of associated gas has long been a practice connected with oil production. As recently as 1980, approximately 10 percent of world annual gas production was lost at the wellhead by this procedure. Historically, Middle Eastern and African oil-producing countries have flared the most gas. Much of the gas yielded is reinjected, but what cannot be reinjected has often been flared because the remote location of many oil wells makes the recovery of gas expensive. As the value of gas has appreciated, however, conservation efforts have increased and gas flaring has been reduced.

Table 3 shows that the estimated total world endowment of natural gas is more than 344,000,000,000,000 cubic metres. About one-third of this gas was originally located in the Soviet Union, which, prior to its dissolution in 1991, had surpassed the United States to become the world's leading producer of natural gas. Together, the Soviet Union and the Middle East originally accounted for more than half of the world's natural gas endowment. The United States also possessed a significant endowment of natural gas, but it has already consumed more than half of its resources. U.S. gas production has been projected to fall by as much as 10 percent by the end of the 20th century because of the declining resource base.

The total gas endowments of Latin America, western Europe, Africa, and Asia and the Pacific region, while significant, are thought to be considerably smaller than those of North America, the former Soviet Union, and the Middle East. However, past gas production in these regions has been somewhat limited; therefore much of the original gas is still available for use.

Russia had the world's largest original gas endowment—more than 98,000,000,000,000 cubic metres. The United States and Iran both had original gas endowments of more than 33,000,000,000,000 cubic metres. The gas endowments of the following countries were in excess of 2,800,000,000,000 cubic metres in descending order: Saudi Arabia, Canada, China, Turkmenistan, Norway, Mexico, the United Arab Emirates, Nigeria, Qatar, Kazakhstan, Venezuela, Indonesia, Kuwait, Australia, Algeria, Uzbekistan, Malaysia, The Netherlands, and Ukraine. These countries originally possessed more than 90 percent of the world's total recoverable natural gas.

Heavy oils and tar sands

Specific gravity of heavy oils

Crude oils below 20° API gravity are usually considered to be heavy. The lighter conventional crudes are often waterflooded to enhance recovery. The injection of water into the reservoir helps to maintain reservoir pressure and displace the oil toward the production wells. In general, waterflooding is most effective with light crude oils of API gravity 25° and higher and becomes progressively less effective with oils below 25° API. With crudes of 20° and lower, waterfloods are essentially ineffective and thermal recovery becomes necessary. Very few thermal projects are successful in recovering oil of less than 10° API gravity. Heavy crude oils have enough mobility that, given time, they will be producible through a well bore in response to thermal recovery methods. Tar sands contain immobile bitumen that will not flow into a well bore even under thermal stimulation. The recovery of these resources requires mining.

HISTORY OF USE

Discovery. In ancient times the Elamites, Chaldeans, Akkadians, and Sumerians mined shallow deposits of asphalt, or bitumen, for their own use. Mesopotamian bitumen was exported to Egypt where it was employed for various purposes, including the preservation of mummies. The Dead Sea was known as Lake Asphaltites (from which the term asphalt was derived) because of the lumps of semisolid petroleum that were washed up on its shores from underwater seeps.

Bitumen had many other uses in the ancient world. It was mixed with sand and fibrous materials for use in the construction of watercourses and levees and as mortar for bricks. It was widely used for caulking ships and in road building. Bitumen also was employed for bonding tools, weapons, and mosaics and in inlaid work and jewel setting. In various areas it was used in paints and for waterproofing baskets and mats. Artistic and religious objects were carved from bitumen-impregnated sands, and the mining of rock asphalt was an important industry.

Centuries later, during the age of exploration, Sir Walter Raleigh found the famous "Pitch Lake" deposits in Trinidad. The Dutch made similar discoveries in Java and Sumatra.

Potential as a crude oil source. In response to thermal recovery methods, world production of heavy oil exceeds 1,000,000 barrels per day, or roughly 2 percent of the total world oil output. In the United States approximately 6 percent of total oil production is derived from heavy oil fields. The production of synthetic oil from the bitumen in tar sands is limited to Alberta, Can., and amounts to about 250,000 barrels per day.

Yet, the development of heavy oil and bitumen reserves is increasing around the world. The increasing volume of cheaper heavy oil in the supply mix has provided an incentive for refiners to upgrade their equipment to process the poorer-quality heavier crudes. The upgrading investments have helped to maintain a demand for heavy oil in spite of the declining price of conventional crudes since the early 1980s. As the demand for heavy oil and syncrude from tar sands remains strong, heavy-hydrocarbon development projects are being initiated in several parts of the world. In addition, unsuccessful attempts to find new giant conventional oil fields in recent years has caused some producers to turn to the marginally economic heavy hydrocarbons to replace depleted reserves.

COMPOSITION AND ORIGIN

Chemical composition. Geochemical analyses indicate that the heavy hydrocarbons are composed primarily of as-

phaltenes, resins, and metals (most commonly vanadium and nickel). The nature of individual heavy oil deposits varies widely as they are rarely chemically homogeneous. Bitumen distribution in a deposit also varies, depending on the permeability and porosity of the reservoir rock.

Degradation of conventional oils

Formation. Nearly all the deposits of heavy hydrocarbons are degraded remnants of accumulations of conventional oils. Degradation begins when oil migrates toward the surface and encounters descending meteoric water (rainwater or any other water of atmospheric origin) containing oxygen and bacteria at temperatures below 93° C. A tarlike material is formed at the oil-water contact, and it eventually invades the entire oil accumulation. A process known as "water washing" removes the more water-soluble light hydrocarbons, particularly the aromatics. Biodegradation preferentially removes the normal paraffins. Heavy hydrocarbon accumulations may represent as little as 10 percent of the original conventional oil. They contain asphaltenes, resins, sulfur, and such metals as vanadium and nickel, which results in an increase in density. These apparently are the residues of a natural concentrating process and were not contributed by other sources. Thus, the deposits were emplaced as medium-gravity crudes, which later became immobilized by degradation in the reservoir. Some of the heavy oils, however, appear thermally immature and therefore may be unaltered.

The geologic environment. Almost all the heavy hydrocarbon deposits have been found in formations of Cretaceous and Tertiary age (about 1,600,000 to 144,000,000 years old). The exceptions include some deposits in Alberta, Can., and in Russia. In Alberta bituminous Paleozoic carbonates unconformably underlie Mesozoic rocks (the Paleozoic Era began about 540,000,000 years ago and lasted until the beginning of the Mesozoic Era, roughly 245,000,000 years ago). In Russia most of the heavy hydrocarbons occur in strata dating back to the Paleozoic Era and earlier (*i.e.*, the late Precambrian, which ended about 540,000,000 years ago). Some heavy hydrocarbons are found in Tertiary rocks in Central Asia.

The most prolific heavy hydrocarbon reservoir sediments are sandstones that were originally deposited in fluvial and deltaic, nearshore environments. The exceptions are the bituminous carbonate rocks of Alberta, Russia, and Central Asia. Smaller deposits of asphaltic carbonate rocks are common, notably in the Middle East and in Italy. Many heavy oil reservoirs have been found offshore beneath the continental shelves of Africa and North and South America. In addition, heavy hydrocarbons have been discovered beneath the Caspian, Mediterranean, Adriatic, Red, Black, North, Beaufort, and Caribbean seas, as well as beneath the Persian Gulf and the Gulf of Mexico.

WORLD DISTRIBUTION

Commercially viable deposits. *Heavy oil.* California accounts for nearly all of the thermally recovered heavy oil in the United States. The largest of the California heavy oil fields is Midway-Sunset, with an ultimate recovery estimated at slightly more than 2,000,000,000 barrels. Almost as large is the Kern River field, projected to ultimately produce slightly less than 2,000,000,000 barrels. Two other California fields, Wilmington and South Belridge, are estimated to have originally contained more than 1,000,000,000 barrels of recoverable heavy oil. There are five additional heavy oil fields estimated to have initially contained more than 500,000,000 barrels.

Four of the world's largest oil fields, the supergiants Al-Burqān in Kuwait, Kirkuk in Iraq, Abū Sa'fah in Saudi Arabia, and the Bolivar Coastal field in Venezuela, contain and have produced very large amounts of heavy oil in addition to conventional oils. Giant fields producing heavy oil include Zubair in Iraq; Duri in Indonesia; Gudao and Karamai in China; Seria in Brunei; Bacab, Chac, and Ebano-Panuco in Mexico; Belayim Land in Egypt; Maydan Mahzam in Qatar; and Uzen and Zhetybay in Kazakhstan.

Some heavy oil fields have been found to be associated with giant gas fields. These include the Bressay, Clair, and Ekofisk gas fields of the North Sea and the Russkoye gas field of Russia.

Table 4 shows world recoverable reserves, undiscovered resources, and total heavy oil endowment by region, as modified from U.S. Geological Survey estimates. Approximately one-half of the world's original heavy oil endowment is thought to have originally existed in the Western Hemisphere. This is due to the enormous heavy oil deposits concentrated in a belt 700 kilometres long by 60 kilometres wide along the Orinoco River in eastern Venezuela.

The Middle East has 36 percent of the world's heavy oil endowment, followed by the United States with 11 percent and Russia with 6 percent. Russia, however, may have large deposits of heavy oil not referenced in available Western technical literature and thus may rank higher in heavy oil resources.

Canadian tar sand deposits

Tar sands. Tar sand deposits occur predominantly in the Western Hemisphere (Table 5, as modified from U.S. Geological Survey estimates). Three-quarters of the total world endowment of bitumen is estimated to occur in the Athabasca region of western Canada. The only two existing commercial bitumen-synthetic oil facilities are located

in the Athabasca River valley of Alberta. One-fifth of the world's bitumen is thought to be in Russia, mostly in the Volga-Urals and Siberian regions.

Status of the world's supply. The world's total original endowment of recoverable heavy oil has been estimated at about 467,500,000,000 barrels. Of this amount, only 14 percent has been produced (about 67,400,000,000 barrels) and only 20 percent (about 93,000,000,000 barrels) is thought to remain undiscovered. Accordingly, there is a known recoverable reserve of approximately 307,000,000,000 barrels, which can be compared with medium and light oil reserves of 1,119,000,000,000 barrels. As world oil production continues, the future concentration of conventional crude oil will increasingly favour the Middle East. Thus, the heavy oil resources, especially those of the Western Hemisphere and Russia, will continue to be exploited. The Middle East, too, has very significant heavy oil resources and has produced more heavy oil than any other region of the world. Such production also is expected to increase.

The world's total original endowment of recoverable bitumen has been estimated at about 354,000,000,000 barrels. Very little of this has so far been mined for upgrading to syncrude. Hence, the world's total recoverable heavy hydrocarbon component is about 661,000,000,000 barrels, compared with 1,119,000,000,000 barrels of medium and light crude oils. If undiscovered resources are added, the heavy hydrocarbons total 754,000,000,000 barrels and the light and medium oils 1,666,000,000,000 barrels. Some 2,420,000,000,000 barrels of crude oil remain from an original world endowment of 3,211,000,000,000 barrels, and heavy hydrocarbons make up almost one-third of the remaining world crude oil resources.

RECOVERY AND EXPLOITATION

Heavy oils. The recovery of heavy crude oils is impeded by a viscous resistance to flow at reservoir temperatures. The heating of heavy crudes markedly improves their mobility and promotes their recovery. Heat may be introduced into the reservoir by injecting a hot fluid, such as steam or hot water, or by burning some of the heavy oil in the reservoir (a process referred to as in situ combustion or fire flooding).

Heating of heavy oils

Steam soak. A common method involving the use of steam to recover heavy oil is known as steam soak, or steam cycling. It is essentially a well-bore stimulation technique in which steam generated in a boiler at the surface is injected into a production well for a number of weeks, after which the well is closed down for several days before being put back into production. In many cases there is a significant increase in output. It is sometimes economic to steam-soak the same well several times, even though heavy oil recovery usually declines with each succeeding treatment. Steam soaks are economically effective only in thick permeable reservoirs in which vertical (gravity) drainage can occur.

Steam flooding. Continuous steam injection heats a larger portion of the reservoir and achieves the most efficient heavy oil recoveries. Known as steam flooding, this technique is a displacement process similar to waterflooding. Steam is pumped into injection wells, which in some cases are artificially fractured to increase reservoir permeability, and the oil is displaced to production wells. Because of the relatively high cost of steam, water is sometimes injected at an optimum time to push the steam toward the production wells. Because the steam serves two functions, the heating and the transporting of the oil, some steam must always be circulated through the rock formation without condensing. Even in some of the most favourable reservoirs, it is necessary to consume an amount of energy equivalent to burning roughly 25 to 35 percent of the heavy oil produced in order to generate the required amount of steam.

In situ combustion. The mechanics of heavy oil displacement in an in situ combustion operation is similar to that in the steam-flooding process except for one difference. Unlike in the latter, steam is produced by vaporizing water already in the rock formation or water that has been injected therein with heat from the in situ combustion of some of the oil in the reservoir. After the in-place heavy oil has been ignited, the burning front is moved along by continuous air injection. In one variation of the in situ combustion process known as forward combustion, air is injected into a well so as to advance the burning front and heat and displace both the oil and formation water to surrounding production wells. A modified form of forward combustion incorporates the injection of cold water along with air to recover some of the heat that remains behind the combustion front. The air-water combination minimizes the amount of air injected and the amount of in-place oil burned (to between 5 and 10 percent). In another variation of in situ combustion called reverse combustion, a short-term forward burn is initiated by air injection into a well that will eventually produce oil, after which the air injection is switched to adjacent wells. This process is used for recovering extremely viscous oil that will not move through a cold zone ahead of a forward-combustion front.

The costs associated with the generation of heat within a heavy oil reservoir and the success of the recovery process are influenced by the depth of the reservoir. In general, shallower reservoirs are candidates for steam soaks and steam floods, deeper reservoirs for in situ combustion.

Solvent extraction. Solvent extractions also have been used to recover heavy oils. In this process a solvent or emulsifying solution is injected into a heavy oil reservoir. The fluid dissolves or emulsifies the oil as it advances through the permeable reservoir. The oil and fluid are then pumped to the surface through production wells. At the surface the oil is separated from the fluid, and the fluid is recycled.

Tar sands. The bitumen in tar sands can be recovered by surface mining. Open-pit mining methods can be employed where thick deposits occur near the surface. Earth-moving equipment is used to strip and stockpile the topsoil, remove and dispose of the overburden, and excavate the tar sand. The recovery efficiency of surface mining tar sands is estimated at roughly 90 percent. A mill is required to separate the bitumen from the sand in order to upgrade it to commercial quality. This process includes crushing the tar sand and separating the bitumen by mixing the crushed ore with steam and hot water. The bitumen is concentrated by floating and is then treated with a solvent for final separation from the sand and water. The cleaned crude bitumen is upgraded in a delayed coking unit, which produces a blend of lighter hydrocarbon fractions that yield synthetic crude oil, naphtha, kerosene, and gas oil. While there are a large number of heavy oil fields in production throughout the world, only two commercial tar sand surface-mining and synthetic-oil processing operations exist. Both are in western Canada.

Surface mining of tar sands

Economic and technical constraints. Unfortunately, there are problems associated with the exploitation of heavy hydrocarbons. Costs for tar sand mining and upgrading are considerably higher than for producing conventional oil, even in most frontier areas. The tar sand that is mined and milled along with the bitumen is very abrasive and causes rapid wear of equipment. Also, mills and upgrading (coking) facilities are very expensive.

Likewise, the heavy oils are a less desirable energy resource than the lighter crudes, for they are much more costly to extract and to process. An average of about one barrel of oil is combusted (or its energy equivalent expended) to produce the heat necessary to net two barrels of recovered heavy oil. This reduces the recoverable oil in a heavy oil reservoir by one-third.

If the heavy oil is transported by pipeline, direct heating is often required before it will flow at an acceptable rate, necessitating the combustion of additional fuel. The refining of heavy oil results in low yields of distillate products (*e.g.*, naphtha, kerosene, jet fuel, gasoline, oil, and diesel) and correspondingly high yields of sulfur and high-viscosity residues (*e.g.*, asphalt and coke) with metals concentrated in them.

Even under thermal stimulation, heavy oil production ranges only from about 5 to 100 barrels per day per well. This can be compared with recoveries in giant conventional oil fields on the order of 10,000 barrels per day per well. Consequently, even though heavy oil fields are exploited at much slower rates than conventional fields, many more wells are still required. This considerably increases development costs.

Oil shale

Oil shale is a sedimentary rock containing various amounts of solid organic material that yields hydrocarbons, along with a variety of solid products, when subjected to pyrolysis—a treatment that consists of heating the rock to about 500° C. The liquid oil extracted from oil shale as well as that derived from tar sands is referred to as syncrude. Most of the solid by-products of oil shale are unusable wastes, but a few of them have commercial value. These include sulfur, ammonia, alumina, soda ash, and nahcolite (a material that can be used in an industrial air-pollution control procedure known as stack-gas scrubbing).

Syncrude

HISTORY OF USE

Discovery and early application. The first notable reference to oil from shale was in 1596, when the personal physician of Duke Frederick of Württemberg mentioned that mineral oil distilled from oil shale could be used for healing. In 1694, during the reign of William and Mary, British Crown Patent No. 330 was granted to three subjects who had found "a way to extract and make great quantityes of pitch, tarr, and oyle out of a sort of stone." Also about this time, enough oil was actually produced by the distillation of oil shale to light the streets of Modena, Italy.

A commercial shale oil industry was founded in 1838 in Autun, Fr., to produce lamp fuel. By the middle of the 19th century the demand for oil was much greater than could be supplied by the whaling industry. As oil prices rose, numerous oil shale retorts were constructed along the Ohio River in the United States. The first one was built in 1855, but all of them had disappeared by 1860 because E.L. Drake's discovery of crude oil in Pennsylvania in 1859 (see above) opened the market to a cheaper source of oil. Oil shale was retorted in Canada from 1859 to 1861 on the shores of Lake Huron in southwestern Ontario but became economically unattractive with the discovery of crude oil nearby. In Scotland, however, a commercial shale oil industry began in 1862 and operated for about 100 years until the resource was depleted.

A number of other countries also developed oil shale processing facilities: Australia in 1865, Brazil in 1881, New Zealand in 1900, Switzerland in 1915, Sweden in 1921, Spain in 1922, and South Africa in 1935. By 1966, however, all these shale oil plants had closed.

In eastern Europe, oil shale retorting was initiated in Estonia in 1921. The process has been continued to the present, with a daily production of approximately 32,000 barrels of oil. An oil shale processing operation that opened in 1929 in Manchuria in northeastern China also is still producing. It yields an estimated 5,000 barrels of oil per day.

The western oil shales of the United States have been considered economically valuable for more than 70 years. During the mid-1800s, oil was burned and distilled locally from shale in Utah. In Colorado, shale oil was used as smudge in peach orchards about the end of the 19th century. No appreciable output of shale oil, however, was realized until the 1920s, when some 3,600 barrels were produced at a U.S. government plant at Rulison, Colo., and more than 12,000 barrels from a private industrial operation in Nevada. These facilities were closed by 1930 in the wake of the discovery of major conventional oil fields in Texas, Oklahoma, and California.

Modern importance. The shale oil industry reached its highest point of development immediately after World War II. At that time, however, plants were small, with capacities of only about 350 to 1,500 barrels of oil per day. Cost of production was high because of the labour necessary for mining and crushing the rock. During the 1950s the low cost of oil shipped from the Middle East made shale oil uneconomic, and the greatly increased consumption of oil made the amount of shale oil produced insignificant. Therefore, all shale oil plants throughout the world closed down between 1952 and 1966, with the exception of those in Estonia and Manchuria, where mining and economic conditions justified continued exploitation.

Competition with conventional oil

The cycles of competition between synthetic and conventional oil are related to discoveries of major conventional oil fields. The giant oil fields found in the Middle East after World War II virtually eliminated any remaining commercial interest in the production of shale oil until the energy shortages of the late 1960s and '70s. These shortages prompted several countries to survey their oil shale deposits in order to determine whether sufficient reserves were present to justify the large investments that would be needed to turn shale oil into a practical energy source.

Brazil and the United States developed pilot plants with which to exploit their deposits of oil shale: the Irati shales of Permian age in Brazil and the Green River shales of Eocene age (about 36,600,000 to 57,800,000 years old) in Colorado, Utah, and Wyoming. These two oil shale deposits are the largest in the world. The Brazilian national oil company, Petróleo Brasileiro (commonly called Petrobrás), developed a commercial shale oil extraction technology on the basis of work at a pilot plant that began operation since 1972. The operation was located at São Mateus do Sul in Paraná in southern Brazil. More than 1,500,000 barrels of shale oil and 20,000 tons of sulfur were extracted from over 3,500,000 tons of Irati oil shale before the project was canceled owing to the relatively low costs of conventional oil after the mid-1980s.

Since the early 1980s, shale oil development in the United States has also been limited in large part because of falling oil prices resulting from increased world crude oil production. The only completed plant capable of producing shale oil is the Unishale B retort in Parachute Creek, Colo. The plant is still in the testing phase, and only experimental amounts of shale oil have been produced. It has a projected capacity of about 10,400 barrels per day, however. In the United States, as in most other countries, shale oil development faces an uncertain future, at least until conventional oil resources are more nearly depleted.

(J.P.Ri./G.I.A.)

COMPOSITION, FORMATION, AND OCCURRENCE

Mineral and organic constituents. The mineral constituents of oil shales vary according to sediment type. Some are true shales in which clay minerals are predominant. Others, such as the Green River shales of the western United States, are carbonates (*e.g.*, dolomites and limestones) with subordinate amounts of other minerals. The various oil shales that have been mined during the past century have ranged from shale to marls and carbonates. The excluded sedimentary variety is sandstone, because the environment in which sandstones are deposited is not compatible with the accumulation and preservation of organic matter.

Kerogen

The organic matter contained in oil shales is principally kerogen, an insoluble solid material. The shales range from brown to black in colour. They have low specific weight and are flammable, burning with a sooty flame. Their external structure is laminar, and, in a stratigraphic section, alternating darker and lighter strata correspond to the periodic changes of organic content. Oil shales are quite resistant to the oxidizing effects of air. In terms of chemical composition, they consist primarily of silica, iron, aluminum, calcium, magnesium, sodium carbonates, silicates, oxides, and sulfides. The chemical composition of the organic matter in oil shales is variable, but the hydrogen content is always high. The oxygen content varies, as does the amount of nitrogen, which is much less abundant.

Formation. Some oil shale kerogens are composed almost entirely of algal remains, whereas others are a mixture of amorphous organic matter with a variable content of identifiable organic remnants. The main algal types are *Botryococcus* and *Tasmanites.*

Botryococcus is a fresh- or brackish-water alga that forms colonies. Permian kerogens from Autun, Fr., and Carboniferous and Permian torbanite from Scotland, Australia, and South Africa appear to consist almost exclusively of

Botryococcus colonies, as does Recent (post-Pleistocene) coorongite from Australia.

Tasmanites is a marine alga the remains of which make up nearly all the kerogen of such oil shales as the Permian tasmanite of Australia and the Jurassic-Cretaceous tasmanite of Alaska. The remains of *Tasmanites* also are present in many other shales, such as the Lower Toarcian shales (those about 190,000,000 years in age) of the Paris Basin in France and the Lower Silurian shales (those about 423,000,000 years in age) of Algeria.

Often only a minor part of the kerogen in oil shales is made of recognizable organic remnants. The rest is amorphous, probably because of microbial alteration during sedimentation. Amorphous organic material (sapropelic matter) associated with minerals constitutes thick accumulations of oil shale, such as the Permian Irati shales of Brazil and the Eocene Green River shales of the western United States. The organic material may have been derived from planktonic organisms (*e.g.*, algae, copepods, and ostracods) and from microorganisms (*e.g.*, bacteria and algae) that normally live in fresh sediment.

A characteristic typical of the various types of oil shale is a very fine lamination of thin alternating layers of minerals and organic matter. This lamination results from sedimentation in quiet waters in which either carbonates are precipitated from solution or clay minerals are transported as extremely fine detritus. Also, a succession of seasonal or other periodic events is suggested by the layering.

Green River shales

The geologic environment. A common geologic environment in which oil shales, often of considerable thickness, are deposited is large lake basins, particularly those of tectonic origin. Mineralogically, these oil shales are marls or argillaceous limestones, which may be associated with volcanic tuffs and evaporites. The major oil shale deposits of this type are the Green River shales of Eocene age in the western United States, along with the oil shales of Triassic age (about 208,000,000 to 245,000,000 years old) in Zaire and the Albert shales of Mississippian origin (roughly 320,000,000 to 360,000,000 years old) in New Brunswick, Can.

Oil shales deposited in shallow marine environments are thinner but of greater areal extent. The mineral phase is mostly clay and silica minerals, though carbonates also may occur. Extensive deposits of black shales of this variety were formed during the Cambrian Period (from about 505,000,000 to 540,000,000 years ago) in northern Europe and Siberia; the Silurian (about 408,000,000 to 438,000,000 years ago) in North America; the Permian (about 245,000,000 to 286,000,000 years ago) in southern Brazil, Uruguay, and Argentina; the Jurassic (about 144,000,000 to 208,000,000 years ago) in western Europe; and the Miocene Epoch of the Tertiary (about 5,300,000 to 23,700,000 years ago) in Italy, Sicily, and California.

Oil shales also have been deposited in small lakes, bogs, and lagoons where they are associated with coal seams. Deposits of this type occur in the Permian sequence of western Europe and in the Tertiary beds of Manchuria (Northeast), China.

WORLD OIL SHALE RESOURCES

Oil shales are found in many places throughout the world, yet worldwide shale oil development has been economically more attractive than conventional oil development for only a few brief periods in the 20th century. In earlier centuries oil shales were successfully exploited in a number of locations (see above).

The United States. Oil shale deposits that are commercially viable at present are the Estonian shales and the Manchurian shales in China. Nearly 60 percent of the world's potentially recoverable shale oil resource is concentrated, however, in the United States (Table 6). The aforementioned western and minable eastern oil shales of the United States have been estimated to contain an in-place oil resource of some 1,670,000,000,000 barrels. Using a 50 percent allowance for unrecoverable shale and a 25 percent allowance for conversion to synthetic fuel, the production potential for shale oil in the United States is estimated to be 626,000,000,000 barrels. The Mahogany Zone of the Parachute Creek Member of the Eocene Green River formation in the Piceance Basin of northwestern Colorado is a major target for future shale oil production. Estimated to contain some 59,000,000,000 barrels of recoverable shale oil, it is a thick, rich, consistent, saucer-shaped bed that outcrops around the edges of the basin, offering opportunities for mining by adits (nearly horizontal passages from the surface). At the centre of the basin the zone is more than 150 metres deep and accessible only by vertical or inclined shafts.

Total	626

*Recovery factor = 37.5 percent of estimated in-place resource. †In billion barrels; figures adapted from *Oil & Gas Journal*, U.S. Geological Survey, and American Association of Petroleum Geologists.

The western oil shales of the United States are richer than its eastern shales, yielding from 84 to 168 litres of raw shale oil for each metric ton of oil shale processed (from 20 to 40 U.S. gallons per short ton). The oil is relatively high in paraffins. Thus, with upgrading, it becomes an excellent refinery feedstock that is well suited to large yields of diesel and jet fuel.

Although the organic content of western and eastern oil shales is the same, the eastern shales yield only 34 to 63 litres of raw oil per metric ton of oil shale. Eastern shale oils are more aromatic and, when upgraded, are better suited as a feed for catalytic crackers in the production of gasoline.

Worldwide. Table 7 provides estimates of the world's recoverable shale oil as reported in the technical literature. Allowance is made for unrecoverable shale and for conversion to synthetic fuel. Brazil's oil shale resources are the world's second largest (28 percent of the total). Estonia, Russia, Zaire, Australia, Canada, Italy, and China also have significant oil shale resources. The world's total recoverable shale oil resource is estimated at some 1,067,000,000,000 barrels.

RECOVERY AND EXPLOITATION

Minimum organic requirement. As noted above, the organic matter in oil shales is kerogen, with no oil and little extractable bitumen naturally present. The kerogen of oil shale is not distinct from the kerogen of petroleum source rocks, and to some extent the pyrolysis process for extracting oil from oil shales is comparable to the burial of source rocks at depth and the subsequent formation of oil by the resulting elevation of temperature.

Nonetheless, oil shale must have a large amount of organic matter to be of commercial interest, larger than the

0.5 percent of organic carbon in a source rock from which commercial accumulations of oil or gas may be generated, provided that depth of burial, migration paths, and trapping mechanisms are favourable. The organic matter in a commercial oil shale must provide more energy than is required to process the shale. If the kerogen content of the shale is 2.5 percent by weight, its total calorific value is needed for processing. This is because at an average pyrolysis temperature of 500° C the energy required for heating is about 250 calories per gram of rock and the calorific value of kerogen is 10,000 calories per gram. Oil shale with a kerogen content below the threshold of 2.5 percent therefore cannot be employed as a source of energy. Frequently used is a lower limit of 5 percent organic content, which corresponds to an oil yield of approximately 25 litres per metric ton (6 U.S. gallons per short ton) of rock. Even this amount is not considered of potentially commercial grade in the United States, where 10 U.S. gallons per short ton (42 litres per metric ton) is often cited as a lower limit for oil shales.

Oil yield per ton

Recovery processes. *Pyrolysis.* The technology for producing oil from oil shale is based on pyrolysis of the rock. The heat breaks the various chemical bonds of the kerogen macromolecule, liberating small molecules of liquid and gaseous hydrocarbons, as well as nitrogen, sulfur, and oxygen compounds. However, since the shale quickly reaches a high temperature, industrial reactions are somewhat different from those that occur under natural subsurface conditions. Thus, liquid industrial products usually include a large proportion of olefins and sulfur and nitrogen compounds. Also, industrial gases may contain large amounts of hydrogen sulfide and ammonia.

Aboveground processing. Three basic steps are involved in the aboveground processing of oil shales—mining, crushing, and retorting (heating). Various retorting processes have been used over the years. The Pumpherston process, which involves external heating through the wall of the retort, was used in Scotland beginning in 1862. This process was widely employed with various refinements introduced later in continental Europe. The capacities of the retorting units, however, were low and energetic balances poor.

Combustion inside the retorting unit results in better energetic balances, but low-calorific gas diluted by nitrogen and combustion products results. This technique is used in Russia and China and is being tested in the United States. Still another method involves the circulation of externally heated gas through the shale. The resulting energetic balance is satisfactory, and the gas produced is of high calorific value. Used in France, this approach was adopted by Brazil and is the subject of experimentation in the United States.

An entirely new experimental process involves heating the shale with hot solids, which ensures a good energetic balance and a high calorific value of the gas produced. In certain parts of the world hot shale ashes are used as a calorific vehicle, while in the United States externally heated ceramic balls are employed. This technology is more complex than any of the others.

Subsurface processing. Subsurface processing differs from aboveground processing in that retorting to produce oil and gas takes place underground, or in situ. The oil shale is fractured underground by explosives and then heated by a controlled underground fire. Fuels produced from the heated oil shale are pumped to the surface and collected. Several in situ processes have been tested in the United States; they have resulted in both high and low rates of recovery efficiency.

Economic and technical constraints. An emerging shale oil industry faces many economic uncertainties, the most significant of which is the comparatively lower price of conventional oil development. The capital requirements for a commercial shale oil project range up to several billion U.S. dollars, making almost any conventional oil development, with comparable production, less expensive. Thus, it is unlikely that wide-scale exploitation of shale oil will occur until conventional and heavy oils are more nearly depleted.

High capital costs

Furthermore, technical difficulties remain in retorting. In the United States, for example, component design problems in the retorting process have hampered the operation of a commercial-scale, aboveground facility. Also, experiments with in situ retorting have resulted in quite varied recovery efficiencies.

In addition, the shale oil industry may be constrained by environmental factors. In semiarid regions, such as the western United States, limited water resources pose a problem because large amounts of water are required for the extraction process. Moreover, mining and processing may have adverse effects on groundwater and air quality. The vast amounts of rock material that have to be moved in a shale oil recovery operation also may adversely affect the integrity of the land, grazing and agricultural activities, and local fauna and flora.

There is little prospect of widespread oil shale exploitation in the near term. Such broad development must await more favourable economic conditions that would most likely be brought about by the depletion of conventional and heavy oil resources. Even then technological and environmental constraints would have to be dealt with. Oil shale could possibly become a major supplier of the world's energy but probably not until well into the 21st century. (J.P.Ri.)

Coal

Coal is a combustible rock that contains more than 50 percent by weight (or 70 percent by volume) carbonaceous matter produced by the compaction and induration of altered plant remains—namely, peat deposits. Different varieties of coal arise because of differences in the kinds of plant material (coal type), degree of coalification (coal rank), and range of impurities (coal grade). Coals are rich in carbon and are usually brown or black in colour. Most occur in stratified, sedimentary deposits; however, these deposits may later be subjected to elevated temperatures and pressures due to igneous intrusions or deformation during orogenesis (*i.e.*, processes of mountain building), resulting in the development of anthracite and even graphite. Although the concentration of carbon in the Earth's crust does not exceed 0.1 percent by weight, it is indispensable to life and constitutes humankind's main source of energy.

Variations among coals

HISTORY OF USE

Discovery and early application. *In ancient times.* The discovery of the use of fire helped to distinguish humans from other animals. Early fuels were primarily wood (and charcoal derived from it), straw, and dried dung. References to the early uses of coal are meagre. Aristotle referred to "bodies which have more of earth than of smoke" and called them "coal-like substances." (It should be noted that biblical references to coal are to charcoal rather than to the rock, coal.) Coal was used commercially by the Chinese long before it was utilized in Europe. Although no authentic record is available, coal from the Fu-shun mine in northeastern China may have been employed to smelt copper as early as 1000 BC. Cast-iron Chinese coins dating to about the 1st century BC are thought to have been made using coal. Stones used as fuel were said to have been produced in China during the Han dynasty (206 BC–AD 220).

In Europe. Coal cinders found among Roman ruins in England suggest that the Romans were familiar with its use before AD 400. The first documented proof that coal was mined in Europe was provided by the monk Reinier of Liège, who wrote (about 1200) of black earth very similar to charcoal used by metalworkers. Many references to coal mining in England, Scotland, and the European continent began to appear in the writings of the 13th century. Coal was, however, used only on a limited scale until the early 18th century when Abraham Darby of England and others developed methods of using coke made from coal in blast furnaces and forges. Successive metallurgical and engineering developments—most notably the invention of the coal-burning steam engine by James Watt—engendered an almost insatiable demand for coal.

Coke

In the New World. Up to the time of the American

Revolution, most coal used in the American colonies came from England or Nova Scotia. Wartime shortages and the needs of the munitions manufacturers, however, spurred on small American coal-mining operations such as those in Virginia on the James River near Richmond. By the early 1830s mining companies had emerged along the Ohio, Illinois, and Mississippi rivers and in the Appalachian regions. As in European countries, the introduction of the steam locomotive gave the American coal industry a tremendous impetus. Continued expansion of industrial activity in the United States and in Europe further promoted the use of coal.

Modern utilization. *As an energy source.* Coal is an abundant natural resource that can be used as a source of energy, as a chemical feedstock from which numerous synthetic compounds (*e.g.*, dyes, oils, waxes, pharmaceuticals, and pesticides) can be derived, and in the production of coke for metallurgical processes. Coal is presently a major source of energy in the production of electrical power using steam generation. In addition, gasification and liquefaction produce gaseous and liquid fuels that can be easily transported (*e.g.*, by pipeline) and conveniently stored in tanks.

Conversion. In general, coal can be considered a hydrogen-deficient hydrocarbon with a hydrogen-to-carbon ratio near 0.8, as compared with a liquid hydrocarbons ratio near 2 and a gaseous hydrocarbons ratio near 4. For this reason, any process used to convert coal to alternative fuels must add hydrogen (either directly or in the form of water). Gasification refers to the conversion of coal to a mixture of gases, including carbon monoxide, hydrogen, methane, and other hydrocarbons, depending on the conditions involved. Gasification may be accomplished either in situ or in processing plants. In situ gasification is accomplished by controlled, incomplete burning of a coal bed underground while adding air and steam. The gases are withdrawn and may be burned to produce heat, generate electricity, or be used as synthesis gas in indirect liquefaction or the production of chemicals.

Liquefaction may be either direct or indirect (*i.e.*, by using the gaseous products obtained by breaking down the chemical structure of coal). Four general methods are used for liquefaction: (1) pyrolysis and hydrocarbonization (coal is heated in the absence of air or in a stream of hydrogen), (2) solvent extraction (coal hydrocarbons are selectively dissolved and hydrogen is added to produce the desired liquids), (3) catalytic liquefaction (hydrogenation takes place in the presence of a catalyst—for example, zinc chloride), and (4) indirect liquefaction (carbon monoxide and hydrogen are combined in the presence of a catalyst).

Problems associated with the use of coal. *Hazards of mining and preparation.* Coal is very abundant; estimates of reserves indicate that enough coal remains to last for many hundreds of years. There is, however, a variety of problems associated with the use of coal. Mining operations are hazardous. Each year hundreds of coal miners lose their lives or are seriously injured. Major mine hazards include roof falls, rock bursts, and fires and explosions. The latter result when flammable gases (such as methane) trapped in the coal are released during mining operations and accidentally are ignited. Promising research in the extraction of methane from coal beds prior to mining is expected to lead to safer mines and provide a source of natural gas that has been wasted for so long. Also, the repeated inhalation of coal dust over extended periods of time can result in serious health problems, as, for example, anthracosis (commonly called black lung disease).

Environmental problems

Coal mines and coal-preparation plants caused much environmental damage in the past (Figure 8). Surface areas exposed during mining, as well as coal and rock waste (which were often dumped indiscriminately), weathered rapidly, producing abundant sediment and soluble

From *The Direct Use of Coal*, Prospects and Problems of Production and Combustion, 1979, Office of Technology Assessment, Washington, D.C.

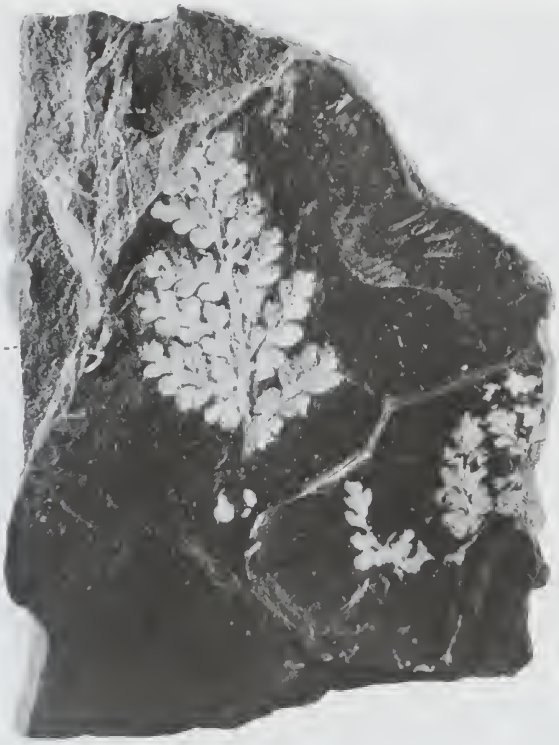

Figure 9: Lignite coal with fern fossilization.
Runk/Schoenberger—Grant Heilman

chemical products such as sulfuric acid and iron sulfates. Nearby streams became clogged with sediment, iron oxides stained rocks, and "acid mine drainage" caused marked reductions in the numbers of plants and animals living in the vicinity. Potentially toxic elements, leached from the exposed coal and adjacent rocks, were released into the environment. Since the 1970s, however, stricter laws have significantly reduced the environmental damage caused by coal mining.

Hazards of utilization. Coal utilization also can cause problems. During the incomplete burning or conversion of coal, many compounds are produced, some of which are carcinogenic. The burning of coal also produces sulfur and nitrogen oxides that react with atmospheric moisture to produce sulfuric and nitric acids—so-called acid rain. In addition, it produces particulate matter (fly ash) that can be transported by winds for many hundreds of kilometres and solids (bottom ash and slag) that must be disposed of. Trace elements originally present in the coal may escape as volatiles (*e.g.*, chlorine and mercury) or be concentrated in the ash (*e.g.*, arsenic and barium). Some of these pollutants can be trapped by using such devices as electrostatic precipitators, baghouses, and scrubbers. Current research on alternative means for combustion (*e.g.*, fluidized bed combustion, magnetohydrodynamics, and low nitrogen dioxide burners) is expected to provide efficient and environmentally attractive methods for extracting energy from coal. Regardless of the means used for combustion, acceptable ways of disposing of the waste products have to be found. Finally, the burning of all fossil fuels (oil and natural gas included) releases large quantities of carbon dioxide (CO_2) into the atmosphere. The CO_2 molecules allow the shorter-wavelength rays from the Sun to enter the atmosphere and strike the Earth's surface, but they do not allow much of the long-wave radiation reradiated from the surface to escape into space. The CO_2 absorbs this upward-propagating infrared radiation and reemits a portion of it downward, causing the lower atmosphere to remain warmer than it would otherwise be. This is the so-called greenhouse effect. (Other gases, such as methane and ozone, are also greenhouse gases.) Whether higher concentrations of CO_2 in the atmosphere will in fact lead to significant climatic changes has not yet been clearly established, but it is a matter of considerable concern among scientists. A rise in the Earth's mean annual temperature of only a few degrees Celsius could cause melting of enough glacial ice to inundate coastal areas. Technologies being considered to reduce carbon dioxide levels include biological fixation, cryogenic recovery, disposal in the oceans and aquifers, and conversion to methanol.

ORIGIN

Coal-forming materials. *Plant matter.* It is generally accepted that most coals formed from plants that grew in and adjacent to swamps in warm, humid regions. Material derived from these plants accumulated in low-lying areas that remained wet most of the time and was converted to peat through the activity of microorganisms. (It should be noted that peat can occur in temperate regions [*e.g.*, Ireland and the state of Michigan in the United States] and even in subarctic regions [*e.g.*, the Scandinavian countries].) Under certain conditions this organic material continued to accumulate and was later converted into coal. Much of the plant matter that accumulates on the surface of the Earth is never converted to peat or to coal, because it is removed by fire or organic decomposition. Hence, the vast coal deposits found in ancient rocks must represent periods during which several favourable biological and physical processes occurred at the same time.

Evidence of plant origin

Evidence that coal was derived from plants comes from three principal sources. First, lignites, the lowest coal rank, often contain recognizable plant remains (Figure 9). Second, sedimentary rock layers above, below, and adjacent to coal seams contain plant fossils in the form of impressions and carbonized films (*e.g.*, leaves and stems) and casts of larger parts such as roots, branches, and trunks. Third, even coals of advanced rank may reveal the presence of precursor plant material. When examined microscopically in thin sections or polished blocks, cell walls, cuticles (the outer wall of leaves), spores, and other structures can still be recognized (see below *Genesis of macerals and rock types*). Algal and fungal remains also may be present. (Algae are major components in boghead coal, which appears to be transitional between coal and petroleum.)

The fossil record. Anthracite (the highest coal rank) material, which appears to have been derived from plants, is known from the Proterozoic of Precambrian times (beginning approximately 2,500,000,000 years ago). Siliceous rocks of the same age contain fossil algae and fungi. These early plants were primarily Protista (solitary or aggregate unicellular organisms that include yellow-green algae, golden-brown algae, and diatoms), which lived in aqueous environments. It was not until the Late Silurian Period (from 408,000,000 to 421,000,000 years ago) that plants are known to have developed the ability to survive on land. Fossil organisms that are reflective of this dramatic evolutionary event have been discovered in Wales and Australia.

Evidence for early coastal forests is preserved in strata of Late Devonian age (about 360,000,000 to 374,000,000 years old). By the latter half of the Paleozoic Era, plants had undergone extensive evolution and occupied many previously vacant environments (this phenomenon is sometimes called adaptive radiation).

Major eras of coal formation

There were two major eras of coal formation in geologic history. The older includes the Carboniferous Period (sometimes divided into the Mississippian and Pennsylvanian periods, from approximately 286,000,000 to 360,000,000 years ago) and the Permian Period (from about 245,000,000 to 286,000,000 years ago). Much of the bituminous coal of eastern North America and Europe is Carboniferous in age. Most coals in Siberia, eastern Asia, and Australia are of Permian origin. The younger era began about 135,000,000 years ago during the Cretaceous Period and reached its peak during the Tertiary Period (about 1,600,000 to 66,400,000 years ago) of the Cenozoic. Most of the coals that formed during this second era are lignites and subbituminous (or brown) coals. These are widespread in such areas as western North America (including Alaska), southern France and central Europe, Japan, and Indonesia.

Late Paleozoic flora included sphenopsids, lycopsids, pteropsids, and Cordaitales. The sphenopsid, *Calamites,* grew as trees in swamps (see Figure 10). *Calamites* had

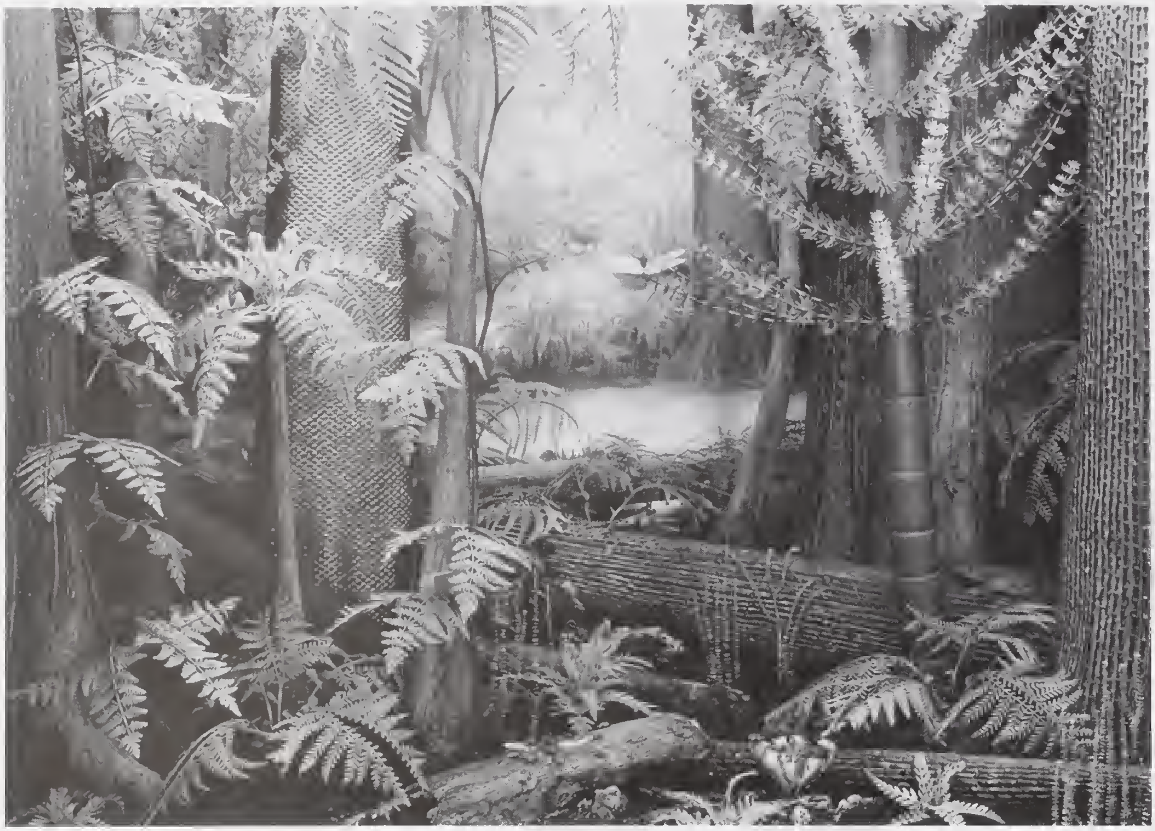

Figure 10: *Pennsylvanian coal forest diorama.*
The lone tree (*Calamites*) with horizontal grooves in the right foreground is a jointed sphenopsid; the large trees with scar patterns are lycopsids.

long, jointed stems with sparse foliage. The lycopsids included species of *Lepidodendron* and *Sigillaria* (up to 30 metres tall) that grew in somewhat drier areas. Pteropsids included both true ferns (Filicineae) and extinct seed ferns (Pteridospermaphyta), which grew in relatively dry environments. The Cordaitales, which had tall stems and long, narrow, palmlike leaves, also favoured drier areas. During the Cretaceous and Cenozoic the angiosperms (flowering plants) evolved, producing a diversified flora from which the younger coals developed.

Formation processes. *Peat.* Although peat is used as a source of energy, it is not usually considered a coal. It is the precursor material from which coals are derived, and the process by which peat is formed is studied in existing swamps in many parts of the world (*e.g.,* the Okefenokee Swamp of Georgia). The formation of peat is controlled by several factors including (1) the evolutionary development of plant life, (2) the climatic conditions (warm enough to sustain plant growth and wet enough to permit the partial decomposition of the plant material and preserve the peat), and (3) the physical conditions of the area (its geographic position relative to the sea or other bodies of water, rates of subsidence or uplift, and so forth). Warm, moist climates are thought to produce broad bands of bright coal. Cooler, temperate climates, on the other hand, are thought to produce detrital coal with relatively little bright coal.

Conditions for peat formation

Initially, the area on which a future coal seam may be developed must be uplifted so that plant growth can be established. Areas near seacoasts or low-lying areas near streams stay moist enough for peat to form, but elevated swamps (some bogs and moors) can produce peat only if the annual precipitation exceeds annual evaporation and little percolation or drainage occurs. Thick peat deposits necessary for coal formation develop at sites where the following conditions exist: slow, continuous subsidence; the presence of such natural structures as levees, beaches, and bars that give protection from frequent inundation; and a restricted supply of incoming sediments that would interrupt peat formation. In such areas the water may become quite stagnant (except for a few rivers traversing the swamp), and plant material can continue to accumulate. Microorganisms attack the plant material and convert it to peat. Very close to the surface where oxygen is still readily available (aerobic, or oxidizing, conditions), the decomposition of the plant material produces mostly gaseous and liquid products. With increasing depth, however, the conditions become increasingly anaerobic (reducing), and molds and peats develop. The process of peat formation—biochemical coalification—is most active in the upper few metres of a peat deposit. Fungi are not found below about 0.5 metre, and most forms of microbial life are eliminated at depths below about 10 metres. If the rate of subsidence and/or the rate of influx of new sediment increases,

the peat will be buried and soon thereafter the coalification process—geochemical coalification—begins. The cycle may be repeated many times, which accounts for the numerous coal seams found in some sedimentary basins.

Coalification. The general sequence of coalification is from lignite to subbituminous to bituminous to anthracite (see below *Ranking by coalification*). Since microbial activity ceases within a few metres of the Earth's surface, the coalification process must be controlled primarily by changes in physical conditions that take place with depth. Some coal characteristics were determined by events that occurred during peat formation—*e.g.*, charcoallike material in coal is attributed to fires that occurred during dry periods while peat was still forming.

Effects of heat and pressure over time

Three major physical factors—duration, increasing temperature, and increasing pressure—may influence the coalification process. In laboratory experiments artificially prepared coals are influenced by the duration of the experiment, but in nature the length of time is substantially longer and the overall effect of time remains undetermined. Low-rank (*i.e.*, brown) coal in the Moscow Basin was deposited during Carboniferous time but was not buried deeply and never reached a higher rank. The most widely accepted explanation is that coalification takes place in response to increasing temperature. In general, temperature increases with depth. This geothermal gradient averages about 30° C per kilometre, but the gradient ranges from less than 10° C per kilometre in regions undergoing very rapid subsidence to more than 100° C per kilometre in areas of igneous activity. Measurements of thicknesses of sedimentary cover and corresponding coal ranks suggest that temperatures lower than 200° C were sufficient to produce coal of anthracite rank. The effect of increasing pressure due to depth of burial is not considered to cause coalification. In fact, increasing overburden pressure might have the opposite effect if such volatile compounds as methane that must escape during coalification are retained. Pressure may influence the porosity and moisture content of coal.

COAL TYPES AND RANKS

Coals may be classified in several ways. One mode of classification is by coal type; such types have some genetic implications because they are based on the organic materials present and the coalification processes that produced the coal. The most useful and widely applied coal classification schemes are those based on the degree to which coals have undergone coalification. Such varying degrees of coalification are generally called coal ranks (or classes). In addition to the scientific value of classification schemes of this kind, the determination of rank has a number of practical applications. Many coal properties are in part determined by rank, including the amount of heat produced during combustion, the amount of gaseous products released upon heating, and the suitability of the coals for liquefaction or for producing coke.

Coal types. *Macerals.* Coals contain both organic and inorganic phases. The latter consist either of minerals such as quartz and clays that may have been brought in by flowing water (or wind activity) or of minerals such as pyrite and marcasite that formed in place (authigenic). Some formed in living plant tissues, while others formed later during peat formation or coalification. Some pyrite (and marcasite) is present in micrometre-sized spheroids called framboids (from their raspberry-like shape) that formed quite early. Framboids are very difficult to remove by conventional coal-cleaning processes.

By analogy to the term mineral, Marie C. Stopes of Great Britain (1935) proposed the term maceral to describe organic constituents present in coals. The word is derived from the Latin *macerare,* meaning "to macerate." (Mineral names often end in "-ite." The corresponding ending for macerals is "-inite.") Maceral nomenclature has been applied differently by some European coal petrologists who studied polished blocks of coal using reflected-light microscopy (their terminology is based on morphology, botanical affinity, and mode of occurrence) and by some North American petrologists who studied very thin slices (thin sections) of coal using transmitted-light microscopy. Various nomenclature systems have been used. A comparison of common coal maceral terms is given in Table 8, and typical macerals are shown in Figure 11.

Vitrinites, exinites, and inertinites

Three major maceral groups are generally recognized: vitrinite, exinite, and inertinite. The vitrinite group is the most abundant, constituting as much as 50 to 90 percent of many North American coals. Vitrinites are derived

Table 9: Coal Type According to Appearance and Composition

type	main components	opaque attritus percent
Banded coal (>5 percent anthraxylon)		
Bright-banded	anthraxylon and translucent attritus	< 20
Semisplint	translucent and opaque attritus	20–30
Splint	opaque attritus	> 30
Nonbanded coal (<5 percent anthraxylon)		
Cannel	attritus with spores	
Boghead	attritus with algae	

primarily from cell walls and woody tissues. They show a wide range of reflectance values (discussed below), but in individual samples these values tend to be intermediate compared with those of the other maceral groups. Several varieties are recognized—*e.g.*, telinite (the brighter parts of vitrinite that make up cell walls) and collinite (clear vitrinite that occupies the spaces between cell walls).

The exinite (or liptinite) group makes up 5 to 15 percent of many coals. Exinites are derived from waxy or resinous plant parts, such as cuticles, spores, and wound resins. Their reflectance values are usually the lowest in an individual sample. Several varieties are recognized, including sporinite (spores typically preserved as flattened spheroids), cutinite (part of cross sections of leaves, often with crenulated surfaces), and resinite (ovoid and sometimes translucent masses of resin). The exinites may fluoresce under ultraviolet light, but with increasing rank their optical properties approach those of the vitrinites, and they become indistinguishable.

The inertinite group makes up from 5 to 40 percent of most coals. Their reflectance values are usually the highest in a given sample. The most common inertinite maceral is fusinite, which has a charcoallike appearance with obvious cell texture. The cells may be either empty or filled with mineral matter, and the cell walls may have been crushed during compaction (bogen texture; Figure 11). Inertinites are strongly altered or degraded plant material that is thought to have been produced during the formation of peat; for example, charcoal produced by a fire in a peat swamp is preserved as fusinite.

Coal rock types. Coals may be classified on the basis of their macroscopic appearance (generally referred to as coal rock type, lithotype, or kohlentype). Four main types are recognized: (1) vitrain (*Glanzkohle* or *charbon brillant*), which is dominated by vitrinite group macerals and appears glassy to the unaided eye, (2) clarain (*Glanzstreifenkohle* or *charbon semi-brillant*), which is composed of both vitrinite and exinite and has an appearance between that of vitrain and durain, (3) durain (*Mattkohle* or *charbon mat*), which is generally composed of fine-grained inertinites and exinites and has a dull, matlike lustre, and (4) fusain (*Faserkohle* or *charbon fibreux*), which is composed mainly of fusinite and resembles wood charcoal (because it soils the hands just as charcoal would).

Banded and nonbanded coals. The term coal type is also employed to distinguish between banded coals and nonbanded coals. Banded coals contain varying amounts of vitrinite and opaque material. They include bright coal, which contains more than 80 percent vitrinite, and splint coal, which contains more than 30 percent opaque matter. The nonbanded varieties include boghead coal, which has a high percentage of algal remains, and cannel coal with a high percentage of spores. The usage of all the above terms is quite subjective.

Ranking by coalification. *Hydrocarbon content.* The oldest coal-classification system was based on criteria of chemical composition. Developed in 1837 by the French chemist Henri-Victor Regnault, it was improved in later systems that classified coals on the basis of their hydrogen and carbon content. However, because the relationships between chemistry and other coal properties are complex, such classifications are rarely used for practical purposes today.

Chemical content and properties. The most commonly employed systems of classification are those based on analyses that can be performed relatively easily in the laboratory, as, for example, determining the percentage of volatile matter lost upon heating to about 950° C or the amount of heat released during combustion of the coal under standard conditions. Table 10 lists the ranks

*Moist coal contains natural inherent moisture but does not include visible water on the surface. †If agglomerating, classify in low-volatile group of the bituminous rank. ‡Coals having 69 percent or more fixed carbon on the dry, mineral-matter-free basis are classified by fixed carbon, regardless of calorific value. §There may be nonagglomerating varieties in these groups of the bituminous rank, there are also notable exceptions in the high-volatile C bituminous group.

Source: *1993 Annual Book of ASTM Standards*, section 5, volume 5.05.

The ASTM system

assigned to coals by the American Society for Testing and Materials (ASTM) on the basis of fixed carbon content, volatile matter content, and calorific value. In addition to the major ranks (lignite, subbituminous, bituminous, and anthracite), each rank may be subdivided into coal groups, such as high-volatile A bituminous coal. Other designations, such as coking coal and steam coal, have been applied to coals, but they tend to differ from country to country.

Coal analyses may be presented in the form of "proximate" (a term derived from the word "approximate") and "ultimate" analyses, whose analytic conditions are prescribed by organizations such as the ASTM. A typical proximate analysis includes the moisture, ash, volatile matter, and fixed carbon contents. (Fixed carbon is the material, other than ash, that does not vaporize when heated in the absence of air. It is usually determined by subtracting the sum of the first three values—moisture, ash, and volatile matter—in weight percent from 100 percent.) It is important for economic reasons to know the moisture and ash contents of a coal because they do not contribute to the heating value of a coal. In most cases ash becomes an undesirable residue and a source of pollution, but for some purposes (*e.g.*, use as a chemical feedstock or for liquefaction) the presence of mineral matter may be desirable. Most of the heat value of a coal comes from its volatile matter, excluding moisture, and fixed carbon content. For most coals, it is necessary to measure the actual amount of heat released upon combustion (expressed in British thermal units [BTUs] per pound or megajoules per kilogram).

Ultimate analyses are used to determine the carbon, hydrogen, sulfur, nitrogen, ash, oxygen, and moisture contents of a coal. For specific applications, other chemical analyses may be employed. These may involve, for example, identifying the forms of sulfur present; sulfur may occur in the form of sulfide minerals (pyrite and marcasite), sulfate minerals (gypsum), or organically bound sulfur. In other cases the analyses may involve determining the trace elements present (*e.g.*, mercury, chlorine), which may influence the suitability of a coal for a particular purpose or help to establish methods for reducing environmental pollution and so forth.

Virtually all classification systems use the percentage of volatile matter present to distinguish coal ranks. In the ASTM classification (Table 10), high-volatile A bituminous (and higher ranks) are classified on the basis of their volatile matter content. Coals of lower rank are classified primarily on the basis of their heat values, because of their wide ranges in volatile matter content (including moisture). The so-called agglomerating character of a coal refers to its ability to soften and swell when heated and to form cokelike masses that are used in the manufacture of steel. The most suitable coals for agglomerating purposes are in the bituminous rank.

STRUCTURE AND PROPERTIES

Volatile matter and fixed carbon

Organic compounds. The plant material from which coal is derived is composed of a complex mixture of organic compounds, including cellulose, lignin, fats, waxes, and tannins. As peat formation and coalification proceed, these compounds, which have more or less open structures, are broken down, and new compounds—primarily aromatic and hydroaromatic—are produced. These compounds are connected by cross-linking oxygen, sulfur, and molecules such as methylene. Some researchers refer to this complex array of cross-linked molecules as a "coal molecule." During coalification, volatile phases rich in hydrogen and oxygen (*e.g.*, water, carbon dioxide, and methane) are produced and escape from the mass; hence, the coal becomes progressively richer in carbon. The classification of coal by rank is based on these changes—*i.e.*, as coalification proceeds, the amount of volatile matter gradually decreases and the amount of fixed carbon increases. As volatiles are expelled, more carbon-to-carbon linkages occur in the remaining coal until, having reached the anthracite rank, it takes on many of the characteristics of the end product of the metamorphism of carbonaceous material—namely, graphite. Coals pass through several structural states, including a glassy (or "liquid") state, as the bonds between the aromatic (benzenelike compounds) nuclei increase.

Properties. Many of the properties of coal are strongly rank-dependent, although other factors such as maceral composition and the presence of mineral matter also influence its properties. Several techniques have been developed for studying the physical and chemical properties of coal, including density measurements, X-ray diffraction, scanning and transmission electron microscopy, infrared spectrophotometry, mass spectroscopy, gas chromatography, thermal analysis, and electrical, optical, and magnetic measurements.

Density. Knowledge of the physical properties of coal is important in coal preparation and utilization. For example, coal density ranges from approximately 1.1 to about 1.5 megagrams per cubic metre, or grams per cubic centimetre (1 megagram per cubic metre equals 1 gram per cubic centimetre). Coal is slightly denser than water (1.0 megagram per cubic metre) and significantly less dense than most rock and mineral matter (*e.g.*, shale has a density of about 2.7 megagrams per cubic metre and pyrite of 5.0 megagrams per cubic metre). Density differences make it possible to improve the quality of a coal by removing

most of the rock matter and sulfide-rich fragments by means of heavy liquid separation (fragments with densities greater than about 1.5 megagrams per cubic metre settle out while the coal floats on top of the liquid) and devices such as cyclones and shaker tables, which also separate coal particles from rock and pyrite on the basis of their different densities.

Porosity. Coal density is controlled in part by the presence of pores that persist throughout coalification. Measurement of pore sizes and pore distribution is difficult; however, there appear to be three size ranges of pores: (1) macropores (diameter greater than 50 nanometres), (2) mesopores (diameter 2 to 50 nanometres), and (3) micropores (diameter less than 2 nanometres). (One nanometre is equal to 10^{-9} metre.) Most of the effective surface area of a coal—about 200 square metres per gram—is not on the outer surface of a piece of coal but is located inside the coal in its pores. The presence of pore space is important in the production of coke, gasification, liquefaction, and the generation of high-surface-area carbon for purifying water and gases. From the standpoint of safety, coal pores may contain significant amounts of adsorbed methane that may be released during mining operations and form explosive mixtures with air. The risk of explosion can by reduced by adequate ventilation during mining or by prior removal of coal-bed methane.

Reflectivity. One of the most important property of coal is its reflectivity (or reflectance)—*i.e.*, its ability to reflect light. Reflectivity is measured by shining a beam of monochromatic light (with a wavelength of 546 nanometres) on a polished surface of the vitrinite macerals in a coal sample and measuring the percentage of the light reflected with a photometer. Vitrinite is used because its reflectivity changes gradually with increasing rank. Fusinite reflectivities are too high due to its origin as charcoal, and exinites tend to disappear with increasing rank. Although little of the incident light is reflected (ranging from a few tenths of a percent to 10 to 12 percent), the value increases with rank and can be used to determine the rank of most coals indirectly (*i.e.*, without measuring the percentage of volatile matter). Typical reflectivity values are shown in Table 11.

The study of coals (and coaly particles called phyterals) in sedimentary basins containing oil and/or gas reveals a close relationship between coalification and the maturation of liquid and gaseous hydrocarbons (Table 11). During the initial stages of coalification (to a reflectivity of almost 0.5 and near the boundary between subbituminous and high-volatile C bituminous coal), hydrocarbon generation produces chiefly methane. The maximum generation of liquid petroleum occurs during the development of high-volatile bituminous coals (in the reflectivity range from roughly 0.5 to about 1.3). With increasing depth and temperature, petroleum liquids break down and, finally, only natural gas (methane) remains. Geologists can use coal reflectivity to anticipate the potential for finding liquid or gaseous hydrocarbons as they explore for petroleum.

Relationship between coalification and petroleum formation

Other properties. Other properties, such as hardness, grindability, ash-fusion temperature, and free-swelling index (a visual measurement of the amount of swelling that occurs when a coal sample is heated in a covered crucible), may affect coal mining and preparation, as well as the way in which a coal is utilized. Hardness and grindability determine the kinds of equipment used for mining, crushing, and grinding coals in addition to the amount of power consumed in their operation. Ash-fusion temperature influences furnace design and operating conditions. The free-swelling index provides preliminary information concerning the suitability of a coal for coke production.

WORLD DISTRIBUTION OF COAL

General occurrence. Coal is a widespread resource of energy and chemicals. Although terrestrial plants necessary for the development of coal did not become abundant until Carboniferous time, large sedimentary basins containing Carboniferous and younger rocks are known on virtually every continent (see Figure 12), including Antarctica (not shown on the map). The presence of coal deposits in regions that now have arctic or subarctic climates (such as Alaska and Siberia) is due to climatic changes and to the tectonic motion of crustal plates that moved ancient continental masses over the Earth's surface, sometimes through subtropical and even tropical regions. The absence of coal in the unshaded map areas (such as Greenland and

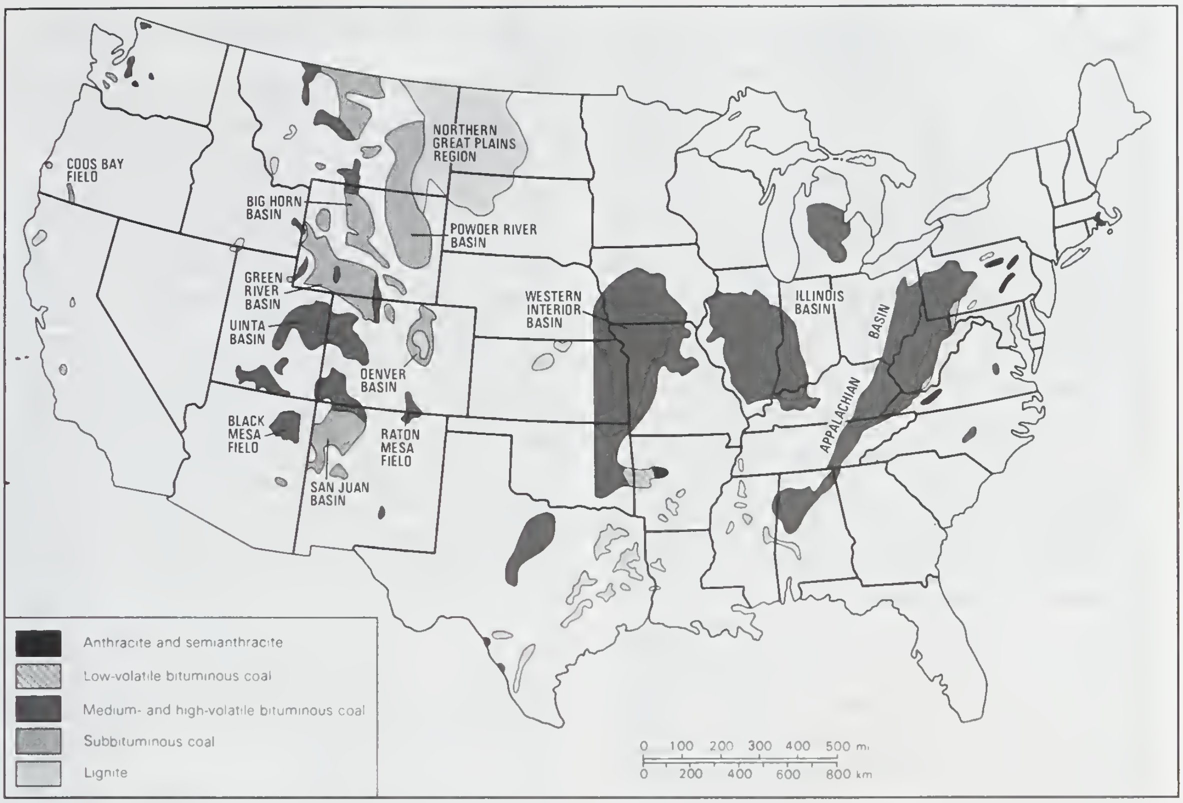

Figure 13: Coal-bearing areas of the conterminous United States.

Adapted from "Coal-Bearing Areas of the United States," *Coal Production 1985*, U.S. Energy Information Administration, 1985 and "Organic Fuel Deposits," *The National Atlas of the United States of America*, U.S. Department of Interior, 1970

much of northern Canada) results from the fact that the rocks found there are older than Carboniferous age and that these regions, known as shields, lacked the abundant terrestrial plant life needed for the formation of major coal deposits.

Resources and reserves. World coal resources are difficult to assess. Although some of the difficulty stems from the lack of accurate data on coal reserves and production figures for individual countries, two fundamental problems make estimates of worldwide reserves and production difficult and subjective.

Difficulty of defining reserves

The first problem concerns the definition of the term reserves. Ideally the reserves for any commodity, including coal, should provide a reasonably accurate estimate of the total recoverable amount. To be economically minable, a coal bed must have some minimum thickness (about 0.6 metre) and be buried less than some maximum depth (roughly 2,000 metres) below the Earth's surface. These values of thickness and depth are not fixed but change with the coal quality, demand, the ease with which overlying rocks can be removed (in surface mining) or a shaft sunk to reach the coal seam (in underground mining), and so forth. The development of new mining techniques can increase the amount of coal extracted relative to the amount that cannot be removed. For example, in underground mining (which accounts for about 60 percent of world coal production), conventional mining methods leave behind large pillars of coal to support the overlying rocks and may recover only about 50 percent of the coal present. On the other hand, longwall mining, in which the equipment removes continuous parallel bands of coal, may recover nearly all of the coal present.

Table 12: World Coal Resources and Reserves, by Major Coal-Producing Countries*

country	geologic resources	technically and economically recoverable reserves
Australia†	600,000	32,800
Canada†	323,036	4,242
China†	1,438,045	98,883
Germany†	246,800	34,419
India†	81,019	12,427
Poland†	139,750	59,600
South Africa	72,000	43,000
United Kingdom†	190,000	45,000
United States†	2,570,398	166,950
Russia, Ukraine, and Kazakhstan	4,860,000	109,900
Other countries	229,164	55,711
Total world	10,750,212	662,932

*In mtce, a unit of measure equaling 1,000,000 tons of coal equivalent.
†Participants of the World Coal Study (WOCOL).
Sources: World Energy Conference, WOCOL Country Reports, and Simon Walker, *Major Coalfields of the World* (1993).

The second problem concerning the estimation of reserves is the rate at which a commodity is consumed. When considering coal as a resource, the number of years that coal will be available may be more important than the total amount of coal reserves. Estimates of how long coal reserves will last range from a few hundred years to more than 1,000 years, depending on technological developments and assumed rates of consumption.

Table 12 indicates the extent of world coal resources using a simple twofold division: (1) geologic resources, including all coal resources whether recoverable or not, and (2) technically and economically recoverable reserves. Note that the latter category constitutes less than 10 percent of the estimated total world coal. The amounts in the table are given in million tons of coal equivalent. One ton of coal equivalent equals 1 metric ton (2,205 pounds) of coal with a heating value of 29.3 megajoules per kilogram (12,600 BTUs per pound). The estimates in Table 12 suggest that the United States has the largest amount of recoverable coal. (The coalfields of the conterminous United States are shown in Figure 13.) Nearly 60 percent of the world's recoverable coal resources are controlled by the United States, the former Soviet republics of Russia, Ukraine, and Kazakhstan, and China. (O.C.K.)

BIBLIOGRAPHY

Oil and natural gas. ROBERT H. DOTT, SR., and MERRILL J. REYNOLDS (comps.), *Sourcebook for Petroleum Geology* (1969), is an excellent collection of petroleum-geology scientific concepts. EDGAR WESLEY OWEN, *Trek of the Oil Finders: A History of Exploration for Petroleum* (1975); and HAROLD F. WILLIAMSON and ARNOLD R. DAUM, *The American Petroleum Industry*, 2 vol. (1959–63, reprinted 1981), relate the history

of petroleum geology and the development of the oil industry. KENNETH K. LANDES, *Petroleum Geology,* 2nd ed. (1959, reprinted 1975); L.W. LEROY, D.O. LEROY, and J.W. RAESE (eds.), *Subsurface Geology: Petroleum, Mining, Construction,* 4th ed. (1977); B.P. TISSOT and D.H. WELTE, *Petroleum Formation and Occurrence,* 2nd rev. ed. (1984); and JOHN M. HUNT, *Petroleum Geochemistry and Geology* (1979), are sources of information on theories of the origin and accumulation of petroleum, as well as on the practical applications of scientific knowledge to petroleum problems. E.N. TIRATSOO, *Oilfields of the World,* 3rd ed., rev. (1986), describes the nature and distribution of the major oil fields of the world. C.D. MASTERS, D.H. ROOT, and E.D. ATTANASI, "Resource Constraints in Petroleum Production Potential," *Science,* 253(5016):146–152 (July 12, 1991), contains U.S. Geological Survey assessments of world oil and gas resources. JOSEPH P. RIVA, JR., *Exploration Opportunities in Latin America* (1992), provides information on Latin American oil and gas reserves, resources, and production potential, and *Petroleum Exploration Opportunities in the Former Soviet Union* (1994), contains similar information for each of the former Soviet republics. MICHEL T. HALBOUTY (ed.), *Future Petroleum Provinces of the World* (1986), contains an annotated list of the world's giant oil and gas fields. KENNETH K. LANDES, *Petroleum Geology of the United States* (1970), describes in detail petroleum geology on a state-by-state basis. JOSEPH P. RIVA, JR., JOHN J. SCHANZ, JR., and JOHN G. ELLIS, *U.S. Conventional Oil and Gas Production: Prospects to the Year 2000* (1985), assesses U.S. domestic reserves, resources, and production potential. JOSEPH P. RIVA, JR., *World Petroleum Resources and Reserves* (1983), treats the formation and accumulation of conventional and unconventional petroleum, exploration and production methods, and petroleum basin geology. G.D. HOBSON (ed.), *Modern Petroleum Technology,* 5th ed., 2 vol. (1984), discusses petroleum engineering, including production, refining, and transport. FILLMORE C.F. EARNEY, *Petroleum and Hard Minerals from the Sea* (1980), examines worldwide development of seabed resources with emphasis on offshore petroleum.

JAMES A. CLARK, *The Chronological History of the Petroleum and Natural Gas Industries* (1963), gives a detailed chronology of both technical and human facts. MALCOLM W.H. PEEBLES, *Evolution of the Gas Industry* (1980), provides international, historical, and technological developments. ARLON R. TUSSING and CONNIE C. BARLOW, *The Natural Gas Industry: Evolution, Structure, and Economics* (1984), examines the natural gas industry in the United States. E.L. RAWLINS and M.A. SCHELLHARDT, *Back-Pressure Data on Natural-Gas Wells and Their Application to Production Practices* (1935, reissued 1970), is a classic report of the U.S. Bureau of Mines describing and explaining the back-pressure method, with an analysis of data for more than 500 gas wells. MORRIS MUSKAT, *Physical Principles of Oil Production,* 2nd ed. (1981), and *The Flow of Homogeneous Fluids Through Porous Media* (1937, reprinted 1982), are fundamental works on the basic principles of gas and petroleum.

Collections of scientific papers may be found in G.D. HOBSON (ed.), *Developments in Petroleum Geology,* 2 vol. (1977–80); and in publications of the American Association of Petroleum Geologists, including the *AAPG Bulletin* (monthly), the October issue of which contains an annual review of significant exploration and production activity; and the *AAPG Memoir* (irregular). *Basic Petroleum Data Book* (three per year); and *Minerals Yearbook,* prepared by the U.S. Bureau of Mines, include annual statistical reviews of the petroleum industry. Each year maps, production figures, and geologic data are published in August by *World Oil* and in December by the *Oil and Gas Journal.* (J.P.Ri./G.I.A.)

Heavy oils, tar sands, and oil shales. Current information concerning the characteristic properties of oil shales, their sources, and special problems of exploitation may be found in the proceedings of meetings, such as *Oil Shale Symposium Proceedings* (annual); material originating at symposia chaired by PAUL B. TARMAN, *Synthetic Fuels from Oil Shale* (1980), *Synthetic Fuels from Oil Shale II* (1982), and *Synthetic Fuels from Oil Shale and Tar Sands* (1983); and H.C. STAUFFER (ed.), *Oil Shale, Tar Sands, and Related Materials* (1981), symposium papers, including essays on oil shale cracking and retorting. General works include KEN P. CHONG and JOHN WARD SMITH (eds.), *Mechanics of Oil Shale* (1984), a collection of summary papers on the exploitation of oil shales; T.F. YEN and GEORGE V. CHILINGARIAN (eds.), *Oil Shale* (1976), background essays on different aspects of oil shale technology and science; PAUL L. RUSSELL, *History of Western Oil Shale* (1980); and PERRY NOWACKI (ed.), *Oil Shale Technical Data Handbook* (1981). The transitional character of kerogen rocks and their limnological and stratigraphical properties are treated in BERNARD DURAND (ed.), *Kerogen: Insoluble Organic Matter from Sedimentary Rocks* (1980); BARTHOLOMEW NAGY and UMBERTO COLOMBO (eds.), *Fundamental Aspects of Petroleum Geochemistry* (1967); and A.I. LEVORSEN, *Geology of Petroleum,* 2nd rev. ed. (1967).

Data on world distribution, exploitation, and technology are included in FERDINAND MAYER, *Weltatlas Erdöl und Erdgas,* 2nd ed. (1976); and T.F. YEN (ed.), *Science and Technology of Oil Shale* (1976). RICHARD F. MEYER (ed.), *Exploration for Heavy Crude Oil and Natural Bitumen* (1987), contains information on the size and distribution of the world's largest accumulations of heavy crude and bitumen. Information on oil shales, tar sands, and heavy oils is presented in *Zeitschrift für Angewandte Geologie* (monthly); *Erdöl-Erdgas* (monthly); and *Oil and Gas Journal* (weekly). (J.P.Ri.)

Coals. HOWARD N. EAVENSON, *Coal Through the Ages,* 2nd ed., rev. (1942), provides information about the early history of coal mining and coal utilization. MARIE C. STOPES and R.V. WHEELER, *Monograph on the Constitution of Coal* (1918), is a classic work on the organic composition of coals. Information on this and other subjects treated in the present article and numerous references to earlier literature may be found in D.W. VAN KREVELEN, *Coal: Typology, Physics, Chemistry, Constitution,* 3rd, completely rev. ed. (1993); E. STACH *et al., Stach's Textbook of Coal Petrology,* 3rd rev. and enlarged ed. (1982; originally published in German, 1935); and DUNCAN MURCHISON and T. STANLEY WESTOLL (eds.), *Coal and Coal-Bearing Strata* (1968). ROBERT A. MEYERS (ed.), *Coal Structure* (1982), examines the nature and origin of coal structure and porosity. SIMON WALKER, *Major Coalfields of the World* (1993), provides information about coal resources worldwide, including in the Commonwealth of Independent States. Methods for estimating world coal reserves, the present status of coal reserves, and the prospects for future development of coal resources are examined in GÜNTER B. FETTWEIS, *World Coal Resources: Methods of Assessment and Resources* (1979; originally published in German, 1976); and CARROLL L. WILSON, *Coal—Bridge to the Future: A Report of the World Coal Study* (1980). DOUGLAS C. PETERS (ed.), *Geology in Coal Resource Utilization* (1991), provides information concerning coal resources, reserve estimation, coal utilization, and the environment. (O.C.K.)

Fungi

The kingdom Fungi (Mycota) comprises a large group of eukaryotic organisms having two common characteristics: anatomically, their principal mode of vegetative growth is through mycelium; physiologically, their nutrition is based on absorption of organic matter. Although historically included in the plant kingdom, fungi lack chlorophyll and other structures common among true plants and have therefore been placed in a separate kingdom. Fungi are the culmination of a major direction in evolution distinctly different from that of plants or animals; this evolutionary line was established by organisms whose nutrition was based on absorption of organic matter. Fungi are among the most widely distributed organisms on Earth and are of great importance. The fungi include yeasts, rusts, smuts, mildews, molds, mushrooms, and others. Many fungi are free-living in soil or water; others form parasitic or symbiotic relationships with plants or animals, respectively. (Slime molds, straddling the animal and plant worlds, are treated in the article PROTISTS.)

The mushrooms, by no means the most numerous or economically significant of the fungi, are the most conspicuous members of the group; thus, the Latin word for mushroom, *fungus* (plural *fungi*), has come to stand for the whole group. Similarly, the study of fungi is known as mycology—a broad application of the Greek word for mushroom, *mykēs*. Fungi other than mushrooms are sometimes collectively called molds, although this term is better restricted to fungi of the sort represented by bread mold.

For coverage of related topics in the *Macropædia* and *Micropædia*, see the *Propædia*, section 313, and the *Index*.

This article is divided into the following sections:

GENERAL FEATURES

Basic structure

A typical fungus consists of a mass of branched, tubular filaments enclosed by a rigid cell wall. The filaments, called hyphae (singular hypha), branch repeatedly into a complicated, radially-expanding network called the mycelium, which makes up the thallus, or undifferentiated body, of the typical fungus. Some fungi, notably the yeasts, do not form a mycelium but grow as individual cells that multiply by budding or, in certain species, by fission. The mycelium grows by utilizing nutrients from the environment and, upon reaching a certain stage of maturity, forms—either directly or in special fruiting bodies—reproductive cells called spores. The spores are released and dispersed by a wide variety of passive or active mechanisms; upon reaching a suitable substrate, the spores germinate and develop hyphae that grow, branch repeatedly, and become the mycelium of the new individual. Fungal growth is mainly confined to the tips of the hyphae.

All fungal structures are, therefore, made of hyphae or portions of hyphae; for example, a mushroom—visibly consisting of a stem supporting a cap with gills on the underside—is constructed entirely of microscopic filaments intricately associated and interwoven. The mushroom is the fruiting body of the mycelium and bears the spores; the main body of the fungus is underground and consists of a huge network of hyphae—the mycelium—spread over a very large area, often several metres (yards) in diameter. This mycelium obtains food from organic matter in the soil and grows outward, just below the surface, in a circular fashion. In certain species the hyphal branches at the edge of the mycelium become organized at intervals into elaborate tissues that develop above ground into mushrooms. Such a circle of mushrooms is known as a fairy ring (see Figure 2) because, in the Middle Ages, it was believed to represent the path of dancing fairies. The ring marks the periphery of an enormous fungus colony, which, if undisturbed, continues to produce ever wider fairy rings year after year.

Size range and diversity of structure. The part of a fungus that is generally visible is the fruiting body, or sporophore. Sporophores vary greatly in size, shape, colour, and longevity. Some are microscopic and completely invisible to the unaided eye; others are no larger than a pin head; still others are gigantic structures. Among the largest sporophores are those of the mushrooms, bracket fungi, and puffballs. Some mushrooms reach a diameter of 20 to 25 centimetres (8 to 10 inches) and a height of 25 to 30 centimetres. Bracket fungi 40 centimetres or more in diameter are not uncommon, and puffballs often exceed that size. The largest puffballs on record measured 150 centimetres in diameter. The number of spores within such giants reaches several trillion.

Distribution and abundance. Fungi are either terrestrial or aquatic, the latter living in freshwater or marine environments. Freshwater species usually do not tolerate high degrees of salinity in nature, although some are found in slightly brackish water; most prefer clean, cool waters, but a few thrive in highly polluted streams. The soil furnishes an ideal habitat for a large number of species. Fungi are found in all temperate and tropical regions of the world where there is sufficient moisture to enable them to grow. They have also been reported from the Arctic and Antarctic regions but are much rarer there, being replaced by lichens, organisms that have fungal and algal components living in symbiosis (see below *Lichens*). In general, fungi are abundant in moist habitats where organic matter is plentiful and less abundant in drier areas or in habitats with little or no organic matter. About 50,000 species of fungi have been identified and described, but it has been estimated that there may be as many as 100,000 to 250,000 total species. Previously undescribed species are constantly being discovered and, as the tropics become more thoroughly explored, many more new species will undoubtedly be found.

Number of species

Importance. In 1928 a green mold accidentally grew in a culture dish of *Staphylococcus* bacteria that the bacteriologist Alexander Fleming was studying in a London hospital. The fungus colony that developed inhibited the growth of the bacteria. Such unavoidable contamination certainly had occurred many times before in laboratories through-

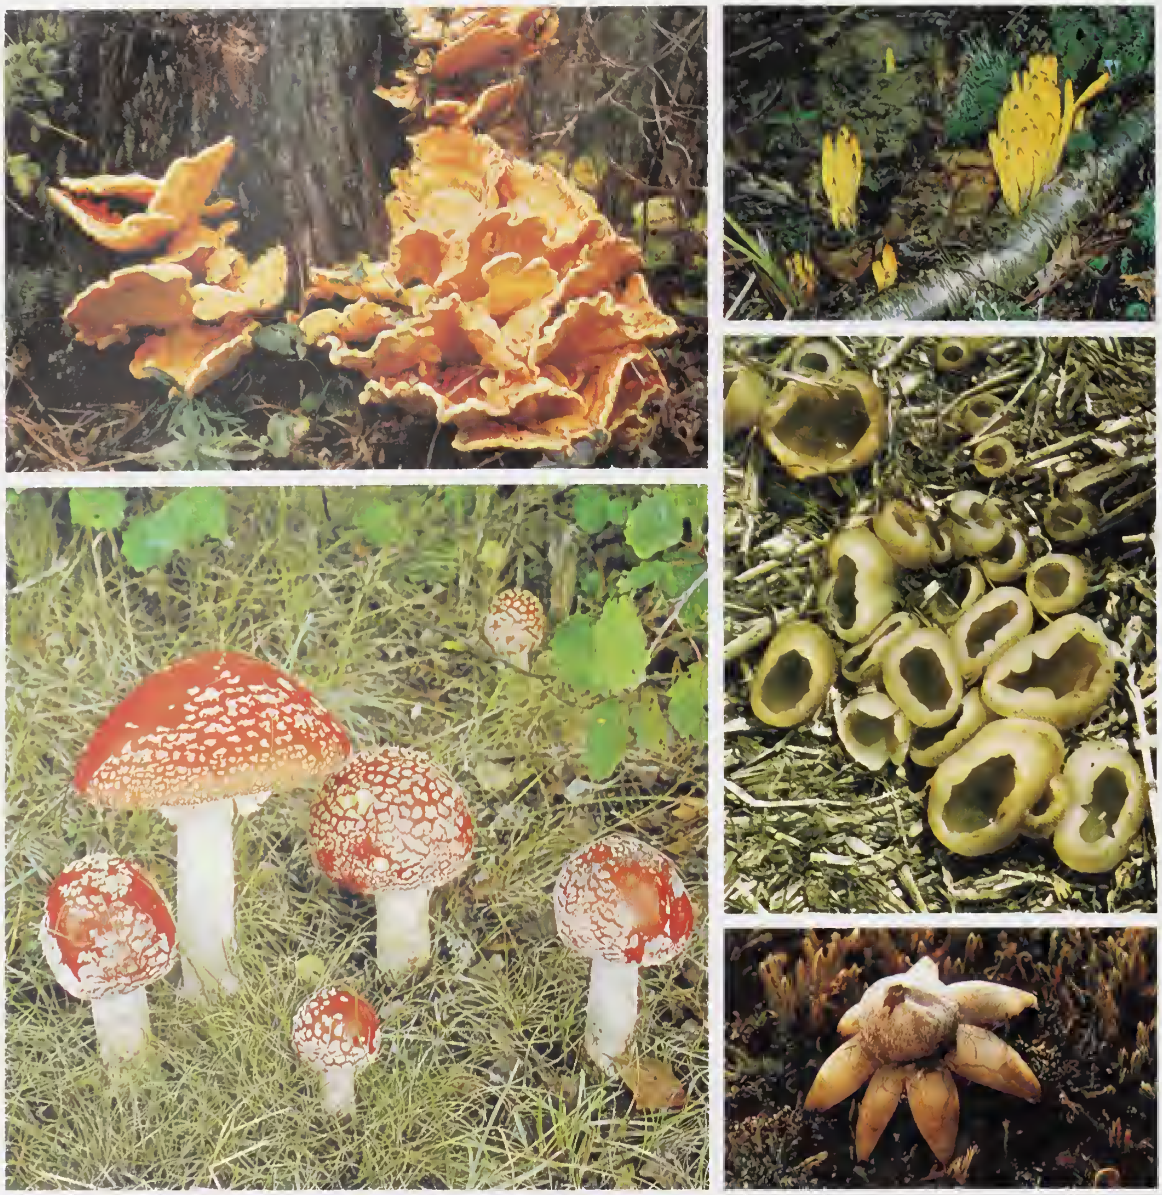

Figure 1: *Fruiting structures among saprophytic higher fungi.*
Plant bodies of these fungi consist of masses (mycelia) of threadlike filaments (hyphae) growing in soil or wood. All the fungi shown are Basidiomycetes except *Peziza*, an ascomycete. (Top left) Bracket fungus, chicken of the woods (*Polyporus sulphureus*), growing on wood. (Top right) Club fungus (*Clavaria*) growing in soil. (Centre right) Cup fungus (*Peziza vesiculosa*) on woody forest litter. (Bottom left) Gill fungus, the poisonous fly agaric (*Amanita muscaria*), growing on soil. (Bottom right) Puffball, the earthstar (*Geastrum*), growing on moist soil among mosses.

out the world, but the people who may have seen such cultures probably regarded them as contaminated plates to be discarded as soon as possible. Fleming, however, carefully recorded his observation and in 1929 published a scientific report announcing the discovery of penicillin, the first of a series of antibiotics—many of them derived from fungi—that have revolutionized medical practice.

Ergotism

In 1951 a strange disease broke out in the small French village of Pont-Saint-Esprit, and several persons died. Doctors were baffled by the mysterious malady until it was recognized as a form of "St. Anthony's fire"—ergotism—that had resulted from eating bread made from contaminated flour. Ergotism was prevalent in northern Europe in the Middle Ages, particularly in regions of high rye-bread consumption; modern grain-cleaning and milling methods have practically eliminated the disease.

The cause of ergotism is ergot—a fungus. More precisely, ergot is a sclerotium (plural sclerotia), a special part of a fungus that develops on grasses and especially on rye. The wind carries the fungal spores to the flowers of the rye, where the spores germinate, infect and destroy the ovaries of the plant, and replace them with masses of microscopic threads cemented together into a hard fungal structure shaped like a rye kernel but considerably larger and darker. This is ergot, and it contains a number of poisonous organic compounds called alkaloids. A mature head of rye may carry several ergots in addition to noninfected kernels. When the grain is harvested, much of the ergot falls to the ground, but some remains on the plants and is mixed with the grain. If the ergot is not removed before milling, the ergotized flour would be converted into bread and other food products and consumed; St. Anthony's fire—for which no cure is known—is the result. The ergot that falls to the ground may be the source of more trouble. Cattle put to graze in the rye fields after harvest are likely to consume enough ergot to bring on abortion of fetuses or death. In the spring, when the rye is in bloom, the ergot remaining on the ground produces tiny, black, mushroomlike bodies that expel large numbers of spores to start a new series of infections.

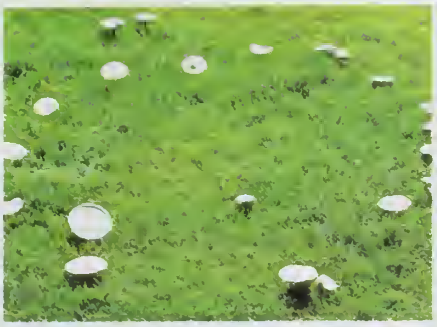

Figure 2: Fairy ring of mushrooms (*Chlorophyllum molybditis*).
Walter Dawn

Among the many interesting chemicals in ergot is lysergic acid, the active principle of the psychedelic drug lysergic acid diethylamide (LSD). Here, then, is a single fungus that can reduce crop yields, cause abortion in cattle, sicken and sometimes kill people, and be used as a source of LSD. On the credit side, ergot provides medical science with drugs useful in inducing labour in pregnant women and in controlling hemorrhage after birth.

The systematic study of fungi began 250 years ago, but humans have been indirectly aware of fungal activity since the first loaf of leavened bread was baked and the first tub of grape must was turned into wine. Yet, even now, few people realize that they are almost constantly either benefited or harmed by these organisms. Fungi are everywhere in very large numbers—in the soil and the air, in lakes, rivers, and seas, on and within plants and animals, in food and clothing, and in the human body; it is this that makes them so important in the human environment. Together with bacteria, fungi are responsible for the disintegration of organic matter and the release, into the soil or atmosphere, of the carbon, oxygen, nitrogen, and phosphorus that otherwise would be forever locked up in undecomposed organic matter. Fungi are essential to many household and industrial processes, notably the making of bread, wine, beer, and certain cheeses. They are used in the production of a number of organic acids, enzymes (biological catalysts), and vitamins and are the sources of a number of antibiotics besides penicillin. Fungi are also used as food: mushrooms, morels, and truffles are epicurean delicacies.

Universal presence of fungi

Studies of fungi have greatly contributed to the accumulation of fundamental knowledge in biology. Current knowledge of biochemistry and cellular metabolism was derived in part from studies of ordinary baker's or brewer's yeast (*Saccharomyces cerevisiae*). Some of these pioneering discoveries were made at the end of the 19th century and continued during the first half of the 20th. From 1920 through the 1940s, geneticists and biochemists who studied mutants of the red bread mold, *Neurospora*, established the one-gene–one-enzyme theory and laid the foundation of modern genetics. These and other fungi continue to be useful for studying cell and molecular biology, genetic engineering, and other basic disciplines of biology.

Although humans have benefited from the activities of certain fungi, they have also learned to look for villains among them. Numerous instances of destruction, disease, and death are directly traceable to fungi. The chestnut forests of the United States, for example, have been destroyed by the chestnut blight fungus, and the elms in both the United States and Europe have been devastated by the fungus that causes Dutch elm disease. Blights, rusts, wilts, and smuts destroy crops as land is cultivated more intensively, though increasingly effective control measures have been developed. Fungi cause various human diseases—*e.g.,* athlete's foot and ringworm, candidiasis and aspergillosis, histoplasmosis and coccidioidomycosis. Mildews, molds, and rots ruin clothing and foods.

Disease-causing fungi

Ancient peoples were familiar with the ravages of fungi in agriculture but attributed these diseases to the wrath of the gods. The Romans even designated a particular deity, Robigus, as the god of rust and, in an effort to propitiate him, organized an annual festival, the Robigalia, in his honour.

The mushrooms, because of their size, are easily seen in fields and forests and consequently were the only fungi known before the invention of the microscope in the 17th century. The microscope made it possible to recognize and identify the great variety of fungal species living on dead or live organic matter, the existence of which could not have been apprehended by the unaided eye.

NATURAL HISTORY

Following a period of intensive growth, which in most fungi consists in the development of an extensive mycelium, fungi enter their reproductive phase by forming and releasing vast quantities of spores. Spores are usually single, but sometimes multiple, cells produced either by fragmentation of the mycelium or within specialized structures (sporangia, gametangia, sporophores, etc.). The main types of reproductive structures also distinguish the major classes of fungi; finer details in these reproductive structures are commonly used to distinguish species among the genera. Spores may be produced either directly by asexual methods or indirectly through sexual reproduction. Sexual reproduction in fungi, as in other living organisms, involves the fusion of two nuclei that are brought together when two sex cells (gametes) unite. Asexual reproduction, which is simpler and more direct, may be accomplished by various methods.

Asexual reproduction. Typically in asexual reproduction, a single individual gives rise to a genetic duplicate of the progenitor without a genetic contribution from another individual. Perhaps the simplest method of reproduction of fungi is by fragmentation of the thallus, the body of a fungus. Some yeasts, which are single-celled fungi, reproduce by simple cell division, in which one cell undergoes nuclear division and splits into two daughter cells; after some growth, these cells divide, and, eventually, a population of cells forms. In filamentous fungi the mycelium may fragment into a number of segments, each of which is capable of growing into a new individual. In the laboratory, fungi are commonly propagated on a layer of solid nutrient agar inoculated either with spores or with fragments of mycelium.

Budding, which is another method of asexual reproduction, occurs in most yeasts and in some filamentous fungi. In this process, a bud develops on the surface of either the yeast cell or the hypha, its cytoplasm being continuous with that of the parent cell. The nucleus of the parent cell then divides; one of the daughter nuclei migrates into the bud, and the other remains in the parent cell. The latter is capable of producing many buds over its surface by continuous synthesis of cytoplasm and repeated nuclear divisions. After a bud develops to a certain point and even before it is severed from the parent cell, it is itself capable of budding by the same process. In this way, a chain of cells may be produced. Eventually, the individual buds pinch off the parent cell and become individual yeast cells. Buds that are pinched off a hypha of a filamentous fungus behave as spores; that is, they germinate, each giving rise to a structure called a germ tube, which develops into a new hypha.

Budding

Although fragmentation, fission, and budding are methods of asexual reproduction in a number of fungi, the majority reproduce asexually by the formation of spores. Spores that are produced asexually are often termed mitospores, and such spores are produced in a variety of ways. For a more detailed discussion of spores, see below *Form and function*.

Sexual reproduction. Sexual reproduction, an important source of genetic variability, allows the fungus to adapt to new environments. The process of sexual reproduction among the fungi is in many ways unique. Whereas nuclear division in other eukaryotes (animals, plants, and protists) involves the dissolution and reformation of the nuclear membrane, the nuclear membrane remains intact throughout the process in fungi, although gaps in its integrity are found in some species. The nucleus of the fungus becomes pinched at its midpoint, and the diploid chromosomes are pulled apart by spindle fibres formed within the intact nucleus. The nucleolus is usually also retained and divided between the daughter cells, although it may be expelled from the nucleus, or it may be dispersed within the nucleus but detectable.

Stages of sexual reproduction

Sexual reproduction in the fungi consists of three sequential stages: plasmogamy, karyogamy, and meiosis. The diploid chromosomes are pulled apart into two daughter cells, each containing a single set of chromosomes (a haploid state). Plasmogamy, the fusion of two protoplasts (the contents of the two cells), brings together two compatible haploid nuclei. At this point, two nuclear types are present in the same cell, a condition called dikaryotic, but the nuclei have not yet fused. Karyogamy results in the fusion of these haploid nuclei and the formation of a diploid nucleus (*i.e.,* a nucleus containing two sets of chromosomes, one from each parent). The cell formed by karyogamy is called the zygote. In most fungi, the zygote is the only cell in the entire life cycle that is diploid. The dikaryotic state that results from plasmogamy is often a prominent condition in fungi and may be prolonged over several generations. In the lower fungi, karyogamy usually follows plasmogamy almost immediately. In the more evolved fungi, however, karyogamy is separated from plasmogamy. Once karyogamy has occurred, meiosis (cell division that reduces the chromosome number to one set per cell) generally follows immediately and restores the haploid phase. Either the haploid nuclei that result from meiosis or their immediate progeny are generally incorporated in spores called meiospores.

Fungi employ a variety of methods to bring together two compatible haploid nuclei (plasmogamy). Some produce specialized sex cells (gametes) that are released from differentiated sex organs called gametangia. In other fungi two gametangia come in contact, and nuclei pass from the male gametangium into the female, thus assuming the function of gametes. In still other fungi the gametangia themselves may fuse in order to bring their nuclei together. Finally, some of the most advanced fungi produce no gametangia at all; the somatic (vegetative) hyphae take over the sexual function, come in contact, fuse, and exchange nuclei.

Fungi in which a single individual bears both male and female gametangia are hermaphroditic fungi. Rarely, gametangia of different sexes are produced by separate individuals, one a male, the other a female. Such species are termed dioecious. Dioecious species usually produce sex organs only in the presence of an individual of the opposite sex.

Mating types

Incompatibility. Many fungi produce differentiated male and female organs on the same thallus but do not undergo self-fertilization because their sex organs are incompatible. Such fungi require the presence of thalli of different mating types in order for sexual fusion to take place. The simplest form of this mechanism occurs in fungi in which there are two mating types, often designated + and − (or *A* and *a*). Gametes produced by one type of thallus are compatible only with gametes produced by the other type. Such fungi are said to be heterothallic. Many fungi, however, are homothallic; *i.e.,* sex organs produced by a single thallus are self-compatible, and a second thallus is unnecessary for sexual reproduction. Some of the most complex fungi (*e.g.,* mushrooms) do not develop differentiated sex organs; rather, the sexual function is carried out by their somatic hyphae, which unite and bring together compatible nuclei in preparation for fusion. Homothallism and heterothallism are encountered in these fungi, as well as in those in which sex organs are easily distinguishable. Compatibility, therefore, refers to a physiological differentiation, and sex refers to a morphological (structural) one; the two phenomena, although related, are not synonymous.

Sexual pheromones (hormones). The formation of sex organs in fungi is often induced by specific organic substances. Although called sex hormones when first discovered, these organic substances are actually sex pheromones, chemicals produced by one partner to elicit a sexual response in the other. In *Allomyces* (Chytridiomycetes) a pheromone named sirenin, secreted by the female gametes, attracts the male gametes, which swim toward the former and fuse with them. In *Achlya* (Oomycetes) a sterol pheromone called antheridiol induces the formation of gametangia and attracts the male to the female. In the Zygomycetes, in which the gametangia are usually not differentiated structurally, a complex biochemical interplay between mating types produces trisporic acid, a pheromone that induces the formation of specialized aerial hyphae. An unidentified volatile factor causes the tips of opposite mating aerial hyphae to grow toward each other and fuse. In yeasts (Ascomycetes and Basidiomycetes) the pheromones are small peptides.

Life cycle. In the life cycle of a sexually reproducing fungus, a haploid phase alternates with a diploid phase (see, for example, Figure 3). The haploid phase ends with nuclear fusion, and the diploid phase begins with the formation of the zygote (the diploid cell resulting from fusion of two haploid sex cells). A special kind of nuclear division, termed meiosis or reduction division, restores the haploid number of chromosomes and initiates the haploid phase, which produces the gametes. In the majority of fungi, all structures are haploid except the zygote. Nuclear fusion takes place at the time of zygote formation, and meiosis follows immediately. Only in the water mold *Allomyces* and a few related genera and in some yeasts is alternation of a haploid thallus with a diploid thallus definitely known. In the class Oomycetes (Figure 4) the thallus is diploid, and meiosis takes place just before the formation of the gametes.

From C J Alexopoulos, *Introductory Mycology*, 2nd ed , copyright © (1962) by John Wiley and Sons, Inc , reprinted by permission

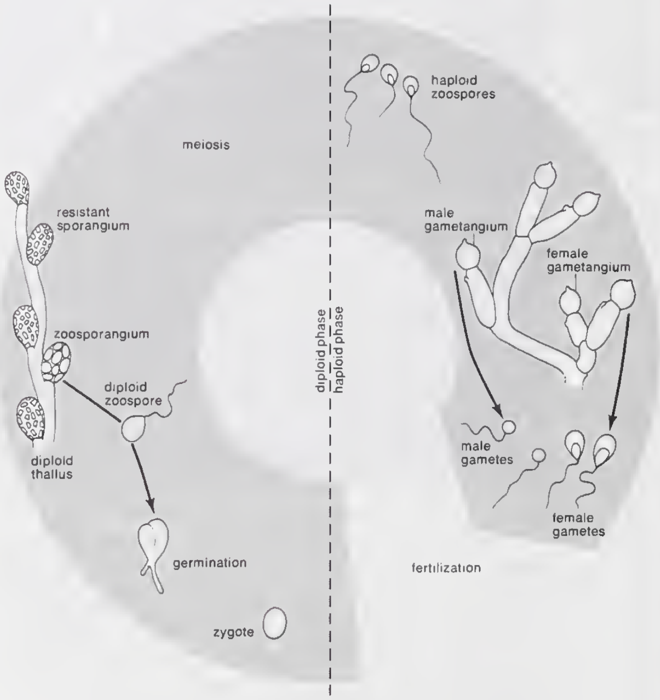

Figure 3: Life cycle of the water mold *Allomyces macrogynus*, a chytridiomycete.

In the higher fungi a third condition is interspersed between the haploid and diploid phases of the life cycle. In these fungi, plasmogamy (fusion of the cellular contents of two hyphae but not of the two haploid nuclei) results in dikaryotic hyphae in which each cell contains two haploid nuclei, one from each parent. Eventually, the nuclear pair fuses to form the diploid nucleus and thus the zygote. In the Basidiomycetes, the most advanced class of fungi, the binucleate cells divide successively and give rise to a binucleate mycelium, which is the main assimilative phase of the life cycle. It is the binucleate mycelium that eventually forms the basidia—the stalked fruiting bodies in which nuclear fusion and meiosis take place prior to the formation of the basidiospores.

Fungi usually reproduce both sexually and asexually. The asexual cycle produces mitospores, and the sexual cycle produces meiospores. Even though both types of spores are

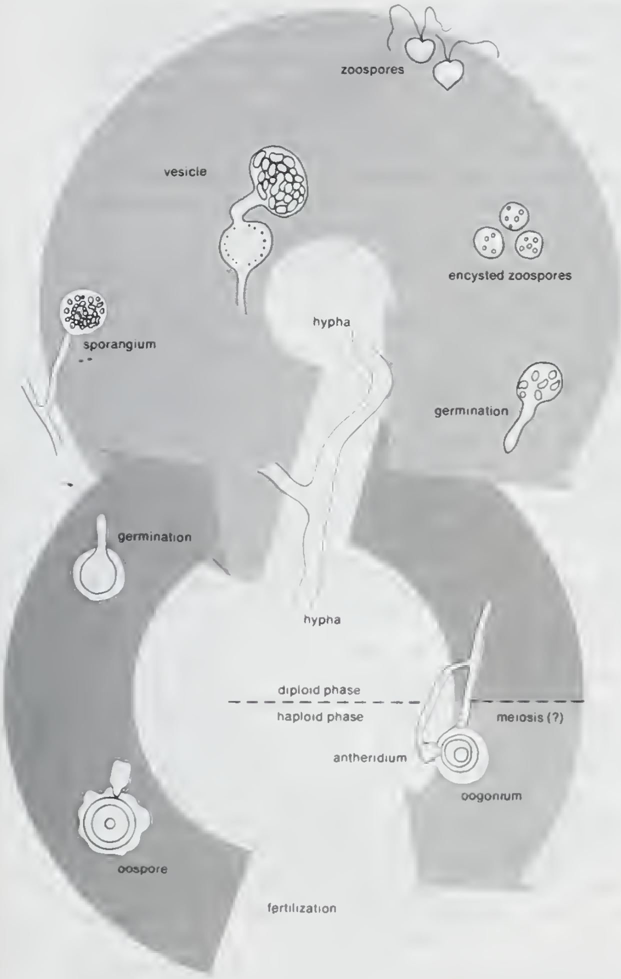

Figure 4: Life cycle of *Pythium debaryanum*, an oomycete.

produced by the same mycelium, they are very different in form and easily distinguished (see below *Sporophores and spores*). The asexual phase usually precedes the sexual phase in the life cycle and may be repeated frequently before the sexual phase appears.

Some fungi differ from others in their lack of one or the other of these stages; some reproduce only sexually (except for fragmentation, which is common in most fungi), and many only asexually. A number of fungi exhibit the phenomenon of parasexuality, in which processes comparable to plasmogamy, karyogamy, and meiosis take place but not at a specified time or at specified points in the life cycle of the organism. Parasexuality is characterized by the prevalence of heterokaryosis in a mycelium—*i.e.*, the presence, side by side, of nuclei of different genetic composition.

Parasexuality

Ecology. Relatively little is known of the effects of the environment on the distribution of fungi that utilize dead organic material as food (saprobic fungi; see below *Nutrition*). The availability of organic food is certainly one of the factors controlling such distribution. A great number of fungi appear able to utilize most types of organic materials, such as lignin, cellulose, or other polysaccharides, which have been added to soils or waters by dead vegetation. It follows that most saprobic fungi may be expected to be cosmopolitan, at least in habitats with a sufficient organic content to support fungal growth. Whereas a great many saprobes are cosmopolitan, some are strictly tropical and others are strictly temperate-zone forms. Fungi with specific nutritional requirements are, of course, more localized.

Moisture and temperature are two additional ecological factors that are important in determining the distribution of fungi. Laboratory studies have shown that many, perhaps the majority, of fungi are mesophilic; *i.e.*, they have an optimum growth temperature of 20°–30° C (68°–86° F). Thermophilic species are able to grow at 50° C (122° F) or higher but are unable to grow below 30° C. Although the optimum temperature for growth of most fungi lies at or above 20° C (68° F), a large number of species are able to grow close to or below 0° C (32° F). The so-called snow molds and the fungi that cause spoilage of refrigerated foods are examples of this group. Obviously, temperature relationships influence the distribution of various species. Certain other effects of temperature are also important factors in determining the habitats of fungi. Many coprophilous (dung-inhabiting) fungi, for example, although able to grow at a temperature of 20°–30° C, require a short period at 60° C (140° F) for their spores to germinate.

Symbionts

Associations. Among symbiotic fungi, those that enter into mycorrhizal relationships and the lichens (see below *Lichens*) are probably the best-known. Another kind of symbiotic relationship between fungi and host organisms is found between fungi and certain insects.

A large number of fungi "infect" the roots of plants, forming an association with them called mycorrhiza (plural mycorrhizae). This association differs markedly from ordinary root infection, which is responsible for root rot diseases. It is a non-disease-producing association in which the fungus invades the root and derives nutrients from it. Mycorrhizal fungi establish a mild form of parasitism that in many instances verges on mutualism; *i.e.*, it is beneficial to the plant as well as to the fungus.

There are two types of mycorrhizae, ectomycorrhizae and endomycorrhizae. Ectomycorrhizae are fungi that are only externally associated with the plant root, while the endomycorrhizae form their associations within the cells of the host.

Among the mycorrhizal fungi are the boletes (Basidiomycetes, family Boletaceae), whose mycorrhizal relationships with larch trees (*Larix*) and other conifers have long been known. Others include the truffles (Ascomycetes, order Tuberales), some of which are believed to form mycorrhizae with oak (*Quercus*) or beech (*Fagus*) trees, and various species of *Rhizoctonia* (mycelial stage of certain Basidiomycetes), which form orchid mycorrhizae.

Insect associations

The symbiotic relationship between certain fungi and insects is exemplified by that of the fungal genus *Septobasidium* and scale insects (order Homoptera) that feed on trees. The mycelium forms elaborate structures over colonies of insects feeding on the bark. Each insect sinks its proboscis (tubular sucking organ) into the bark and remains there the rest of its life, sucking sap. The fungus sinks haustoria (special absorbing structures) into the bodies of some of the insects and feeds on them without killing them. The parasitized insects are, however, rendered sterile.

The perpetuation of the insect species and the spread of the fungus are accomplished by the uninfected members of the colony, which live in fungal "houses," safe from enemies. Newly hatched scale insects crawl over the surface of the fungus, which is at that time sporulating. Fungal spores adhere to the young insects, germinate, and infect them. As the young insects settle down in a new place on the bark to begin feeding, they establish new fungal colonies. Thus, part of the insect colony is sacrificed to the fungus as food in return for the fungal protection provided for the rest of the insects. The insect is parasitic on the tree and the fungus is parasitic on the insect, but the tree is the ultimate victim.

The sooty molds constitute another interesting ecological group of fungi associated with insects. The majority of these are tropical or subtropical, but some species occur in the temperate zones. All sooty molds are epiphytic (*i.e.*, they grow on the surfaces of other plants), but only in areas where scale insects are present. The fungi parasitize neither the plants nor the insects but rather obtain their nourishment exclusively from the honeydew secretions of the scale insects. Growth of the dark mycelium over the plant leaves, however, is often so dense as to reduce greatly the intensity of the light that reaches the leaf surface; this reduction in turn significantly reduces the rate of photosynthesis.

FORM AND FUNCTION

Septate and nonseptate hyphae

Structure of the thallus. In almost all fungi the hypha, and therefore the thallus—the undifferentiated, nutrient-absorbing body of the fungus—has cell walls. (The thalli of the true slime molds lack cell walls and, for this and other reasons, are classified as protists rather than fungi.) A hypha is a multibranched tubular cell filled with cytoplasm. The tube itself may be either continuous throughout or divided into compartments, or cells, by cross walls called septa (singular septum). In nonseptate (*i.e.*, coenocytic) hyphae the nuclei are scattered throughout the cytoplasm. In septate hyphae each cell may contain one to many nuclei, depending on the type of fungus or the stage of hyphal development. The cells of fungi are similar in structure to those of many other organisms. The minute nucleus, readily seen only in young portions of the hypha, is surrounded by a double membrane and typically contains one nucleolus. In addition to the nucleus, various organelles, such as the endoplasmic reticulum, the Golgi apparatus, ribosomes, and liposomes, are scattered throughout the cytoplasm.

Hyphae usually are either nonseptate (generally in the more primitive fungi) or incompletely septate. This permits the movement of cytoplasm (cytoplasmic streaming) from one cell to the next. Cytoplasmic streaming, however, is movement in only one direction (toward the growing end of the hypha), and it is movement that does not effect locomotion. In those septae that are nonperforated, thin cytoplasmic strands called plasmodesmata can develop outside the hyphal wall between adjacent cells.

Variations in the structure of septae are numerous in the fungi. Some fungi have sievelike septae, called pseudosepta, while fungi in other groups have septae with one to few pores which are small enough in size that they regulate the movement of nuclei and cytoplasm to adjacent cells. Many of the Basidiomycetes have a somewhat characteristic septal structure, called the dolipore septum, composed of a septal pore cap surrounding a septal swelling and septal pore. This organization permits cytoplasm and small organelles to pass through but restricts the movement of nuclei to varying degrees, forcing the nucleus to constrict as it passes through.

The hyphal wall

The wall of the hypha is complex in both composition and structure. Its exact chemical composition varies in different fungal groups. In some fungi the wall contains considerable quantities of cellulose, a complex carbohydrate that is the chief constituent of the cell walls of plants; in most fungi, however, two different polymers, chitin and a special β-1,3-1,6-glucan (a polymer of glucose linked at the third carbon and branched at the sixth), are the main structural components of the wall. In a few fungi, both chitin and cellulose are components of the cell wall. Among the many other chemical substances in the walls of fungi are some that may thicken or toughen the wall of tissues, thus imparting rigidity and strength. The chemical composition of the wall of a particular fungus may vary at different stages of the organism's growth—a possible indication that the wall plays some part in determining the form of the fungus. In some yeasts, fusion of sexually functioning cells is brought about by the interaction of specific chemical substances on the walls of two compatible mating types.

When the mycelium grows in or on a surface—the soil, a log, a culture medium—it appears as a mass of loose, cottony threads. The richer the composition of the growth medium, the more profuse the threads and the more feltlike the mass. On the sugar-rich growth substances used in laboratories, the assimilative (somatic) hyphae are so interwoven as to form a thick, almost leathery colony. On the soil, inside a leaf, in the skin of animals, or in other parasitized plant or animal tissues, the hyphae are usually spread in a loose network. The mycelium of the so-called higher fungi does, however, become organized at times into compact masses of different sizes that serve various functions. Some of these masses, called sclerotia, become extremely hard and serve to carry the fungus over periods of adverse conditions of temperature and moisture. Ergot is an example. The underground sclerotia of *Poria cocos*, an edible pore fungus known in the United States under the Indian name tuckahoe, may reach a diameter of 20 to 25 centimetres. Various other tissues are also produced by the interweaving of the assimilative hyphae of some fungi. Stromata (singular stroma) are cushionlike tissues that bear spores in various ways. Rhizomorphs are long strands of parallel hyphae cemented together. Those of the honey mushroom *Armillariella mellea*, which are black and resemble shoestrings, are intricately constructed and are differentiated to conduct water and food materials from one part of the thallus to another.

Sporophores and spores. When the mycelium of a fungus reaches a certain stage of growth, it begins to produce spores either directly on the somatic hyphae or, more often, on special sporiferous (spore-producing) hyphae, which may be loosely arranged or grouped into intricate structures called the fruiting bodies or sporophores. The type of sporophore produced is characteristic of the group to which a fungus belongs, and the classification of fungi is based almost entirely on the characters of their sporophores and spores.

The lower (*i.e.*, more primitive) fungi produce spores in sporangia, which are saclike sporophores whose entire cytoplasmic contents cleave into spores, called sporangiospores. Thus, they differ from more advanced fungi in that their asexual spores are endogenous. Sporangiospores are either naked and flagellated (zoospores) or walled and nonmotile (aplanospores). The more primitive aquatic and terrestrial fungi tend to produce zoospores. The zoospores of aquatic fungi swim in the surrounding water by means of one or two variously located flagella (whiplike organs of locomotion), depending on the group to which the fungus belongs. Zoospores produced by terrestrial fungi are released after a rain from the sporangia in which they are borne and swim for a time in the rainwater between soil particles or on the wet surfaces of plants, where the sporangia are formed by parasitic fungi. After some time, the zoospores lose their flagella, surround themselves with walls, and encyst. Each cyst germinates by producing a germ tube. The germ tube may develop a mycelium or a reproductive structure, depending on species and environmental conditions. The bread molds (Zygomycetes), which are the most advanced of the lower fungi, produce only aplanospores (nonmotile spores) in their sporangia.

More advanced fungi

The more advanced fungi (Ascomycetes, Deuteromycetes, and Basidiomycetes) do not produce motile spores of any kind even though some of them are aquatic in fresh or marine waters. In these fungi, asexually produced spores (usually called conidia) are produced exogenously, typically formed terminally or laterally on special spore-producing hyphae, the conidiophores, which are variously arranged—*i.e.*, singly on the hyphae or grouped in special asexual fruiting bodies such as flask-shaped pycnidia, mattresslike acervuli, cushion-shaped sporodochia, or sheaflike synnemata.

Sexually produced spores of the higher fungi result from meiosis and are formed either in saclike structures (asci) typical of the Ascomycetes or on the surface of typically club-shaped structures (basidia) typical of the Basidiomycetes. Asci and basidia may be borne naked, directly on the hyphae, or in various types of sporophores, called ascocarps or basidiocarps, depending on whether they bear asci or basidia, respectively. Well-known examples of ascocarps are the morels, the cup fungi, and the truffles. Commonly encountered basidiocarps are mushrooms, puffballs, stinkhorns, and bird's-nest fungi.

Growth. Under favourable environmental conditions, fungal spores germinate and form hyphae. During this process, the spore absorbs water through its wall, the cytoplasm becomes activated, nuclear division takes place, more cytoplasm is synthesized, and from the wall of the spore a germ tube bulges out, enveloped by a wall of its own that is formed as the tube grows.

The hypha may be roughly divided into three regions: (1) the apical zone about 5–10 micrometres (0.0002–0.0004 inch) in length, (2) the subapical region, extending about 40 micrometres back of the apical zone, which is rich in cytoplasmic components, such as nuclei, Golgi apparatus, ribosomes, mitochondria, the endoplamsic reticulum, and vesicles, but is devoid of vacuoles, and (3) the zone of vac-

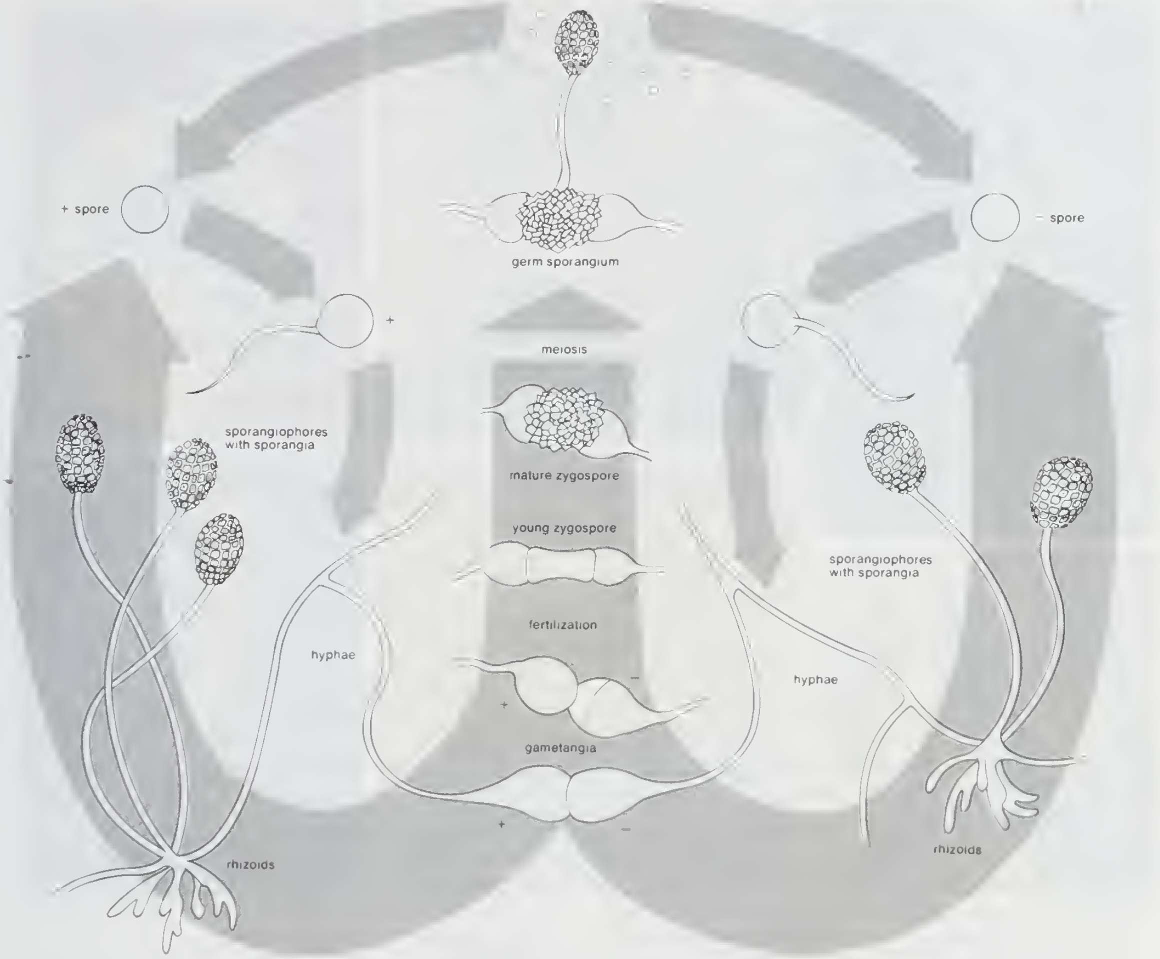

Figure 5: Life cycle of the common bread mold *Rhizopus stolonifer*, a zygomycete.

uolation, which is characterized by the presence of many vacuoles and the accumulation of lipids.

Growth of hyphae takes place almost exclusively in the apical zone (*i.e.,* at the very tip). This is the region where the cell wall extends continuously to produce a long hyphal tube. The cytoplasm within the apical zone is filled with numerous vesicles. These bubblelike structures are usually too small to be seen with an ordinary microscope but are clearly evident under the electron microscope. In higher fungi (Ascomycetes and Basidiomycetes), the apical vesicles can be detected with an ordinary microscope equipped with special optics (phase contrast), as a round spot with a somewhat diffuse boundary. This body is universally known by its German name, the Spitzenkörper, and its position determines the direction of growth of a hypha.

The growing tip eventually gives rise to a branch. This is the beginning of the branched mycelium. Growing tips that come in contact with neighbouring hyphae often fuse with them to form a hyphal net. In such a vigorously growing system, the cytoplasm is in constant motion, streaming toward the growing tips. Eventually, the older hyphae become highly vacuolated and may be stripped of most of their cytoplasm. All living portions of a thallus are potentially capable of growth. If a small piece of mycelium is placed under conditions favourable for growth, it develops into a new thallus even if no growing tips are included in the severed portion.

Growth of a septate mycelium (*i.e.,* with cross walls between adjacent cells) entails the formation of new septa in the young hyphae. Septa are formed by ringlike growth from the wall of the hypha toward the centre until the septa are complete. In the higher fungi the septum stops growing before it is complete; the result is a central pore through which the cytoplasm flows, thus establishing organic connection throughout the thallus.

The individual fungus is potentially immortal, for it continues to grow at the hyphal tips as long as conditions remain favourable. It is possible that, in undisturbed places, mycelia exist that have grown continuously for many thousands of years. The older parts of the hyphae die and decompose, releasing nitrogen and other nutrients into the soil.

Nutrition. Unlike green plants, which use carbon dioxide and light as sources of carbon and energy, respectively, fungi meet these two requirements by assimilating preformed organic matter; carbohydrates are the preferred nutrient source. Fungi can readily absorb and metabolize a variety of soluble carbohydrates, such as glucose, xylose, sucrose, and fructose, but are also characteristically well equipped to use insoluble carbohydrates like starches, cellulose, hemicelluloses, and lignin. To do so, they must first digest these polymers extracellularly. Saprobic fungi obtain their food from dead organic material; parasitic fungi do so by feeding on living organisms (usually plants), thus causing disease.

External digestion of food

Fungi secure food through the action of enzymes (biological catalysts) secreted into the surface on which they are growing; the enzymes digest the food, which then is absorbed directly through the hyphal walls. The rotting of fruits, such as peaches and citrus fruits in storage, demonstrates this phenomenon, in which the infected parts are softened by the action of the fungal enzymes. In brown rot of peaches, the softened area is somewhat larger than the actual area invaded by the hyphae: the periphery of the brown spot has been softened by enzymes that act ahead of the invading mycelium. Food must enter the hyphae in solution, and, since most fungi have no special absorbing organs, the entire mycelial surface is capable of taking in materials dissolved in water. Some fungi, however, produce special rootlike hyphae, called rhizoids, which anchor the thallus to the growth surface and proba-

bly also absorb food. Many parasitic fungi are even more specialized in this respect, producing special absorptive organs called haustoria.

Saprobiosis. Together with the bacteria, saprobic fungi are to a large extent responsible for the decomposition of organic matter. They are also responsible for the decay and decomposition of foodstuffs. Among other destructive saprobes are fungi that destroy timber and timber products as their mycelia invade and digest the wood; many of these produce their spores in large, woody, fruiting bodies—*e.g.,* bracket or shelf fungi. Paper, textiles, and leather are often attacked and destroyed by fungi. This is particularly true in tropical regions, where temperature and humidity are often very high.

The nutritional requirements of saprobes (and of some parasites that can be cultivated artificially) have been determined by growing fungi experimentally on various synthetic substances of known chemical composition. Fungi usually exhibit the same morphological characteristics in these culture media as they do in nature. Carbon is supplied in the form of sugars or starch; the majority of fungi thrive on such sugars as glucose, fructose, mannose, maltose, and, to a lesser extent, sucrose. Decomposition products of proteins—*e.g.,* proteoses, peptones, and amino acids—can be used by most fungi as nitrogen sources; ammonium compounds and nitrates also serve for many species. It is doubtful, however, that any fungus can combine, or fix, atmospheric nitrogen into usable compounds. Chemical elements such as phosphorus, sulfur, potassium, magnesium, and small quantities of iron, zinc, manganese, and copper are needed by most fungi for vigorous growth; elements such as calcium, molybdenum, and gallium are required by at least some species. Oxygen and hydrogen are absolute requirements; they are supplied in the form of water or are obtained from carbohydrates. Many fungi, deficient in thiamine and biotin, must obtain these vitamins from the environment; most fungi appear able to synthesize all other vitamins necessary for their growth and reproduction. As a rule, fungi are aerobic organisms; *i.e.,* they require free oxygen. Fermentations, however, take place under anaerobic conditions as well. Knowledge of the physiology of saprobic fungi has enabled industry to use several species for fermentation purposes.

Parasitism. In contrast with the saprobic fungi, parasitic fungi attack living organisms, penetrate their outer defenses, invade them, and obtain nourishment from living cytoplasm, causing disease and sometimes the death of the host. Most pathogenic (disease-causing) fungi are parasites of plants, but several are known to cause diseases of humans and lower animals. Most parasites enter the host through a natural opening, such as a stomate (microscopic air pore) in a leaf, a lenticel (small opening through bark) in a stem, a broken plant hair or a hair socket in a fruit, or a wound in the plant or animal epidermis (skin). Such wounds may be insect punctures or accidentally inflicted scratches, cuts, or bruises. Among the most common and widespread diseases of plants caused by fungi are the various downy mildews (*e.g.,* of grape, onion, tobacco), the powdery mildews (*e.g.,* of grape, cherry, apple, peach, rose, lilac), the smuts (*e.g.,* of corn, wheat, onion), the rusts (*e.g.,* of wheat, oats, beans, asparagus, snapdragon, hollyhock), apple scab, brown rot of stone fruits, and

Fungus-caused diseases

various leaf spots, blights, and wilts. These diseases cause great damage annually throughout the world.

Infection of a plant takes place when the spores of a pathogenic fungus fall on the leaves or the stem of a susceptible host and germinate, each producing a germ tube. The tube grows on the surface of the host until it finds an opening; then the tube enters the host, puts out branches between the cells of the host, and forms a mycelial network within the invaded tissue. The germ tubes of some fungi produce special pressing organs called appressoria, from which a microscopic, needlelike peg presses against and punctures the epidermis of the host; after penetration, a mycelium develops in the usual manner. Many parasitic fungi absorb food from the host cells through the hyphal walls appressed against the cell walls of the host's internal tissues. Others produce haustoria (special absorbing structures) that branch off from the intercellular hyphae and penetrate the cells themselves. Haustoria, which may be short, bulbous protrusions or large branched systems filling the whole cell, are characteristically produced by obligate (*i.e.,* invariably parasitic) parasites; some facultative (*i.e.,* occasionally parasitic) parasites such as the potato blight, *Phytophthora infestans,* also produce them. Obligate parasites, which require living cytoplasm and have extremely specialized nutritional requirements, are exceptionally difficult, and often impossible, to grow. Examples of obligate parasites are the downy mildews, the powdery mildews, and the rusts.

Predation. A number of fungi have developed ingenious mechanisms for trapping microorganisms, such as amoebas, roundworms (nematodes), and rotifers. After the prey is captured, the fungus penetrates its body and quickly destroys it. Many of these fungi secrete adhesive substances over the surface of their hyphae, so that a passing animal that touches any portion of the mycelium adheres firmly to it. Soon a penetration tube grows out of a hypha and penetrates the host's soft body. This haustorium grows and branches, and enzymes secreted by it quickly kill the animal, whose cytoplasm serves as food for the fungus.

Animal-trapping fungi

Other fungi produce hyphal loops in which small animals become ensnared until the fungus is able to send haustoria into their bodies and kill them. Perhaps the most amazing of these fungal traps are the so-called constricting rings of some species of *Arthrobotrys, Dactylella,* and *Dactylaria*—soil-inhabiting fungi easily grown under laboratory conditions. In the presence of nematodes, the mycelium produces large numbers of rings through which the average nematode is barely able to pass. When a nematode rubs the inner wall of a ring, which usually consists of three cells with touch-sensitive inner surfaces, the cells of the ring swell rapidly, and the resulting constriction holds the worm tightly. All efforts of the nematode to free itself fail, and a hypha, which grows out of one of the swollen ring cells at its point of contact with the worm, penetrates the animal's body, branches therein, and kills the host, which is then used for food by the fungus. In the absence of nematodes, these fungi do not usually produce rings in appreciable quantities. A substance (nemin) of largely unknown chemical composition is secreted by the nematodes and stimulates the fungus to form the mycelial rings. (C.J.Al./Ed.)

Lichens. *General features.* A lichen is an association between a fungus and an alga that results in a form distinct from either symbiont. Although lichens appear to be single plants, under a microscope the association is seen to consist of millions of cells of algae (called the phycobiont) woven into a matrix formed of the filaments of the fungus (called the mycobiont). The majority of mycobionts are placed in a single group of Ascomycetes called the Lecanorales, which are characterized by an open, often button-shaped fruit called an apothecium. The remaining mycobionts are distributed among various fungal groups—*e.g.,* Sphaeriales, Caliciales, Myrangiales, Pleosporales, and Hysteriales. Although there are various types of phycobionts, most of them also belong to a single group; *i.e.,* half the lichen associations contain species of *Trebouxia,* a single-celled green alga.

Authorities have not been able to establish with any certainty when and how these associations evolved, although lichens must have evolved more recently than their components and probably arose independently from different groups of fungi and algae. It seems, moreover, that the ability to form lichens can spread to new groups of fungi and algae. Lichens are a biological group lacking formal status in the taxonomic framework of living organisms. Although the mycobiont and phycobiont have Latin names, the product of their interaction, a lichen, does not. Earlier names given to lichens as a whole now are considered names for the fungus alone. Classification of lichens is difficult and remains controversial. Part of the problem is that the taxonomy of lichens was established before their dual nature was recognized; *i.e.,* the association was treated as a single entity.

Taxonomic status

Approximately 15,000 different kinds of lichens, some of which provide forage for reindeer and products for humans, have been described. Some lichens are leafy and form beautiful rosettes on rocks and tree trunks; others are filamentous and drape the branches of trees, sometimes reaching a length of 2.75 metres (9 feet). At the opposite extreme are those smaller than a pin head and seen only with a magnifying lens. Lichens grow on almost any type of surface and can be found in almost all areas of the world. They are especially prominent in bleak, harsh regions where few plants can survive. They grow farther north and farther south and higher on mountains than most plants.

The thallus of a lichen has one of several characteristic growth forms (crustose, foliose, or fruticose—see below *Form and function*). Crustose thalli, which resemble a crust closely attached to a surface, are drought-resistant and well adapted to dry climates. They prevail in deserts, Arctic and Alpine regions, and ice-free parts of Antarctica. Foliose, or leafy, thalli grow best in areas of frequent rainfall; two foliose lichens, *Hydrothyria venosa* and *Dermatocarpon fluviatile,* grow on rocks in freshwater streams of North America. Fruticose (stalked) thalli and filamentous forms prefer to utilize water in vapour form and are prevalent in humid, foggy areas such as seacoasts and mountainous regions of the tropics.

Humans have used lichens as food, as medicine, and in dyes. A versatile lichen of economic importance, *Cetraria islandica,* commonly called Iceland moss, sometimes is used either as an appetite stimulant or as a foodstuff in reducing diets; it has also been mixed with bread. Iceland moss also has been used to treat diabetes, nephritis, and catarrh. Lichens have little medical value. One lichen, *Lecanora esculenta,* is reputed to be the manna that in ancient days fell from the skies and served as a food source for humans and domestic animals.

Lichens as dye sources

Lichens are well known as dye sources. Dyes derived from them have an affinity for wool and silk and are formed by decomposition of certain lichen acids and conversion of the products. One of the best-known lichen dyes is orchil, which has a purple or red-violet colour. Orchil-producing lichens include species of *Ochrolechia, Roccella,* and *Umbilicaria.* Litmus, formed from orchil, is widely used as an acid-base indicator. Synthetic coal tar dyes, however, have replaced lichen dyes in the textile industry, and usage of orchil now is limited to its use as a food-colouring agent and an acid-base indicator. A few lichens (*e.g., Evernia prunastri*) are used in the manufacture of perfumes.

Caribou and reindeer depend on lichens for two-thirds of their food supply. In northern Canada an acre of land undisturbed by animals for 120 years or more may contain 250 kilograms (560 pounds) of lichens; some forage lichens that form extensive mats on the ground are *Cladonia alpestris, C. mitis, C. rangiferina,* and *C. sylvatica.* Arboreal lichens such as *Alectoria, Evernia,* and *Usnea* also are valuable as forage. An acre of mature black spruce trees in northern Canada, for example, may contain more than 270 kilograms of lichens on branches within 3 metres of the ground.

Form and function. Although the fungal symbionts of many lichens have fruiting structures on or within their thalli and may release numerous spores that develop into fungi, indirect evidence suggests that natural unions of fungi and algae occur only rarely among some lichen groups, if indeed they occur at all. In addition, free-living, potential phycobionts are not widely distributed; *e.g.*, despite repeated searches, free-living populations of *Trebouxia* have not been found. This paradox, an abundance of fungal spores and a lack of algae capable of forming associations, implies that the countless spores produced by lichen fungi are functionless, at least so far as propagation of the association is concerned. Some phycobionts—*i.e.*, species of *Nostoc* and *Trentpohlia*—can exist as free-living populations, so that natural reassociations could occur in a few lichens.

Some lichens have solved or bypassed the problem of recombination. In a few lichens (*e.g., Endocarpon, Staurothele*) algae grow among the tissues of a fruiting body and are discharged along with fungal spores; such phycobionts are called hymenial algae. When the spores germinate, the algal cells multiply and gradually form lichens with the fungus. Other lichens form structures, especially soredia, that are effective in distributing the association. A soredium, consisting of one or several algal cells enveloped by threadlike fungal filaments, or hyphae, may develop into a thallus under suitable conditions. Lichens without soredia may propagate by fragmentation of their thalli. Many lichens develop small thalloid extensions, called isidia, that also may serve in asexual propagation if broken off from the thallus.

In addition to these mechanisms for propagation, the individual symbionts have various methods of reproduction. Ascolichens—*i.e.*, lichens in which the mycobiont is an ascomycete—for example, form fruits (ascocarps) similar to those of free-living ascomycetes, except that the mycobiont's fruits are capable of producing spores for a longer period of time. The algal symbiont within the lichen thallus reproduces by the same methods as its free-living counterpart.

Most lichen phycobionts are penetrated to varying degrees by specialized fungal structures called haustoria. *Trebouxia* lichens have a pattern in which deeply penetrating haustoria are prevalent in associations lacking a high degree of thalloid organization. On the other hand, superficial haustoria prevail among forms with highly developed thalli. *Lecanora* and *Lecidea*, for example, have individual algal cells with as many as five haustoria that may extend to the cell centre. *Alectoria* and *Cladonia* have haustoria that do not penetrate far beyond the algal cell wall. A few phycobionts, such as *Coccomyxa* and *Stichococcus*, which are not penetrated by haustoria, have thin-walled cells that are pressed close to fungal hyphae.

Benefits of symbiosis

The flow of nutrients and metabolites between the symbionts is the basic foundation of the symbiotic system. A simple carbohydrate formed in the algal layer eventually is excreted, taken up by the mycobiont, and transformed into a different carbohydrate. The release of carbohydrate by the phycobiont and its conversion by the mycobiont occur rapidly. Whether or not the fungus influences the release of carbohydrate by the alga is not known with certainty, but it is known that carbohydrate excretion by the alga decreases rapidly if it is separated from the fungus.

Carbohydrate transfer is only one aspect of the symbiotic interaction in lichens. The alga may provide the fungus with vitamins, especially biotin and thiamine, important because most lichen fungi that are grown in the absence of algae have vitamin deficiencies. The alga also may contribute a substance that causes structural changes in the fungus since it forms the typical lichen thallus only in association with an alga.

One contribution of the fungus to the symbiosis concerns absorption of water vapour from the air; the process is so effective that, at high levels of air humidity, the phycobionts of some lichens photosynthesize at near-maximum rates. The upper region of a thallus provides shade for the underlying algae, some of which are sensitive to strong light. In addition, the upper region may contain pigments or crystals that further reduce light intensity and act as filters, absorbing certain wavelengths of light.

Lichens synthesize a variety of unique organic compounds that tend to accumulate within the thallus; many of these substances are coloured and are responsible for the red, yellow, or orange colour of lichens.

Thalloid types

A lichen thallus or composite body has one of two basic structures. In a homoiomerous thallus, the algal cells, distributed throughout the structure, are more numerous than those of the fungus. The more common type of thallus, a heteromerous thallus, has four distinct layers, three of which are formed by the fungus and one by the alga. The fungal layers are called upper cortex, medulla, and lower cortex. The upper cortex consists of either a few layers of tightly packed cells or hyphae that may contain pigments. A cuticle may cover the cortex. The lower cortex, which is similar in structure to the upper cortex, participates in the formation of attachment structures called rhizines. The medulla, located below the algal layer, is the widest layer of a heteromerous thallus. It has a cottony appearance and consists of interlaced hyphae. The loosely structured nature of the medulla provides it with numerous air spaces and allows it to hold large amounts of water. The algal layer, about three times as wide as a cortex, consists of tightly packed algal cells enveloped by fungal hyphae from the medulla.

A heteromerous thallus may have a stalked (fruticose), crustlike (crustose), or a leafy (foliose) form; many transitional types exist. It is not known, moreover, which growth form is primitive and which is advanced. Fruticose lichens, which usually arise from a primary thallus of a different growth form (*i.e.*, crustose, foliose), may be shrubby or pendulous or consist of upright stalks. The fruticose form usually consists of two thalloid types: the primary thallus is crustlike or lobed; the secondary thalli, which originate from the crust or lobes of the primary thallus, consists of stalks that may be simple, cup-shaped, intricately branched, and capped with brown or red fruiting bodies called apothecia. Fruticose forms such as *Usnea* may have elongated stalks with a central solid core that provides strength and elasticity to the thallus.

The crustose thallus is in such intimate contact with the surface to which it is attached that it usually cannot be removed intact. Some crustose lichens grow beneath the surface of bark or rock so that only their fruiting structures penetrate the surface. Crustose lichens may have a hypothallus—*i.e.*, an algal-free mat of hyphae extending beyond the margin of the regular thallus. Crustose form varies: granular types such as *Lepraria*, for example, have no organized thalloid structure; but some *Lecanora* species have highly organized thalli, with lobes that resemble foliose lichens lacking a lower cortex.

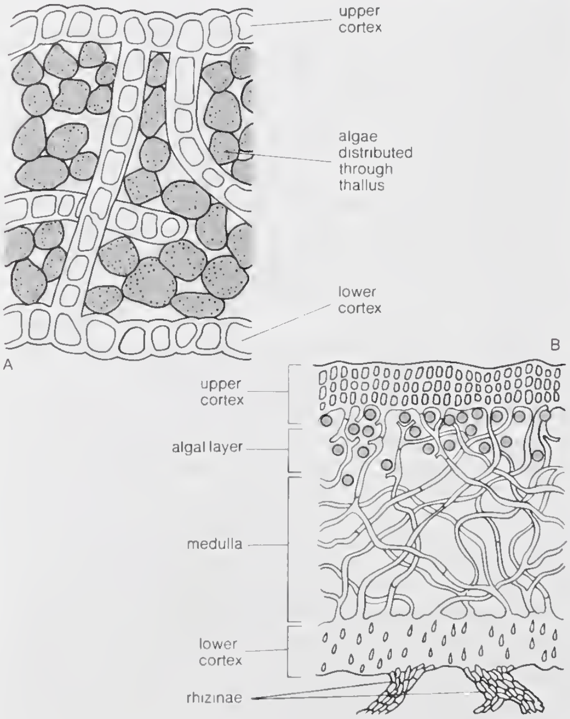

Figure 7: *Distinctions based on distribution of algal cells.* (A) Homoiomerous thallus; (B) heteromerous thallus.

The foliose forms are flat, leaflike, and loosely attached to a surface. The largest known lichens have a foliose form; species of *Sticta* may attain a diameter of about a metre. Other common foliose genera include *Cetraria, Parmelia, Peltigera,* and *Physcia. Umbilicaria,* called the common rock tripe, differs from other foliose forms in its mode of attachment in that its platelike thallus attaches at the centre to a rock surface.

Fruiting bodies and spores

The complex fruiting bodies (ascocarps) of lichen fungi are of several types. The factors that induce fruiting in lichens have not been established with certainty. Spores of lichen fungi (ascospores) are of extremely varying sizes and shapes; *e.g., Pertusaria* has one or two large spores in one ascus (saclike bodies containing the ascospores), and *Acarospora* may have several hundred small spores per ascus. Although in most species the ascospore generally has one nucleus, it may be single-celled or multicellular, brown or colourless; the *Pertusaria* spore, however, is a single cell containing 200 nuclei. Another type of fungal spore may be what are sometimes called spermatia (male fungal sex cells) or pycnidiospores; it is not certain that these structures have the ability to germinate and develop into a fungal colony. Few lichen fungi produce conidia, a type of asexual spore common among ascomycetes.

The metabolic activity of lichens is greatly influenced by the water content of the thallus. The rate of photosynthesis may be greatest when the amount of water in the thallus is from 65 to 90 percent of the maximum. During drying conditions, the photosynthetic rate decreases and below 30 percent is no longer measurable. Although respiration also decreases rapidly below 80 percent water content, it persists at low rates even when the thallus is air-dried. Since lichens have no mechanisms for water retention or uptake from the surface to which they are attached, they very quickly lose the water vapour they absorb from the air. The rapid drying of lichens is a protective device; *i.e.,* a moisture-free lichen is more resistant to temperature and light extremes than is a wet one. Frequent drying and wetting of a thallus is one of the reasons lichens have a slow growth rate.

Maximum photosynthesis in lichens takes place at temperatures of 15° to 20° C. More light is needed in the spring and summer than in the winter. The photosynthetic apparatus of lichens is remarkably resistant to cold temperatures. Even at temperatures below 0° C, many lichens can absorb and fix considerable amounts of carbon dioxide. Respiration is much less at low temperatures so that, in nature, the winter months may be the most productive ones for lichens. (V.A./Ed.)

EVOLUTION AND PHYLOGENY

The origin of the fungi is obscure, the fossil record being scanty and virtually meaningless. The older theory supposed the fungi to have originated by loss of chlorophyll from one or two groups of algae, one school favouring the development of the fungi monophyletically (*i.e.,* from a single ancestor) from the green algae, the other postulating that the lower fungi originated from the green algae but that the Ascomycetes came from the class Florideae of the red algae and later gave rise to the Basidiomycetes. Most present-day mycologists derive the fungi from ancestral flagellates (algal or protozoan organisms bearing flagella, whiplike swimming organs) but yield that the Oomycetes may belong to a different evolutionary line because of their unique biochemical and cytological features: they synthesize the amino acid lysine, they have cellulosic walls and a special organization of the tryptophan-synthesizing enzymes; their thallus is diploid; and they reproduce through oogamy (production of differentiated egg cells).

Taxonomic criteria

As for the interrelationships among fungal groups, there is much controversy. The modern tendency is to emphasize flagellation as an important phylogenetic criterion in the lower fungi. Thus, all the posteriorly uniflagellate fungi (*i.e.,* those with a single flagellum located at the rear end of the organism) are brought together in one class, Chytridiomycetes, all the anteriorly uniflagellate in the class Hyphochytridiomycetes, and so on, as may be seen in the section on classification below. Whether the Plasmodiophoromycetes should be grouped with the Myxomycetes (slime molds) and removed from the fungi because of their plasmodial phase and their swarm cells, which bear two anterior whiplash flagella, is a moot question.

Biochemical characters have been useful markers to map the probable evolutionary relationships of fungi. Because of common biochemical attributes, such as similarity in wall composition (presence of both chitin and β-1,3-1,6-glucan), the same pattern of organization of tryptophan enzymes, and synthesis of lysine by the same unique pathway (aminoadipic acid), the Chytridiomycetes, Ascomycetes, and Basidiomycetes are believed to constitute the main axis of fungal evolution, with the flagellated Chytridiomycetes representing the most primitive or ancestral forms. Other major groups of fungi, Zygomycetes (mucorales), Hemiascomycetes (ascomycetous yeasts), and Heterobasidiomycetes (basidiomycetous yeasts), are also in the same evolutionary camp; they have chitinous walls and make lysine by the aminoadipic acid pathway but show significant differences in cell-wall composition and organization of tryptophan biosynthetic enzymes. Hence, these fungal groups are believed to be side branches from the main evolutionary axis.

Virtually all mycologists agree that the Basidiomycetes have been derived from the Ascomycetes. This opinion is based on the similarity of the nuclear cycle of the ascus and basidium, the supposed homology of the clamp connection (a structure joining two adjacent cells in the Basidiomycetes) with the crozier (a hook-shaped terminal cell found in Ascomycetes), and the similarity of the binucleate mycelium of Basidomycetes with the ascogenous (ascus-producing) hyphae of Ascomycetes. Not all, however, are agreed as to which group of Ascomycetes gave rise to the Basidiomycetes, nor indeed as to which Basidiomycetes are primitive and which are advanced. Whether the holobasidium (simple, club-shaped basidium) or the heterobasidium (septate or deeply divided basidium) came first is a highly controversial question that has a great bearing on the origin of the Basidiomycetes. Also, the fact that the dolipore (inflated) septum has not been found in the rusts or smuts or in any clearly nonbasidiomycetous group poses an interesting question on the origin of the Basidiomycetes.

CLASSIFICATION

Distinguishing taxonomic features. The fungi as a group are distinguished from other organisms by the nature of their somatic (body) and reproductive structures and by the mode of nutrition they employ. Within the division Mycota, the classes are further distinguished by variations of these characteristics, particularly those involving reproductive stages.

Annotated classification. The following classification is adapted from G.W. Martin in Ainsworth's *Dictionary of the Fungi,* 5th ed. (1961).

KINGDOM MYCOTA (fungi)

Eukaryotic (with true nuclei), achlorophyllous (without chlorophyll), acellular, unicellular, or multicellular organisms; microscopic or macroscopic in size; usually with cell walls and filaments; typically reproducing by spores produced asexually or sexually; walls containing chitin, cellulose, or both, among other substances; about 50,000 living species; fewer than 500 fossil species known.

Division Eumycota (true fungi)

Assimilative stage walled, typically filamentous (a mycelium), sometimes unicellular, usually eucarpic (having only part of the thallus forming a fruiting structure); asexual reproduction by fission, budding, fragmentation, or, more typically, by spores; sexual reproduction by various means, usually resulting in the formation of resting structures or meiospores.

Class Chytridiomycetes

Unicellular or filamentous, holocarpic (having all of the thallus involved in the formation of the fruiting body) or eucarpic; motile cells (zoospores or planogametes) characterized by a single, posterior, whiplash flagellum; mostly aquatic fungi saprobic or parasitic on algae, fungi, or, less often, on flowering plants.

Order Chytridiales. Mycelium lacking but rhizoids (short absorbing filaments) or rhizomycelium often present; chiefly freshwater saprobes or parasites of algae and fungi; some terrestrial species, such as *Olpidium brassicae* and *Synchytrium endobioticum*, cause plant disease; about 550 species.

Order Blastocladiales. Water molds with a restricted thallus, characterized by the production of thick-walled, pitted, resistant sporangia; sexual reproduction by isogamous (equal in size and alike in form) or anisogamous (unequal in size but still similar in form) planogametes; *Allomyces* exhibits an alternation of 2 equal generations; most are saprobes, but various species of *Coelomomyces* are parasitic in mosquito larvae; uniquely, their hyphae are devoid of cell walls; more than 50 species.

Order Monoblepharidales. Water molds with an extensive, foamy mycelium; sexual reproduction by a motile male gamete (antherozoid) fertilizing a nonmotile differentiated egg, resulting in a thick-walled oospore; about 20 species.

Class Hyphochytridiomycetes

A small group of mostly marine fungi very similar to the order Chytridiales but with motile cells bearing a single tinsel flagellum (*i.e.*, a flagellum with short side branches along the central axis, comblike).

Order Hyphochytriales. Characters of the class; about 15 species.

Class Plasmodiophoromycetes

Endoparasites (internal parasites) of fungi or plants often causing hypertrophy (excessive abnormal growth); assimilative stage an endophytic (living within plant tissue) plasmodium that becomes converted into a group of zoosporangia (structures producing motile asexual spores) or a large number of small, walled spores; motile cells with 2 unequal, anterior, whiplash flagella.

Order Plasmodiophorales. Characters of the class; *Plasmodiophora* and *Spongospora* cause serious plant diseases; about 35 species.

Class Oomycetes

Aquatic, amphibious, or terrestrial fungi; saprobic, facultatively (occasionally) or obligately (invariably) parasitic on plants, a few on fish; asexual reproduction typically by zoospores with 2 anterior or lateral flagella, 1 whiplash, 1 tinsel; sexual reproduction usually by contact of differentiated gametangia (gamete- or sex-cell-producing structures) with nuclei from the male fertilizing differentiated eggs and resulting in thick-walled oospores; thallus probably diploid with meiosis occurring in the gametangia.

Order Lagenidiales. Holocarpic, unicellular or filamentous water molds, parasitic on algae and fungi or saprobic; oogonium (egg-producing structure) typically containing a single egg; about 85 species.

Order Saprolegniales. Mostly eucarpic, filamentous water molds or soil fungi; saprobic or parasitic; hyphae without constrictions or cellulin plugs; oogonia containing 1 to many free eggs; some species are diplanetic, *i.e.*, they produce 2 types of zoospores, primary (pear-shaped with anterior flagella) and secondary (kidney-shaped with lateral flagella); some (*Aphanomyces*) cause root rots; others (*Saprolegnia*) infect fish and fish eggs; about 200 species.

Order Leptomitales. Aquatic saprobes found often in polluted waters; eucarpic; hyphae constricted, with cellulin plugs, arising from a well-defined basal cell; oogonium typically containing a single egg, which may be free or embedded in periplasm (a peripheral layer of protoplasm); 20 species.

Order Peronosporales. Aquatic or terrestrial; parasitic on algae or vascular plants, the latter mostly obligate parasites causing downy mildews; zoosporangia, in advanced species, borne on well-differentiated sporangiophores, deciduous and behaving as conidia (asexually produced spores); about 250 species.

Class Zygomycetes

Terrestrial saprobes or parasites of plants, animals, or humans; asexual reproduction by aplanospores (nonmotile spores) in sporangia or by conidia; sexual reproduction by fusion of morphologically similar gametangia, sometimes differing in size, resulting in thick-walled zygospores.

Order Mucorales. Often called the bread molds; saprobic, weakly parasitic on plants, or parasitic on humans and then causing mucormycosis (a pulmonary infection); asexual reproduction by sporangiospores, 1-spored sporangiola (a small deciduous sporangium), or conidia; in the genus *Pilobolus* the heavily cutinized sporangium is forcibly discharged; about 360 species.

Order Entomophthorales. Insect parasites or saprobes, some implicated in animal or human diseases; asexual reproduction by modified sporangia functioning as conidia, forcibly discharged; about 150 species.

Order Zoopagales. Parasitic on amoebas, rotifers, nematodes, or other small animals, which they trap by various specialized mechanisms; asexual reproduction by conidia borne singly or in chains, not forcibly discharged; about 60 species.

Class Trichomycetes

Commensals (organisms living parasitically on another organism but conferring some benefit in return, or at least not harming the host) with a filamentous thallus attached by a holdfast or basal cell to the digestive tract or external cuticle of living arthropods; asexual reproduction by sporangiospores (a spore borne within a sporangium), trichospores (zoospores or ciliated spores), arthrospores (a spore resulting from fragmentation of a hypha), or amoeboid cells; sexual reproduction, where known, zygomycetous.

Order Amoebidiales. Thallus coenocytic (without cross walls, with numerous freely distributed nuclei) arising from a holdfast; amoeboid cells formed; about 12 species.

Order Eccrinales. Thallus coenocytic, attached by a holdfast to the digestive tract of arthropods; aplanosporangia produced in succession; more than 50 species.

Order Asellariales. Thallus branched, septate, attached by a basal coenocytic cell; asexual reproduction by arthrospores; 6 species.

Order Harpellales. Thallus simple or branched, septate; asexual reproduction by trichospores; sexual reproduction zygomycetous; about 35 species.

Class Ascomycetes

Saprobic or parasitic on plants, animals, or humans; some are unicellular but most are filamentous, the hyphae septate with 1, rarely more, perforations in the septa; cells uninucleate or multinucleate; asexual reproduction by fission, budding, fragmentation, or, more typically, by conidia usually produced on special sporiferous (spore-producing) hyphae, the conidiophores, which are borne loosely on somatic (main-body) hyphae or variously assembled in asexual fruiting bodies; sexual reproduction by various means resulting in the production of meiosphores (ascospores) formed by free-cell formation in saclike structures (asci), which are produced naked or, more typically, are assembled in characteristic open or closed fruiting bodies (ascocarps); among the largest and most commonly known ascomycetes are the morels, cup fungi, saddle fungi, and truffles.

Subclass Hemiascomycetidae. Asci naked, formed from single cells or on hyphae; no ascocarps or ascogenous hyphae produced; saprobic or parasitic.

Order Protomycetales. Spore sac compound (a synascus); a poorly known small group of plant-parasitic ascomycetes; 20 or more species.

Order Endomycetales. Mostly saprobic, a few parasitic; zygote or single cell transformed directly into the ascus; mycelium sometimes lacking; this group includes the yeasts and their relatives.

Order Taphrinales. Parasites on vascular plants; asci produced from binucleate ascogenous (ascus-producing) cells formed from the hyphae in the manner of chlamydospores (thick-walled spores); 90 or more species.

Subclass Euascomycetidae. Asci unitunicate (ascus wall single-layered), borne in various types of ascocarps; saprobic or parasitic on plants, animals, or humans.

Order Eurotiales. Asci globose to broadly oval, typically borne at different levels in cleistothecia (completely closed ascocarp or fruiting structure); most of the human and animal dermatophytes belong here, also many saprobic soil or coprophilous fungi; possibly up to 150 species.

Order Microascales. Asci evanescent (quickly deteriorating), borne at different levels in perithecia (closed ascocarps with a pore in the top) with ostioles (the opening of the perithecium), or sometimes a long necklike structure terminating in a pore; some serious plant parasites such as *Ceratocystis ulmi* (Dutch elm disease) and *C. fagacearum* (oak wilt) belong here; about 100 species.

Order Onygenales. Asci formed in a mazaedium (a fruiting body consisting of a powdery mass of free spores interspersed with sterile threads, enclosed in a peridium or wall structure), evanescent, and liberating the ascospores as a powdery mass among sterile threads; about 25 species.

Order Erysiphales. Obligate parasites on flowering plants causing powdery mildews; mycelium white, superficial in most, feeding by means of haustoria sunken into the epidermal cells of the host; 1 to several asci in a cleistothecium, if more than 1, in a basal layer at maturity; asci globose to broadly oval; cleistothecia with appendages; about 150 species.

Order Meliolales. Mycelium dark, superficial on leaves and stems of vascular plants, typically bearing appendages (termed hyphopodia or setae); asci in basal layers in ostiolate perithecia without appendages; mostly tropical fungi; more than 1,000 species.

Order Chaetomiales. Asci in basal layers in superficial perithecia that bear conspicuous, straight or curly, simple or branched hairs on the surface; asci evanescent; about 110 species.

Order Xylariales. Perithecia with dark, membranous or carbonous (appearing as black burned wood) walls, with or without a stroma (a compact structure on or in which fructifications are formed); asci persistent, borne in a basal layer among paraphyses (elongate structures resembling asci but sterile), which may ultimately gelatinize and disappear; a rather large group of fungi one of which, *Neurospora crassa,* has been used extensively in genetic and biochemical studies; approximately 4,500 species.

Order Diaporthales. Perithecia immersed in plant tissue or in a stroma with their long ostioles protruding; ascal stalks gelatinizing, freeing the asci from their basal attachment; paraphyses lacking; the chestnut blight fungus (*Endothia parasitica*) belongs here; close to 500 species.

Order Hypocreales. Perithecia and stromata when present, brightly coloured, soft, fleshy, or waxy, when fresh; asci borne in a basal layer among apical paraphyses; about 800 species.

Order Clavicipitales. Perithecia immersed in a stroma that issues from a sclerotium (a hard-resting body resistant to unfavourable environmental conditions); asci with a thick apex penetrated by a central canal through which the septate, threadlike ascospores are ejected; the ergot fungus (*Claviceps purpurea*), cause of ergotism in plants, animals, and humans, and the original source of LSD, belongs to this order; some other Clavicipitales parasitize insect larvae; about 170 species.

Order Coryneliales. Asci in ascostromata with funnel-shaped ostioles at maturity; about 20 species.

Order Coronophorales. Asci in ascostromata with irregular or round, never funnel-shaped, openings; about 30 species.

Order Laboulbeniales. Ascomycetes of uncertain affinity; minute parasites of insects and arachnids with mycelium represented only by haustoria and stalks; about 1,635 species.

Order Ostropales. Ascocarp a loculelike apothecium (an open, often cuplike ascocarp); asci inoperculate (without a terminal pore) constructed as in the Clavicipitales; ascospores septate, threadlike; about 80 species.

Order Phacidiales. Ascocarp an apothecium immersed in a black stroma, the upper covering of which splits in stellate (star-shaped) or irregular fashion when ascospores mature; about 150 species.

Order Helotiales. Ascocarp an apothecium bearing inoperculate asci exposed from an early stage; some important plant diseases are caused by members of this group (for example, *Monilinia fructicola* causes brown rot of stone fruits), the earth tongues (*Geoglossaceae*) also belong here; more than 1,500 species.

Order Pezizales. Ascocarp an apothecium bearing operculate (with a hinged cap) asci above the ground; apothecia often large, cup- or saucer-shaped, spongy, brainlike, saddle-shaped, etc.; this group includes the morels, the false morels, and the saddle fungi among others; about 700 species.

Order Tuberales (truffles). The ascocarps, mostly closed and borne below the ground, are considered to be modified apothecia; the asci are globose, broadly oval, or club-shaped; about 230 species.

Subclass Loculoascomycetidae. Asci bitunicate, borne in ascostromata; saprobic or parasitic on plants.

Order Myriangiales. Asci borne singly in locules arranged at various levels in a more or less globose stroma; about 100 species.

Order Dothideales. Asci borne in fascicles (clusters) in a locule devoid of sterile elements; about 600 species.

Order Pleosporales. Asci borne in a basal layer among pseudoparaphyses; more than 2,000 species.

Order Microthyriales. Stroma flattened, hemispherical, opening by a pore or tear; base usually lacking; asci borne among pseudoparaphyses; mostly tropical fungi; about 1,200 species.

Order Hysteriales. Stroma boat-shaped, opening by a longitudinal slit, which renders it apothecium-like; asci borne among pseudoparaphyses; about 110 species.

Class Basidiomycetes

Saprobic or parasitic on plants or insects; filamentous; the hyphae septate, the septa typically inflated (dolipore) and centrally perforated; mycelium of 2 types, primary of uninucleate cells, succeeded by secondary, consisting of dikaryotic cells, this often bearing bridgelike clamp connections over the septa; asexual reproduction by fragmentation, oidia (thin-walled, free, hyphal cells behaving as spores), or conidia; sexual reproduction by fusion of hyphae (somatogamy), fusion of an oidium with a hypha (oidization), or fusion of a spermatium (a nonmotile male structure that empties its contents into a receptive female structure during plasmogamy—a kind of gamete) with a specialized receptive hypha (spermatization), resulting in dikaryotic hyphae that eventually give rise to basidia, either singly on the hyphae or in variously shaped basidiocarps; meiospores (basidiospores) borne on basidia; in the rusts (Uredinales) and smuts (Ustilaginales), the dikaryotic hyphae produce teleutospores (thick-walled resting spores), which are a part of the basidial apparatus; this is a large class of fungi containing the rusts, smuts, jelly fungi, club fungi, coral and shelf fungi, mushrooms, puffballs, stinkhorns, and bird's-nest fungi.

Subclass Heterobasidiomycetidae. Basidia septate or deeply divided or arising from a teleutospore or cyst; basidiospores often germinating by repetition, budding, or production of conidia; includes the jelly fungi, the rusts, and the smuts.

Order Tremellales (jelly fungi). Fruiting bodies (basidiocarps) well-formed, appearing as inconspicuous horny crusts when dry but usually bright-coloured to black gelatinous masses after a rain; a few are parasitic on mosses, vascular plants, or insects; most are saprobes; about 500 species.

Order Uredinales (rusts). Parasitic on vascular plants; basidial apparatus consists of a thick-walled teleutospore (probasidium), which either gives rise to a 4-celled tube (metabasidium) on which basidiospores are borne or which itself becomes 4-celled and produces basidiospores directly; basidiospores forcibly discharged; many rusts are heteroecious, *i.e.,* they require 2 species of host to complete their life cycle; rusts are among the fungi most destructive to agriculture; about 4,600 species.

Order Ustilaginales (smuts). Called smuts because the masses of spores (sori) are usually black and dusty; basidial apparatus consisting of a thick-walled teleutospore (probasidium), which, upon germination, gives rise to a septate or nonseptate tube (metabasidium), which bears the basidiospores; basidiospores not forcibly discharged, germinating usually by budding or by fusing and then producing a mycelial germ tube; various cereal smuts are of great economic importance; about 700 species.

Subclass Homobasidiomycetidae. Includes the great majority of the Basidiomycetes; most produce conspicuous, large-fruiting bodies, which bear the spores on basidia; basidia are simple, cylindrical, or club-shaped; basidiospores, which may or may not be forcibly discharged, germinate directly into a mycelium.

Order Exobasidiales. Basidiocarps lacking; basidia produced in a layer on the surface of parasitized vascular plants; 15 species.

Order Polyporales. Basidiocarps present; a large and probably heterogeneous order of fungi in which the basidia are borne in various ways but rarely on gills; includes the coral fungi, the club fungi, the chanterelles, and the pore (shelf or bracket) fungi among others; common genera include *Stereum, Clavaria, Hydnum, Cantharellus, Polyporus, Fomes; Schizophyllum* has been used extensively for genetic research; up to 2,500 species.

Order Agaricales (mushrooms and boletes). Basidia produced in layers (hymenia) on the underside of fleshy fruiting bodies (basidiocarps), in tubes (boletes) or on gills (mushrooms); some of these fungi form mycorrhizae, some are parasitic and cause root rots; most are saprobic; 4,000 to 5,000 species.

Order Hymenogastrales. Basidiocarps underground or on the surface but usually buried in humus, remaining closed, the interior (gleba) disintegrating into a slimy mass containing the spores; about 225 species.

Order Lycoperdales (puffballs). Gleba dry and powdery at maturity; consisting of small, pale spores and well-developed capillitium; about 160 species.

Order Sclerodermatales. These are puffballs with a hard peridium enclosing a dry, powdery gleba consisting of large, dark spores and some capillitium; about 120 species.

Order Phallales (stinkhorns). Gleba slimy and fetid at maturity; exposed on an elongated or net-shaped receptacle; *Phallus, Mutinus, Dictyophora, Simblum, Clathrus* are temperate-zone genera; about 70 species.

Order Nidulariales (bird's-nest fungi). The gleba separates into chambers, which become thick-walled, waxy, and hard—these are the peridioles ("eggs"), which are evident within a cuplike or gobletlike basidiocarp, the whole resembling a bird's nest at maturity—*Cyathus* and *Crucibulum* are the 2 most widely distributed genera; about 60 species.

Form-class Deuteromycetes

Fungi with septate mycelium reproducing only asexually and resembling asexual stages of Ascomycetes and Basidiomycetes.

Form-order Sphaeropsidales. Conidia borne in pycnidia; about 5,500 species.

Form-order Melanconiales. Conidia borne in acervuli; about 1,000 species.

Form-order Moniliales. Conidia borne on variously assembled conidiophores but never in pycnidia or acervuli; 10,000 or more species.

Form-order Mycelia Sterilia. No conidia produced; probably mycelial stages of Basidiomycetes; about 200 species.

Critical appraisal. Although the fungi were traditionally classified in the plant kingdom, some of their characteristics argue strongly against such affinities. Chief among them are their heterotrophy and the almost universal presence of chitin, which is also found in the skin of many invertebrate animals such as insects, in their walls. The classification followed in this article and in other articles in the *Ma-*

cropædia removes the fungi from the plant kingdom and includes them instead in a separate kingdom—Fungi. The slime molds (Myxomycetes, or Mycetozoa) are placed in the kingdom Protista. Older classification systems applied the name Phycomycetes (algal fungi) to the six classes of "lower fungi" (Chytridiomycetes, Hyphochytridiomycetes, Plasmodiophoromycetes, Oomycetes, Zygomycetes, and Trichomycetes). Although no longer recognized as a formal taxonomic category, the name Phycomycetes is still a useful term for designating those fungi that produce their spores in sporangia and have, in most cases, coenocytic hyphae. These "lower fungi" have been included by some protistologists in the kingdom Protista (see PROTISTS). A definitive classification of the "lower fungi" and protists remains to be agreed upon, however, and the classifications presented above and in the article PROTISTS reflect differences among scientists concerning taxonomy.

The groups that are designated as the form-class Deuteromycetes (also sometimes called "Fungi Imperfecti") consist of organisms whose sexual stages either have not been found or do not exist, together with the asexual stages of some sexually reproducing species. It has happened that sexual stages have been found for some species in this group, and, whenever this occurs, the species is immediately given a name appropriate to its proper taxonomic group. Sometimes, however, it has been found advisable to maintain the form-category name even though sexual stages are known, and this has led to the unusual condition of one species having been assigned two scientific names, only one of which, of course, is valid—the one applying to the sexual stage. The practice is justified mainly for the convenience of having a classification system, artificial though it is, into which conidial (asexual) forms may be grouped and studied. It has even been found useful to extend the concept of form categories to include the conidial stages of known sexually reproducing fungi, mainly Ascomycetes. Since many of these fungi, particularly the parasitic ones, are usually encountered only in the conidial stage, they can be easily identified by making use of the form-category classification. The convenience is great and the practice so widespread that in 1950 the International Botanical Congress legalized the use of form-names for conidial stages, recognizing, of course, the name of the perfect (sexual) stage as the official name of the whole organism. BIBLIOGRAPHY

General works: D.L. HAWKSWORTH, B.C. SUTTON, and G.C. AINSWORTH, *Ainsworth & Bisby's Dictionary of the Fungi*, 7th ed. (1983), remains the standard reference for terminology and definitions; WALTER H. SNELL and ESTHER A. DICK, *A Glossary of Mycology*, rev. ed. (1971), is an excellent dictionary of mycological terms; JOHN RAMSBOTTOM, *Mushrooms & Toadstools* (1953), offers a beautifully illustrated discussion of the occurrence and activities of one group of fungi; and CONSTANTINE J. ALEXOPOULOS and CHARLES W. MIMS, *Introductory Mycology*, 3rd ed. (1979), is an excellent text for both beginning and advanced students. ELIZABETH MOORE-LANDECKER, *Fundamentals of the Fungi*, 3rd ed. (1990), is a good introduction. Other introductions include LILIAN E. HAWKER, *Fungi*, 2nd ed. (1974); JOHN WEBSTER, *Introduction to Fungi*, 2nd ed. (1980); and J.H. BURNETT, *Fundamentals of Mycology*, 2nd ed. (1976), somewhat difficult for the novice. HAROLD C. BOLD, CONSTANTINE J. ALEXOPOULOS, and THEODORE DELEVORYAS, *Morphology of Plants and Fungi*, 5th ed. (1987); and C.T. INGOLD, *The Biology of Fungi*, 5th ed. (1984), offer surveys of the subject. FREDERICK A. WOLF and FREDERICK T. WOLF, *The Fungi*, 2 vol. (1947, reissued 1969), discusses morphology, taxonomy, physiology, genetics, ecology, and medical and industrial mycology. ERNST ATHEARN BESSEY, *Morphology and Taxonomy of Fungi* (1950, reprinted 1985), is a reference strong on phylogeny and the bibliography of classification. WILLIAM D. GRAY, *The Relation of Fungi to Human Affairs* (1959), discusses useful and destructive fungi, with emphasis on the application of mycology to industry; and D.L. HAWKSWORTH and B.E. KIRSOP (eds.), *Filamentous Fungi* (1988), explores applications of these fungi to biotechnology. G.C. AINSWORTH and ALFRED S. SUSSMAN (eds.), *The Fungi*, 4 vol. in 5 (1965–73), an advanced treatise written by specialists in various fields, discusses fungi in terms of cells, the organism, populations, and classification. A large number of topics on the biology of fungi are discussed by specialists in the following collections: JOHN E. SMITH, DAVID R. BERRY, and BJORN KRISTIANSEN (eds.), *The Filamentous Fungi*, 4 vol. (1975–83); ANTHONY H. ROSE and J. STUART HARRISON (eds.), *The Yeasts*, 2nd ed., 3 vol. (1987–89); and GARRY T. COLE and BRYCE KENDRICK (eds.), *Biology of Conidial Fungi*, 2 vol. (1981). Questions of morphological development are covered in JOHN E. SMITH (ed.), *Fungal Differentiation: A Contemporary Synthesis* (1983); PAUL J. SZANISZLO and JAMES L. HARRIS (eds.), *Fungal Dimorphism: With Emphasis on Fungi Pathogenic for Humans* (1985); and G. TURIAN and H.R. HOHL (eds.), *The Fungal Spore, Morphogenetic Controls* (1981). A.H. REGINALD BULLER, *Researches on Fungi*, 7 vol. (1909–50), is a classic collection of studies on various aspects of fungi, particularly strong on spore dispersal, development, and sexual reproduction; the first six volumes were reprinted in 1958. A useful guide of laboratory procedures for studying and handling fungi is presented in RUSSELL B. STEVENS (ed.), *Mycology Guidebook* (1974, reprinted with corrections and index by JOSEPH F. AMMIRATI, 1981). General discussion of physiological topics include MICHAEL O. GARRAWAY and ROBERT C. EVANS, *Fungal Nutrition and Physiology* (1984); DAVID H. GRIFFIN, *Fungal Physiology* (1981); and IAN K. ROSS, *Biology of the Fungi: Their Development, Regulation, and Associations* (1979). For an overview of progress in modern genetics of fungi, including genetic engineering, see J.W. BENNETT and LINDA L. LASURE (eds.), *Gene Manipulations in Fungi* (1985); WILLIAM E. TIMBERLAKE (ed.), *Molecular Genetics of Filamentous Fungi* (1985); and JOHN F. PEBERDY and LAJOS FERENCZY (eds.), *Fungal Protoplasts: Application in Biochemistry and Genetics* (1985).

Special subjects: LUCY KAVALER, *Mushrooms, Molds and Miracles* (1965), discusses various discoveries of fungal products. VALENTINA P. WASSON and R. GORDON WASSON, *Mushrooms, Russia, and History*, 2 vol. (1957), is an ethnomycological classic. C.T. INGOLD, *Dispersal in Fungi* (1953, reprinted with additions 1968), and *Spore Liberation* (1965), discuss the means by which fungi liberate their spores. KARL ESSER and RUDOLF KUENEN, *Genetics of Fungi* (1967; originally published in German, 1965), offers a general treatment; and JOHN R. RAPER, *Genetics of Sexuality in Higher Fungi* (1966), explores life cycles and sexual mechanisms in Ascomycetes and Basidiomycetes. D. PARKINSON and J.S. WAID (eds.), *The Ecology of Soil Fungi* (1960), is a series of essays; T.W. JOHNSON, JR., and F.K. SPARROW, JR., *Fungi in Oceans and Estuaries* (1961), provide important references; and WM. BRIDGE COOKE, *The Fungi of Our Mouldy Earth*, new ed. (1986), studies the fungi of the environment, with emphasis on water. CHESTER W. EMMONS *et al.*, *Medical Mycology*, 3rd ed. (1977); and CLYDE M. CHRISTENSEN, *Molds, Mushrooms, and Mycotoxins* (1975), study pathogenic fungi. J. WALTER WILSON and ORDA A. PLUNKETT, *The Fungous Diseases of Man* (1965), is a medical treatise. JOHN WILLARD RIPPON, *Medical Mycology: The Pathogenic Fungi and the Pathogenic Actinomycetes*, 3rd ed. (1988), is a textbook. E.C. LARGE, *The Advance of the Fungi* (1940, reprinted 1962), is a classic book on plant-disease fungi. Special biochemical topics are discussed in J.W. BENNETT and ALEX CIEGLER (eds.), *Secondary Metabolism and Differentiation in Fungi* (1983); and JOHN D. WEETE, *Lipid Biochemistry of Fungi and Other Organisms* (1980).

Special groups of fungi: CLYDE M. CHRISTENSEN, *Common Fleshy Fungi*, 2nd ed. (1955), is an easy-to-use manual for identifying common mushrooms; J. WALTON GROVES, *Edible and Poisonous Mushrooms of Canada*, rev. ed. (1979), identifies mushrooms; L.R. HESLER, *Mushrooms of the Great Smokies* (1960), is a field guide, with black-and-white photographs; RENÉ POMERLEAU and H.A.C. JACKSON, *Mushrooms of Eastern Canada and the United States*, trans. from French (1951), is a good manual; ALEXANDER H. SMITH, *Mushrooms in Their Natural Habitats*, 2 vol. (1949), is useful for the Pacific Northwest region; and GARY H. LINCOFF, *The Audubon Society Field Guide to North American Mushrooms* (1981), identifies many species. KENNETH B. RAPER and CHARLES THOM, *A Manual of the Penicillia* (1949, reprinted 1968); and KENNETH B. RAPER and DOROTHY I. FENNELL, *The Genus Aspergillus* (1965, reprinted 1977), are helpful. See also K.J. SCOTT and A.K. CHAKRAVORTY (eds.), *The Rust Fungi* (1982); and ROBERT W. LICHTWARDT, *The Trichomycetes, Fungal Associates of Arthropods* (1986).

Lichens: MASON E. HALE, JR., *The Biology of Lichens*, 3rd ed. (1983), is an intermediate-level introduction, and *How to Know the Lichens*, 2nd ed. (1979), is an authoritative guide. ANNIE L. SMITH, *Lichens* (1921, reprinted with additions 1975), a classic work on lichenology, is still a useful reference source. See also DAVID L. HAWKSWORTH and DAVID J. HILL, *The Lichen-Forming Fungi* (1984). YASUHIKO ASAHINA and SHOJI SHIBATA, *Chemistry of Lichen Substances* (1954, reprinted 1971; originally published in Japanese, 1949), is a classic reference book. BRUCE FINK, *The Lichen Flora of the United States* (1935, reissued 1971), is an advanced source. G.G. NEARING, *The Lichen Book* (1947, reissued 1962), is a good popular guide with drawings, popular names, and descriptions.

Galaxies

The stars of the universe are gathered together in numerous giant assemblages known as galaxies. Many such assemblages are so enormous that they contain hundreds of billions of stars. Nature has provided an immensely varied array of galaxies, ranging from faint, diffuse dwarf objects to brilliant, spiral-shaped giants. Virtually all galaxies appear to have been formed soon after the universe began, and they pervade space, even into the depths of the farthest reaches penetrated by powerful modern telescopes. Galaxies usually exist in clusters, some of which in turn are grouped into larger clusters measuring hundreds of millions of light-years across. (A light-year is the distance traversed by light in one year, traveling at a velocity of 300,000 kilometres per second, or 650,000,000 miles per hour.) These so-called superclusters are separated by nearly empty voids, causing the gross structure of the universe to look somewhat like a network of sheets and chains of galaxies.

Galaxies differ from one another in shape, with variations resulting from the way in which the systems were formed. Depending on the initial conditions in the pregalactic gas some 15,000,000,000 years ago, galaxies formed either as slowly turning, smoothly structured, round systems of stars and gas or as rapidly rotating pinwheels of such entities. Other differences between galaxies have been observed and are thought to reflect evolutionary changes. Some galaxies are rife with activity: they are the sites of star formation with its attendant glowing gas and clouds of dust and molecular complexes. Others, by contrast, are quiescent, having long ago ceased to form new stars. Perhaps the most conspicuous evolutionary changes in galaxies occur in their nuclei, where evidence suggests that in many cases supermassive objects—probably black holes—formed when the galaxies were young. Such phenomena occurred several billion years ago and are now observed as brilliant objects called quasars.

The existence of galaxies was not recognized until the early 20th century. Since then, however, galaxies have become one of the focal points of astronomical investigation. The notable developments and achievements in the study of galaxies are surveyed here. Much attention is also devoted to the Milky Way Galaxy—the local galaxy to which the Sun and Earth belong—and the galaxies and related objects that lie outside it. Included in the discussion are the properties, structures, and major components of the Milky Way system and the external galaxies; the distribution of the latter in clusters and superclusters; and the evolution of galaxies and quasars. For specifics about the components of galaxies, see STARS AND STAR CLUSTERS, NEBULA, and COSMOS.

For coverage of other related topics in the *Macropædia* and *Micropædia*, see the *Propædia*, sections 131 and 132, and the *Index*.

This article is divided into the following sections:

Historical survey of the study of galaxies

EARLY OBSERVATIONS AND CONCEPTIONS

The notion of spiral nebulas

The dispute over the nature of what were once termed spiral nebulas stands as one of the most significant in the development of astronomy. On this dispute hinged the question of the magnitude of the Cosmos: were we confined to a single, limited stellar system that lay embedded alone in empty space, or was our Milky Way Galaxy just one of millions of galaxies that pervaded space, stretching beyond the vast distances probed by our most powerful telescopes? How this question arose and how it was resolved is an important element in the development of our prevailing view of the universe.

Up until 1925 spiral nebulas and their related forms had uncertain status. Some scientists, notably Heber D. Curtis of the United States and Knut Lundmark of Sweden, had argued that they might be remote aggregates of stars similar in size to the Milky Way Galaxy. Centuries earlier the German philosopher Immanuel Kant, among others, had suggested much the same idea, but that was long before the tools were available to actually measure distances and thus prove it. During the early 1920s astronomers were divided. Although some deduced that spiral nebulas were actually extragalactic star systems, there was evidence that convinced many that such nebulas were local clouds of material, possibly new solar systems in the process of forming.

The problem of the Magellanic Clouds. It is now known that the nearest external galaxies are the Magellanic Clouds, two patchy, irregular objects visible in the skies of the Southern Hemisphere. For years, most experts who regarded the Clouds as portions of the Milky Way system separated from the main stream could not study them because of their position. (Both Magellanic Clouds are too far south to be seen from the United States.) Moreover, the irregular shapes of the objects and their numerous hot, blue stars, star clusters, and gas clouds did indeed make them resemble the southern Milky Way.

Discovery of the period–luminosity relation

The American astronomer Harlow Shapley, noted for his far-reaching work on the size and structure of the Milky Way Galaxy, was one of the first to appreciate the importance of the Magellanic Clouds in terms of the nature of spiral nebulas. To gauge the distance of the Clouds, he made use of the period–luminosity (P–L) relation discovered by Henrietta Leavitt of the Harvard College Observatory. In 1912 Leavitt had found that there was a close correlation between the periods of pulsation (variations in light) and the luminosities (intrinsic, or absolute, brightnesses) of a class of stars called Cepheid variables in the Small Magellanic Cloud. Leavitt's discovery, however, was of little practical value until Shapley worked out a calibration of the absolute brightnesses of pulsating stars closely analogous to the Cepheids, the so-called RR Lyrae variables (see below). With this quantified form of the P–L relation, he was able to calculate the distances to the Magellanic Clouds, determining that they were about 75,000 light-years from the Earth. The significance of the Clouds, however, continued to elude scientists of the time. For them, these objects still seemed to be anomalous, irregular patches of the Milky Way, farther away than initially thought but not sufficient to settle the question of the nature of the Cosmos.

Novas in the Andromeda Nebula. An unfortunate misidentification hampered the early recognition of the northern sky's brightest nearby galaxy, the Andromeda Nebula, also known as M31. In 1885 a bright star, previously invisible, appeared near the centre of M31, becoming almost bright enough to be seen without a telescope. As it slowly faded again, astronomers decided that it must be a nova, a "new star," similar to the class of temporary stars found relatively frequently in populous parts of the Milky Way. If this was the case, it was argued, then its extraordinary brightness must indicate that M31 cannot be very far away, certainly not outside of the local system of stars. Designated S Andromeda in conformity with the pattern of terminology applied to stars of variable brightness, this supposed nova was a strong argument in favour of the hypothesis that nebulas are nearby objects in the Milky Way system.

By 1910, however, there was evidence that S Andromeda might have been wrongly identified. Deep photographs were being taken of M31 with the Mount Wilson Observatory's newly-completed 152-centimetre (60-inch) telescope, and the astronomers at the observatory, especially J.C. Duncan and George W. Ritchey, were finding faint objects, just resolved by the longest exposures, which also seemed to behave like novas. These objects, however, were about 10,000 times fainter than S Andromeda. If they were ordinary novas then M31 must be millions of light-years away; but then the nature of S Andromeda became a difficult question. At this vast distance its total luminosity would have to be immense—an incomprehensible output of energy for a single star.

Completion of the 254-centimetre (100-inch) telescope on Mount Wilson in 1917 resulted in a new series of photographs that captured even fainter objects. More novas were found in M31, mainly by Milton L. Humason, who was an assistant at the time to Edwin P. Hubble, one of the truly outstanding astronomers of the day. Hubble eventually studicd 63 of these stars, and his findings proved to be one of the final solutions to the controversy (see below *The distance to the Andromeda Nebula*).

The scale of the Milky Way Galaxy. At the same time that spiral nebulas were bcing studied and debated, the Milky Way Galaxy became the subject of contentious discussion. During the early years of the 20th century, most astronomers believed that the Milky Way was a disk-shaped system of stars with the Sun near the centre and with the edge along a thick axis only about 15,000 light-years away. This view was based on statistical evidence involving star counts and the spatial distribution of a variety of cosmic objects—open star clusters, variable stars, binary systems, and clouds of interstellar gas. All of these objects seemed to thin out at distances of several thousand light-years.

Significance of Shapley's research on globular clusters

This conception of the Milky Way Galaxy was challenged by Shapley in 1917, when he released the findings of his study of globular clusters. He had found that these spherically symmetrical groups of densely packed stars, as compared to the much closer open clusters, were unusual in their distribution. While the known open clusters are concentrated heavily in the bright belt of the Milky Way, the globulars are for the most part absent from those areas, except in the general direction of the constellation Sagittarius where there is a concentration of faint globulars. Shapley's plot of the spatial distribution of these stellar groupings clarified this peculiar fact: the centre of the globular cluster system—a huge, almost spherical cloud of clusters—lies in that direction, some 30,000 light-years from the Sun. Shapley assumed that this centre must also be the centre of the Milky Way Galaxy. The globular clusters, he argued, form a giant skeleton around the disk of the Milky Way, and thus the system is immensely larger than was previously thought, its total extent measuring nearly 100,000 light-years (see below *The Milky Way Galaxy: Size and mass*).

Shapley succeeded in making the first reliable determination of the size of the Milky Way Galaxy largely by using Cepheids and RR Lyrae stars as distance indicators. His approach was based on the period–luminosity relation discovered by Leavitt and on the assumption that all of these variables have the same P–L relation. As he saw it, this assumption was most likely true in the case of the RR Lyrae stars, because all variables of this type in any given globular cluster have the same apparent brightness. If all RR Lyrae variables have the same intrinsic brightness, then it follows that differences in apparent brightness must be due to different distances from the Earth. The final step in developing a procedure for determining the distances of variables was to calculate the distances of a handful of such stars by an independent method so as to enable calibration. Shapley could not make use of the trigonometric parallax method since there are no variables close enough for direct distance measurement. However, he had recourse to a technique devised by the Danish astronomer Ejnar Hertzsprung that could determine distances to certain nearby field variables (*i.e.,* those not associated with any particular cluster) using measurements of their proper motions and the radial velocity of the Sun (see below *Stellar motions*). Accurate measurements of the proper motions of the variables based on long-term observations were available, and the Sun's radial velocity could be readily determined spectroscopically. Thus, by availing himself of this body of data and adopting Hertzsprung's method, Shapley was able to obtain a distance scale for Cepheids in the solar neighbourhood.

Shapley applied the zero point of the Cepheid distance scale to the globular clusters he had studied with the 152-centimetre telescope at Mount Wilson. Some of these clusters contained RR Lyrae variables, and for these Shapley could calculate distances in a straightforward manner from the period–luminosity relation. For other globulars he made distance determinations using a relationship that he discovered between the brightnesses of the RR Lyrae stars and the brightness of the brightest red stars. For still others he made use of apparent diameters, which he found to be relatively uniform for clusters of known distance. The final result was a catalog of distances for 69 globular clusters, from which Shapley deduced his revolutionary model of the Milky Way—one that not only significantly extended the limits of the galactic system but that also displaced the Sun from its centre to a location nearer its edge.

Shapley's work caused astronomers to ask themselves certain questions: How could the existing stellar data be so wrong? Why couldn't they see something in Sagittarius, the proposed galactic centre, 30,000 light-years away? The reason for the incorrectness of the star count methods was not learned until 1930, when Lick Observatory astronomer Robert J. Trumpler, while studying open clusters, discovered that interstellar dust pervades the plane of the Milky Way Galaxy and obscures objects beyond only a few thousand light-years. This dust thus renders the centre of the system invisible optically and makes it appear that globular clusters and spiral nebulas avoid the band of the Milky Way.

The zone of avoidance

Shapley's belief in the tremendous size of the local galactic system helped to put him on the wrong side of the argument about other galaxies. He thought that if the Milky Way was so immense, the spiral nebulas must lie within it. His conviction was reinforced by two lines of evidence. One of these has already been mentioned—the nova S Andromeda was so bright as to suggest that the Andromeda Nebula most certainly was only a few hundred light-years away. The second came about because of a very curious error made by one of Shapley's colleagues at Mount Wilson Observatory, Adrian van Maanen.

The van Maanen rotation. During the early 20th century one of the most important branches of astronomy was astrometry, the precise measurements of stellar positions and motions. Van Maanen was one of the leading experts in this field. Most of his determinations of stellar positions were accurate and have stood the test of time, but he made one serious and still poorly understood error when he pursued a problem tangential to his main interests. In a series of papers published in the early 1920s, van Maanen reported on his discovery and measurement of the rotation of spiral nebulas. Using early 152-centimetre plates taken by others as well as more recent ones taken about 10 years later, van Maanen measured the positions of several knotlike, nearly stellar images in the spiral arms of some of the largest known spiral nebulas (*e.g.*, M33, M101, and M51). Comparing the positions, he found distinct changes indicative of a rotation of the spiral pattern against the background of surrounding field stars. In each case, the rotation occurs in the sense that the spiral arms trail. The periods of rotation were all approximately 100,000 years. Angular motions were about 0.02 second of arc per year.

Shapley seized the van Maanen results as evidence that the spirals must be nearby; otherwise, their true space velocities of rotation would have to be impossibly large. For example, if M51 is rotating at an apparent rate of 0.02 second of arc per year, its true velocity would be immense if it is a distant galaxy. Assuming that a distance of 10,000,000 light-years would lead to an implausibly large rotation velocity of 12,000 kilometres per second (km/sec), Shapley argued that if a more reasonable velocity were adopted, say, 100 km/sec, then the distances would be all less than 100,000 light-years, putting all the spirals well within the Milky Way Galaxy.

It is unclear just why such a crucial measurement went wrong. Van Maanen repeated the measures and obtained the same answer even after Hubble demonstrated the truth about the distances to the spirals (see below). However, subsequent workers, using the same plates, failed to find any rotation. Among the various hypotheses that science historians have proposed as an explanation for the error are two particularly reasonable ideas: (1) possibly the fact that spiral nebulas look like they are rotating (*i.e.*, they resemble familiar rotational patterns that are perceivable in nature) may have influenced the observer subconsciously, and this subtle effect manifested itself in prejudicing the delicate measurements; or (2) possibly the first set of plates was the problem. Many of these plates had been taken in an unconventional manner by Ritchey, who swung the plateholder out of the field whenever the quality of the images was temporarily poor because of atmospheric turbulence. The resulting plates appeared excellent, having been exposed only during times of very fine seeing; however, according to some interpretations, the images had a slight asymmetry that led to a very small displacement of star images compared to nonstellar images. Such an error could look like rotation if not recognized for what it really was. In any case, the van Maanen rotation was accepted by many astronomers, including Shapley, and temporarily sidetracked progress toward recognizing the truth about galaxies.

The Shapley–Curtis debate. The nature of galaxies and scale of the Cosmos were the subject of the "Great Debate," a public program arranged in 1920 by the National Academy of Sciences at the Smithsonian Institution in Washington, D.C. Featured were talks by Shapley and the aforementioned Heber Curtis, who were recognized as spokesmen for opposite views on the nature of spiral nebulas and the Milky Way. This so-called debate has often been cited as an illustration of how revolutionary new concepts are assimilated by science. It is sometimes compared to the debate, centuries before, over the motions of the Earth (the Copernican revolution); and, though as a focal point it can be used to define the modern controversy, it actually was much more complicated.

A careful reading of the documents involved suggests that on the broader topic of the scale of the universe, both men were making incorrect conclusions but for the same reasons—namely, for being unable to accept and comprehend the incredibly large scale of things. Shapley correctly argued for an enormous Milky Way Galaxy on the basis of the period–luminosity relation and the globular clusters, while Curtis incorrectly rejected these lines of evidence, advocating instead a small galactic system. Given a Milky Way system of limited scale, Curtis could argue for and consider plausible the extragalactic nature of the spiral nebulas. Shapley, on the other hand, incorrectly rejected the island universe theory of the spirals (*i.e.*, the hypothesis that there existed beyond the boundaries of the Milky Way comparable galaxies) because he felt that such objects would surely be engulfed by the local galactic system. Furthermore, he put aside the apparent faint novas in M31, preferring to interpret S Andromeda as an ordinary nova, for otherwise that object would have been unbelievably luminous. Unfortunately for him such phenomena—called supernovas—do in fact exist, as was realized a few years later. Curtis was willing to concede that there might be two classes of novas; yet, because he considered the Milky Way to be small, he underestimated their differences. The van Maanen rotation also entered into Shapley's arguments: if spiral nebulas were rotating so fast, they must be within the Milky Way as he conceived it. For Curtis, however, the matter provided less of a problem: even if spiral nebulas did rotate as rapidly as claimed, the small scale of Curtis' universe allowed them to have physically reasonable speeds.

Shapley's rejection of the island universe theory

The Shapley–Curtis debate took place near the end of the era of the single-galaxy universe. In just a few years the scientific world became convinced that Shapley's grand scale of the Milky Way Galaxy was correct and at the same time that Curtis was right about the nature of spiral nebulas. Such objects indeed lie even outside Shapley's enormous Milky Way, and they range far beyond the distances that in 1920 seemed too vast for many astronomers to comprehend.

Hubble's discovery of extragalactic objects. During the early 1920s Hubble detected 15 stars in the small, irregular cloudlike object NGC 6822 that varied in luminosity, and he suspected that they might include Cepheids. After considerable effort, he determined that 11 of them were in fact Cepheid variables, with properties indistinguishable from those of normal Cepheids in the Milky Way Galaxy and in the Magellanic Clouds. Their periods ranged from 12 to 64 days, and they were all very faint, much fainter than their Magellanic counterparts. Nevertheless, they fit a period–luminosity relation of the same nature as had been discovered by Leavitt (see above).

Hubble then boldly assumed that the P–L relation was universal and derived an estimate for the distance to NGC 6822 using Shapley's most recent (1925) version of the calibration of the relation. This calibration was wrong, as is now known, because of the confusion at that time over the nature of Cepheids. Shapley's calibration included certain Cepheids in globular clusters that subsequent investigators found to have their own fainter P–L relation. (Such Cepheids have been designated Type II Cepheids to distinguish them from the normal variety, which are referred to as Type I.) Thus, Hubble's distance for NGC 6822

NGC 6822 as the first recognized external galaxy

was too small: he calculated a distance of only 700,000 light-years. Today it is recognized that the actual distance is closer to 2,000,000 light-years. In any case, this vast distance—even though underestimated—was large enough to convince Hubble that NGC 6822 must be a remote, separate galaxy, much too far away to be included even in Shapley's version of the Milky Way system. Technically, then, this faint nebula can be considered to be the first recognized external galaxy. The Magellanic Clouds continued to be regarded simply as appendages to the Milky Way, and the other bright nebulas, M31 and M33, were still being studied at the Mount Wilson Observatory. Although Hubble did announce his discovery of Cepheids in M31 at a meeting in 1924, he did not complete his research and publish the results for this conspicuous spiral galaxy until five years later.

While the Cepheids made it possible to determine the distance and nature of NGC 6822, some of its other features corroborated the conclusion that it was a separate, distant galaxy. Hubble discovered within it five diffuse nebulas, which are glowing gaseous clouds composed mostly of ionized hydrogen designated H II regions. (H stands for hydrogen and II indicates that most of it is ionized; H I, by contrast, signifies neutral hydrogen.) He found that these five H II regions had spectra like those of gas clouds in the Milky Way system—*e.g.,* the Orion and Eta Carinae nebulas. Calculating their diameters, Hubble ascertained that the sizes of the diffuse nebulas were normal, similar to those of local examples of giant H II regions.

Five other diffuse objects discerned by Hubble were definitely not gaseous nebulas. He compared them with globular clusters (both in the Milky Way Galaxy and in the Magellanic Clouds) and concluded that they were too small and faint to be normal globular clusters. Convinced that they were most likely distant galaxies seen through NGC 6822, he dismissed them from further consideration. Modern studies suggest that Hubble was too hasty. Though probably not true giant globular clusters, these objects are in all likelihood star clusters in the system, fainter, smaller in population, and probably somewhat younger than normal globular clusters.

The uniformity of nature

The Dutch astronomer Jacobus Cornelius Kapteyn showed in the early 20th century that statistical techniques could be used to determine the stellar luminosity function for the solar neighbourhood. (The luminosity function is a curve that shows how many stars there are in a given volume for each different stellar luminosity.) Anxious to test the nature of NGC 6822, Hubble counted stars in the galaxy to various brightness limits and found a luminosity function for its brightest stars. When he compared it with Kapteyn's, the agreement was excellent—another indication that the Cepheids had given about the right distance and that the basic properties of galaxies were fairly uniform. Step by step, Hubble and his contemporaries piled up evidence for the fundamental assumption that has since guided the astronomy of the extragalactic universe, the uniformity of nature. By its bold application, astronomers have moved from a limiting one-galaxy Cosmos to an immense vastness of space populated by billions of galaxies, all grander in size and design than the Milky Way system had once been thought to be.

The distance to the Andromeda Nebula. In 1929 Hubble published his epochal paper on M31, the great Andromeda Nebula. Based on 350 photographic plates taken at Mount Wilson, his study provided evidence that M31 is a giant stellar system like the Milky Way Galaxy.

Because M31 is much larger than the field of view of the 152-centimetre and 254-centimetre telescopes at Mount Wilson, Hubble concentrated on four regions, centred on the nucleus and at various distances along the major axis. The total area studied amounted to less than half the galaxy's size, and the other unexplored regions remained largely unknown for 50 years. (Modern comprehensive optical studies of M31 have only been conducted since about 1980.)

Hubble pointed out an important and puzzling feature of the resolvability of M31. Its central regions, including the nucleus and diffuse nuclear bulge, were not well resolved into stars, one reason that the true nature of M31 had previously been elusive. However, the outer parts along the spiral arms in particular were resolved into swarms of faint stars, seen superimposed over a structured background of light. Current understanding of this fact is that spiral galaxies typically have central bulges made up exclusively of very old stars, the brightest of which are too faint to be visible on Hubble's plates. Only in 1944 did the German-born astronomer Walter Baade finally resolve the bulge of M31. Using red-sensitive plates and very long exposures, he managed to detect the brightest red giants of this old population. Out in the arms there exist many young, bright, hot, blue stars, and these are easily resolved. The brightest are so luminous that they can even be seen with moderate-size telescopes.

Cepheid variables in the Andromeda Galaxy

The most important of Hubble's discoveries was that of M31's population of Cepheid variables. Forty of the 50 variables detected turned out to be ordinary Cepheids with periods ranging from 10 to 48 days. A clear relation was found between their periods and luminosities, and the slope of the relation agreed with those for the Magellanic Clouds and NGC 6822. Hubble's comparison indicated that M31 must be 8.5 times more distant than the Small Magellanic Cloud (SMC), which would imply a distance of 2,000,000 light-years if the modern SMC distance were used (the 1929 value employed by Hubble was about two times too small). Clearly, M31 must be a distant, large galaxy.

Other features announced in Hubble's paper were M31's population of bright, irregular, slowly varying variables. One of the irregulars was exceedingly bright; it is among the most luminous stars in the galaxy and is a prototype of a class of high-luminosity stars now called Hubble–Sandage variables, which are found in many giant galaxies. Eighty-five novas, all behaving very much like those in the Milky Way Galaxy, were also analyzed. Hubble estimated that the true occurrence rate of novas in M31 must be about 30 per year, a figure that was later confirmed by the American astronomer Halton C. Arp in a systematic search.

Hubble found numerous star clusters in M31, especially globular clusters, 140 of which he eventually cataloged. He clinched the argument that M31 was a galaxy similar to the Milky Way by calculating its mass and mass density. Using the velocities that had been measured for the inner parts of M31 by spectrographic work, he calculated (on the basis of the distance derived from the Cepheids) that M31's mass must be about 3,500,000,000 times that of the Sun. Today, astronomers have much better data, which indicate that the galaxy's true total mass must be at least 100 times greater than Hubble's value, but even that value clearly showed that M31 is an immense system of stars. Furthermore, Hubble's estimates of star densities demonstrated that the stars in the outer arm areas of M31 are spread out with about the same density as in the Milky Way system in the vicinity of the Sun.

RECENT DEVELOPMENTS

Until about 1950 scientific knowledge of galaxies advanced slowly. Only a very small number of astronomers took up galaxy studies, and only a very few telescopes were suitable for significant research. It was an exclusive field, rather jealously guarded by its practitioners, and so progress was orderly but limited.

During the decade of the 1950s the field began to change. Ever larger optical telescopes became available, and the space program resulted in a sizable increase in the number of astronomers emerging from universities. New instrumentation enabled investigators to explore galaxies in entirely new ways, making it possible to detect their radio radiation, infrared and ultraviolet emissions, and eventually even radiation at X-ray wavelength. Whereas in the 1950s there was only one telescope larger than 254 centimetres (100 inches) and only about 10 astronomers conducting research on galaxies worldwide, by the 1980s the number of large telescopes had grown 10-fold and the number of scientists devoted to galaxy study was in the hundreds. Galaxies are now extensively studied with giant arrays of ground-based radio telescopes, Earth-orbiting X-ray, ultraviolet, and infrared telescopes, and high-speed electronic computers, giving rise to remarkable advances in knowledge and understanding.

Types of galaxies

PRINCIPAL SCHEMES OF CLASSIFICATION

Almost all current systems of galaxy classification are outgrowths of the initial scheme proposed by Hubble in 1926. In Hubble's scheme, which is based on the optical appearance of galaxy images on photographic plates, galaxies are divided into three general classes: ellipticals, spirals, and irregulars. His basic definitions are as follows:

Elliptical galaxies. Galaxies of this class have smoothly varying brightnesses, with the degree of brightness steadily decreasing outward from the centre. They appear elliptical in shape, with lines of equal brightness made up of concentric and similar ellipses. These galaxies are nearly all of the same colour: they are somewhat redder than the Sun.

Spiral galaxies. These galaxies are conspicuous for their spiral-shaped arms, which emanate from or near the nucleus and gradually wind outward to the edge. There are usually two opposing arms arranged symmetrically around the centre. The nucleus of a spiral galaxy is a sharp-peaked area of smooth texture, which can be quite small or, in some cases, can make up the bulk of the galaxy. The arms are embedded in a thin disk of stars. Both the arms and the disk of a spiral system are blue in colour, whereas its central areas are red like an elliptical galaxy.

Irregular galaxies. Most representatives of this class consist of grainy, highly irregular assemblages of luminous areas. They have no noticeable symmetry nor obvious central nucleus, and they are generally bluer in colour than are the arms and disks of spiral galaxies. An extremely small number of them, however, are red and have a smooth, though nonsymmetrical, shape.

Hubble subdivided these three classes into finer groups according to subtle differences in shape, as described in detail below. Other classification schemes similar to Hubble's follow this pattern but subdivide the galaxies differently. A notable example of one such system is that of Gerard de Vaucouleurs. This scheme, which has evolved considerably since its inception in 1959, includes a large number of codes for indicating different kinds of morphological characteristics visible in the images of galaxies. The major Hubble galaxy classes form the framework of de Vaucouleurs's scheme, and its subdivision includes different families, varieties, and stages, as shown in Table 1.

Examples of the de Vaucouleurs classification scheme are for galaxy M33, the Triangulum Nebula, which is classified as SA(s)cd, and the nearby small galaxy NGC 6822, classified as IB(s)m.

Van den Bergh's luminosity classification

An entirely different kind of classification scheme is the luminosity classification developed in 1960 by Sidney van den Bergh. Based on morphological considerations, luminosity classes are assigned to individual galaxies within the Hubble classes. Those that are the most luminous are given a luminosity class of I, and the intrinsically faintest members of a class are assigned a V or VI, recalling the general approach of the luminosity class scheme used for stellar spectra (see STARS AND STAR CLUSTERS). Thus a very luminous galaxy with open, resolved arms would be an Sc I galaxy, while a somewhat intrinsically fainter object with the same basic structure would be an Sc II or Sc III galaxy. To assign a luminosity class, a galaxy's image has to be compared with a set of standard images of galaxies for which distances are known and for which luminosity classes have been established by van den Bergh.

Classification schemes based on criteria other than optical appearance have been proposed. There is, for example, the Morgan scheme (proposed by W.W. Morgan), which combines information on the spectrum of a galaxy with its general shape. Here, a class is coded with a letter that indicates the spectral type of the galaxy in the blue (either as measured or as determined from the galaxy's bulge morphology, which correlates with the spectral type): *e.g.*, a, af, f, fg, g, gk, k, for increasing dominance by cooler stars. The code then includes a capital letter to indicate general morphology—*e.g.*, E, S, or I—in accordance with Hubble's general classes. This is followed by a number that indicates the overall optical shape of the image, with 0 representing a circular image and a 10 (never actually realized) standing for a linear, infinitely thin image. An example is the galaxy M31, the Andromeda Nebula, which is classified as kS5 in the Morgan system.

Table 1: De Vaucouleurs's Classification of Galaxies

classes	families	varieties	stages	type
Ellipticals				E
			elliptical (0–7)	E0
			intermediate	E0-1
			late elliptical	E$^+$
Lenticulars				S0
	ordinary			SA0
	barred			SB0
	mixed			SAB0
		inner ring		S(r)0
		S-shaped		S(s)0
		mixed		S(rs)0
			early	S0$^-$
			intermediate	S0°
			late	S0$^+$
Spirals	ordinary			SA
	barred			SB
	mixed			SAB
		inner ring		S(r)
		S-shaped		S(s)
		mixed		S(rs)
			0/a	S0/a
			a	Sa
			ab	Sab
			b	Sb
			bc	Sbc
			c	Sc
			cd	Scd
			d	Sd
			dm	Sdm
			m	Sm
Irregulars	ordinary			IA
	barred			IB
	mixed			IAB
		S-shaped		I(s)
			Magellanic	Im
			non-Magellanic	I0
Peculiars				P
Peculiarities (all types)			peculiarity	P
			uncertain	:
			doubtful	?
			spindle	sp
			outer ring	(R)
			pseudo outer ring	(R)

Classification of radio galaxies

Systems that separate galaxies according to the character of their radio structure and the strength of their radio emissions also have been devised. For example, radio galaxies can be classified according to the following scheme:

g: galaxies with normal radio fluxes.

R: galaxies with strong radio emission. Many have distorted morphology, with evidence of explosive events or interactions with companions.

cD: galaxies with abnormally large, distended shapes, always found in the central areas of galaxy clusters and hypothesized to consist of merged galaxies.

S: Seyfert galaxies, originally recognized by the American astronomer Carl K. Seyfert from optical spectra. These objects have very bright nuclei with strong emission lines of hydrogen and other common elements, showing velocities of hundreds or thousands of kilometres per second. Most are radio sources.

N: galaxies with small, very bright nuclei and strong radio emission, probably similar to Seyfert galaxies but more distant.

Q: quasars, small, extremely luminous objects, many of which are strong radio sources. Quasars apparently are related to Seyfert and N galaxies but have such bright nuclei that the underlying galaxy can be detected only with great difficulty.

Although such schemes are sometimes used for special purposes, including, for example, certain kinds of statistical studies, the general scheme of Hubble in its updated form is the one most commonly used and so will be described in detail in the following section.

CLASSES OF GALAXIES

In *The Hubble Atlas of Galaxies* (1961), Allan R. Sandage drew on Hubble's notes and his own research on galaxy morphology to revise the Hubble classification scheme. Some of the features of this revised scheme are subject to argument because of the findings of very recent research, but its general features, especially the coding of types, remain viable. A description of the classes as defined by Sandage is given here, along with observations concerning needed refinements of some of the details.

Elliptical galaxies. These systems exhibit certain characteristic properties. They have complete rotational symmetry; *i.e.*, they are figures of revolution with two equal principal axes. They have a third smaller axis that is the presumed axis of rotation. The surface brightness of ellipticals at optical wavelengths decreases monotonically outward from a maximum value at the centre, following a common mathematical law of the form:

$$I = I_o(r/a + 1)^{-2},$$

where I is the intensity of the light, I_o is the central intensity, r is the radius, and a is a scale factor. The isophotal contours exhibited by an elliptical system are similar ellipses with a common orientation, each centred on its nucleus. No galaxy of this type is flatter than $b/a = 0.3$, with b and a the minor and major axes of the elliptical image, respectively. Ellipticals contain neither interstellar dust nor bright stars of spectral types 0 and B. Many, however, contain evidence of the presence of low-density gas in their nuclear regions. Ellipticals are red in colour, and their spectra indicate that their light comes mostly from old stars, especially evolved red giants.

Subclasses of elliptical galaxies

Subclasses of elliptical galaxies are defined by their apparent shape, which is of course not necessarily their three-dimensional shape. The designation is E*n*, where *n* is an integer defined by

$$n = 10(a - b)/a.$$

A perfectly circular image will be an E0 galaxy, while a flatter object might be an E7 galaxy. (As explained above, elliptical galaxies are never flatter than this, so there are no E8, E9, or E10 galaxies.)

Although the above-cited criteria are generally accepted, current high-quality measurements have shown that some significant deviations exist. Most elliptical galaxies do not, for instance, exactly fit the intensity law formulated by Hubble; deviations are evident in their innermost parts and in their faint outer parts. Furthermore, many elliptical galaxies have slowly varying ellipticity, with the images being more circular in the central regions than in the outer parts. The major axes sometimes do not line up either, their position angles varying outward. Finally, astronomers have found that a few ellipticals do in fact have small numbers of luminous 0 and B stars as well as dust lanes.

Spiral galaxies. Spirals are characterized by circular symmetry, a bright nucleus surrounded by a thin outer disk, and a superimposed spiral structure. They are divided into two parallel classes: normal spirals and barred spirals. The normal spirals have arms that emanate from the nucleus, while barred spirals have a bright linear feature called a bar straddling the nucleus, with the arms unwinding from the ends of the bar. The normal spirals are designated "S" and the barred varieties "SB." Each of these classes is subclassified into three types according to the size of the nucleus and the degree to which the spiral arms are coiled. The three types are denoted with the lowercase letters "a," "b," and "c." There also exist galaxies that are intermediate between ellipticals and spirals. Such systems have the disk shape characteristic of the latter but no spiral arms. These intermediate forms bear the designation "S0" (Figure 1).

Normal and barred spirals

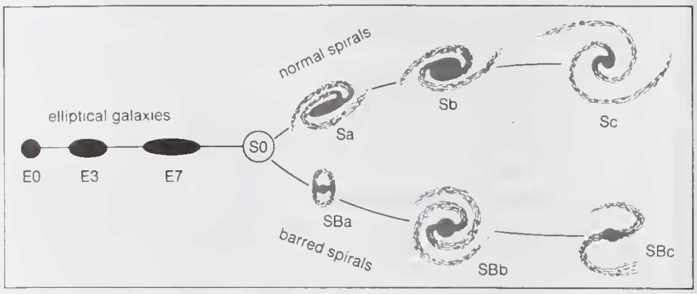

Figure 1: Hubble's system of classification for galaxies (see text).

S0 galaxies. These systems exhibit some of the properties of both the ellipticals and the spirals and seem to be a bridge between these two more common galaxy types. Hubble introduced the S0 class long after his original classification scheme had been universally adopted largely because he noticed the dearth of highly flattened objects that otherwise had the properties of elliptical galaxies. Sandage's elaboration of the S0 class yielded the characteristics described here.

S0 galaxies have a bright nucleus that is surrounded by a smooth, featureless bulge and a faint outer envelope. They are thin; statistical studies of the ratio of the apparent axes (seen projected onto the sky) indicate that they have intrinsic ratios of minor to major axes in the range 0.1 to 0.3. Their structure does not generally follow the luminosity law of elliptical galaxies, but it has a form more like that for spiral galaxies. Some S0 systems have a hint of structure in the envelope, either faintly discernible armlike discontinuities or narrow absorption lanes produced by interstellar dust. Several S0 galaxies are otherwise peculiar, and it is difficult to classify them with certainty. They can be thought of as peculiar Irr galaxies (*i.e.*, Irr II galaxies [see below]) or simply as some of the 1 or 2 percent of galaxies that do not fit easily into the Hubble scheme. Among these are such galaxies as NGC 4753 that has irregular dust lanes across its image and NGC 128 that has a double, almost rectangular, bulge around a central nucleus. Another type of peculiar S0 is found in NGC 2685. This nebula in the constellation Ursa Major has an apparently edge-on disk galaxy at its centre, with surrounding hoops of gas, dust, and stars arranged in a plane that is at right angles to the apparent plane of the central object.

Sa galaxies. These normal spirals have narrow, tightly wound arms, which usually are visible due to the presence of interstellar dust and in many cases bright stars as well. Most of them have a large, amorphous bulge in the centre, but there are some that violate this criterion, having a small nucleus around which is arranged an amorphous disk with superimposed faint arms. NGC 1302 is an example of the normal type of Sa galaxy, while NGC 4866 is representative of one with a small nucleus and arms consisting of thin dust lanes on a smooth disk.

Sb galaxies. This intermediate type of spiral typically has a medium-sized nucleus. Its arms are more widely spread than those of the Sa variety and appear less smooth. They contain stars, star clouds, and interstellar gas and dust. Sb galaxies show wide dispersions in details in terms of their shape. Hubble and Sandage observed, for example, that in certain Sb galaxies the arms emerge at the nucleus, which is often quite small. Other members of this subclass have arms that begin tangent to a bright, nearly circular ring, while still others reveal a small, bright spiral pattern inset into the nuclear bulge. In any of these cases, the spiral arms may be set at different pitch angles. (A pitch angle is defined as the angle between an arm and a circle centred on the nucleus and intersecting the arm.)

Hubble and Sandage noted further deviations from the standard shape established for Sb galaxies. A few systems exhibit a chaotic dust pattern superimposed upon the tightly wound spiral arms. Some have smooth, thick arms of low surface brightness, frequently bounded on their inner edges with dust lanes. Finally, there are those with a large, smooth nuclear bulge from which the arms emanate, flowing outward tangent to the bulge and forming short arm segments. This is the most familiar type of Sb galaxy and is best exemplified by the giant Andromeda Galaxy.

Many of these variations in shape remain unexplained. Theoretical models of spiral galaxies based on a number of different premises can reproduce the basic Sb galaxy

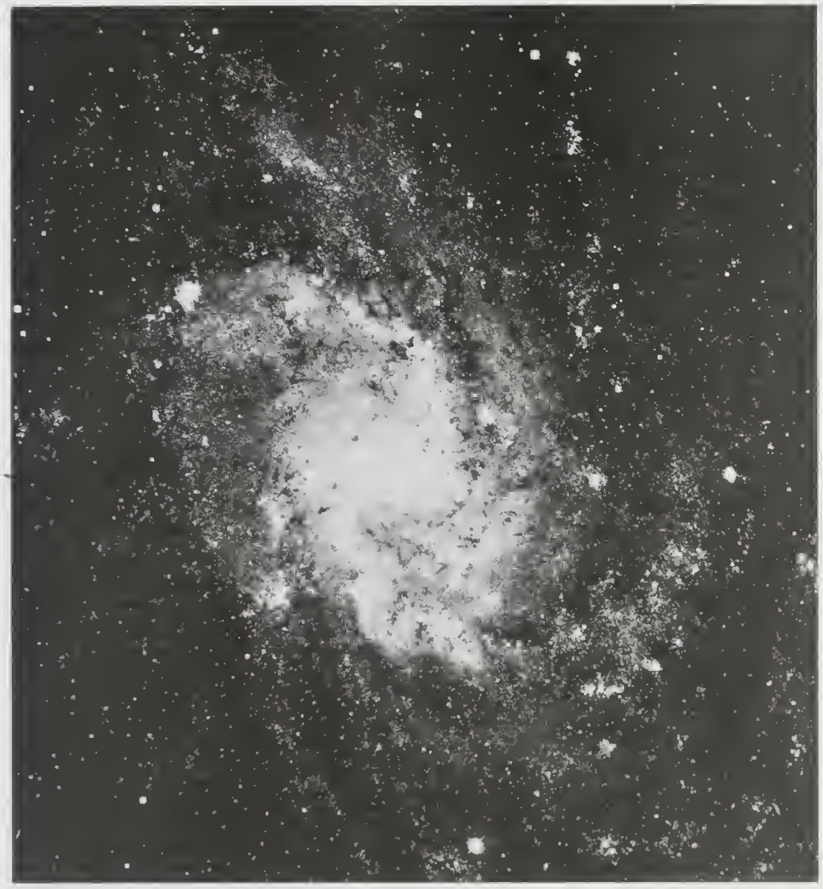

Figure 2: M33, a spiral galaxy in the constellation Triangulum.

By courtesy of the National Optical Astronomy Observatories

shape (see below *The Milky Way Galaxy*), but many of the deviations noted above are somewhat mysterious in origin and must await more detailed and realistic modeling of galactic dynamics.

Sc galaxies. These galaxies characteristically have a very small nucleus and multiple spiral arms that are open, with relatively large pitch angles. The arms, moreover, are lumpy, containing as they do numerous irregularly distributed star clouds, stellar associations, star clusters, and gas clouds known as emission nebulas.

As in the case of Sb galaxies, there are several recognizable subtypes among the Sc systems. Sandage has cited six subdivisions: (1) galaxies, such as the Whirlpool Nebula (M51), that have thin, branched arms that wind outward from a tiny nucleus, usually extending out about 180° before branching into multiple segments; (2) systems with multiple arms that start tangent to a bright ring centred on the nucleus; (3) those with arms that are poorly defined and that span the entire image of the galaxy; (4) those with a spiral pattern that cannot easily be traced and that are multiple and punctuated with chaotic dust lanes; (5) those with thick, loose arms that are not well defined—*e.g.*, the nearby galaxy M33, the Triangulum Nebula (Figure 2); and (6) transition types, which are almost so lacking in order that they could be considered irregular galaxies.

Some classification schemes, such as that of de Vaucouleurs, give the last of the above-cited subtypes a class of its own, type Sd (Figure 3). It also has been found that some of the variations noted here for Sc galaxies are related to total luminosity. Galaxies of the fifth subtype, in particular, tend to be intrinsically faint, while those of the first subtype are among the most luminous spirals known. This correlation is part of the justification for the luminosity classification discussed earlier.

SB galaxies. The luminosities, dimensions, spectra, and distributions of the barred spirals tend to be indistinguishable from those of normal spirals. The subclasses of SB systems exist in parallel sequence to those of the latter.

Subclasses of SB galaxies

There are SB0 galaxies that feature a large nuclear bulge surrounded by a disklike envelope across which runs a luminous, featureless bar. Some SB0 systems have short bars, while others have bars that extend across the entire visible image. Occasionally there is a ringlike feature external to the bar. SBa galaxies have bright, fairly large nuclear bulges and tightly wound, smooth spiral arms that emerge from the ends of the bar or from a circular ring external to the bar. SBb systems have a smooth bar as well as relatively smooth and continuous arms. In some galaxies of this type, the arms start at or near the ends of the bar, with conspicuous dust lanes along the inside of the bar that can be traced right up to the nucleus. Others have arms that start tangent to a ring external to the bar. In SBc galaxies, both the arms and the bar are highly resolved into star clouds and stellar associations. The arms are open in form and can start either at the ends of the bar or tangent to a ring.

From Paul W Hodge *The Physics and Astronomy of Galaxies and Cosmology* (1966)

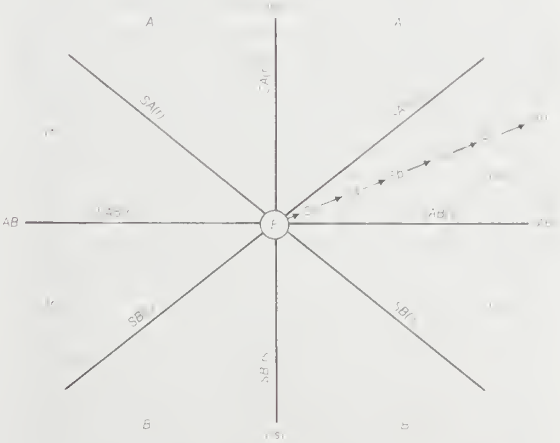

Figure 3: Gerard de Vaucouleurs's pinwheel diagram, a flat projection of his three-dimensional classification system.

Irregular galaxies. Hubble recognized two types of irregular galaxies, Irr I and Irr II. The Irr I type is the most common of the irregular systems, and it seems to fall naturally on an extension of the spiral classes, beyond Sc, into galaxies with no discernible spiral structure. They are blue, highly resolved, and have little or no nucleus. The Irr II systems are rare objects. They include various kinds of chaotic galaxies for which there apparently are many different explanations. Table 2 compares various subgroups of this rather confusing assembly of objects.

Table 2: Types of Irr II Galaxies

	dusty	star-forming	tidally interacting
Examples	NGC 4433 NGC 4753 NGC 5363	NGC 1569 NGC 4691 NGC 5253	NGC 520 NGC 3448 NGC 5195
Spectra	F2–GO	A–F	A–F
$(B-V)$ colour	0.9–1.2	0.3–0.6	0.7–1.0
Radio luminosity	normal	normal	strong
Diffuse emission	normal	strong	sometimes strong
H II regions	absent	present	present
Hα filaments	absent	present	absent
Dust content	very large	large	normal

Some irregular galaxies, like spirals, are barred. They have a nearly central bar structure dominating an otherwise chaotic arrangement of material. The Large Magellanic Cloud is a well-known example. The Hubble system does not normally recognize this as a subtype, though the de Vaucouleurs classification scheme includes it and its related types as Im and IB (see Table 1).

The Milky Way Galaxy

Large spiral system

The Milky Way Galaxy, sometimes simply called the Galaxy, is a spiral system consisting of several billion stars, one of which is the Sun. It takes its name from the Milky Way, the irregular luminous band of stars and gas clouds that stretches across the sky. Although the Earth lies well within the Galaxy, astronomers do not have as clear an understanding of its nature as they do of some external star systems. Because a thick layer of interstellar dust obscures much of the Galaxy from scrutiny by optical telescopes, astronomers can only determine its large-scale structure with the aid of radio and infrared telescopes, which can detect the forms of radiation that penetrate the obscuring matter.

SIZE AND MASS

As noted earlier, the first reliable measurement of the size of the Milky Way Galaxy was made in 1917 by Harlow Shapley. He arrived at his size determination by establishing the spatial distribution of globular clusters. Instead of a relatively small system with the Sun near its centre, as had previously been thought, Shapley found that the Galaxy was immense, with the Sun nearer the edge than the centre (Figure 4). Assuming that the globular clusters outlined the Galaxy, he determined that it has a diameter of about 100,000 light-years and that the Sun lies about 30,000 light-years from the centre. His values have held up remarkably well over the years. Although dependent in part on the particular component being discussed, with neutral hydrogen somewhat more widely dispersed and dark (*i.e.,* nonobservable) matter perhaps filling an even larger volume than expected, the stellar disk of the Milky Way system is just about as large as Shapley's model predicted. The most distant stars and gas clouds of the system that have had their distance determined reliably lie roughly 72,000 light-years from the galactic centre, while the distance of the Sun from the centre has been found to be approximately 27,000 light-years.

The total mass of the Galaxy, which had seemed reasonably well established during the 1960s, has become a matter of considerable uncertainty. Measuring the mass out to the distance of the farthest large hydrogen clouds is a relatively straightforward procedure. The measurements required are the velocities and positions of neutral hydrogen gas, combined with the approximation that the gas is rotating in nearly circular orbits around the centre of the Galaxy. A rotation curve, which relates the circular velocity of the gas to its distance from the galactic centre, is constructed. The shape of this curve and its values are determined by the amount of gravitational pull that the Galaxy exerts on the gas. Velocities are low in the central parts of the system because not much mass is interior to the orbit of the gas; most of the Galaxy is exterior to it and does not exert an inward gravitational pull. Velocities are high at intermediate distances because most of the mass in that case is inside the orbit of the gas clouds and the gravitational pull inward is at a maximum. At the farthest distances, the velocities decrease because nearly all the mass is interior to the clouds. This portion of the Galaxy is said to have Keplerian orbits, since the material should move in the same manner that the German astronomer Johannes Kepler discovered the planets to move within the solar system, where virtually all the mass is concentrated inside the orbiting bodies. The total mass of the Galaxy is then found by constructing mathematical models of the system with different amounts of material distributed in various ways and by comparing the resulting velocity curves with the observed one. As applied in the 1960s, this procedure indicated that the total mass of the Galaxy was approximately 200,000,000,000 times the mass of the Sun.

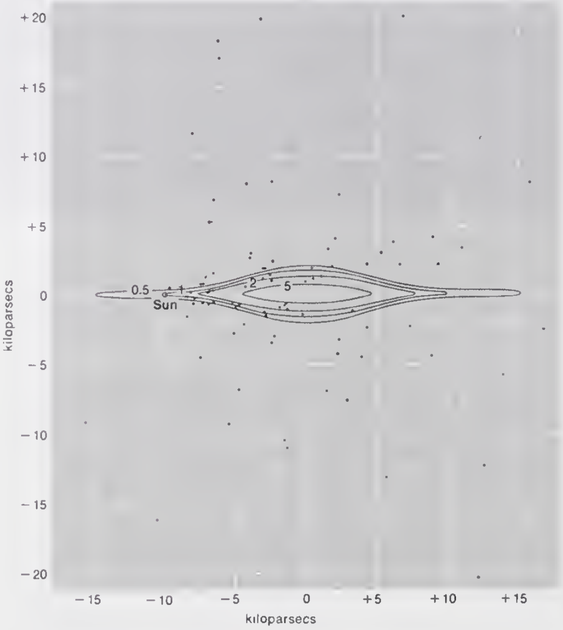

Figure 4: The distribution of globular clusters projected on a plane perpendicular to the galactic plane and passing through the galactic centre and the Sun. Lines of equal mass density are also drawn, but the high stellar density in the galactic centre is not indicated. North is at the top. Distances from the centre of the Galaxy in kiloparsecs are given below and to left of figure.

During the 1980s, however, refinements in the determination of the velocity curve began to cast doubts on the earlier results. The downward trend to lower velocities in the outer parts of the Galaxy was found to have been in error. Instead, the curve remained almost constant, indicating that there continue to be substantial amounts of matter exterior to the measured hydrogen gas. This in turn indicates that there must be some undetected material out there that is completely unexpected. It must extend considerably beyond the previously accepted positions of the edge of the Galaxy, and it must be dark at virtually all wavelengths, as it remains undetected even when searched for with radio, X-ray, ultraviolet, infrared, and optical telescopes. Until the dark matter is identified and its distribution determined, it will be impossible to measure the total mass of the Galaxy from the rotation curve, and so all that can be said is that the mass is

Dark matter

perhaps five or 10 times larger than thought earlier. That is to say, the mass, including the dark matter, must be about 1,000,000,000,000 times the mass of the Sun, with considerable uncertainty.

The nature of the dark matter in the Galaxy remains one of the major questions of galactic astronomy. Other galaxies also appear to have such matter in their outer parts. The only possible kinds of material that are consistent with the nondetections are all rather unlikely, at least according to present understanding in physics and astronomy. Planets and rocks would be impossible to detect, but it is extremely difficult to understand how they could materialize in sufficient numbers in the outer parts of galaxies where there are no stars or even interstellar gas and dust from which they could be formed. Massive neutrinos and other exotic, hypothetical subatomic particles also might be difficult to detect, but there is no good evidence that they even exist, and therefore they can only be considered a highly conjectural solution to the puzzle. It will take considerable effort to identify the dark matter with any degree of certainty. In the meantime it must be said that astronomy does not know what makes up much of the universe.

MAJOR COMPONENTS

Stars and stellar populations. The concept of different populations of stars has undergone considerable change over the last several decades. Before the 1940s astronomers were aware of differences among stars and had largely accounted for most of them in terms of different masses, luminosities, and orbital characteristics around the Galaxy. Understanding of evolutionary differences, however, had not yet been achieved, and differences in the chemical abundances in the stars were known but their significance was not comprehended. At this juncture chemical differences seemed exceptional and erratic and remained uncorrelated with other stellar properties. There was still no systematic division of stars even into different kinematic families in spite of the advances in theoretical work on the dynamics of the Galaxy.

Principal population types. In 1944 Baade announced the successful resolution into stars of the centre of the Andromeda Galaxy, M31, and its two elliptical companions, M32 and NGC 205. He found that the central parts of Andromeda and the accompanying galaxies were resolved at very much fainter magnitudes than were the outer spiral arm areas of M31. Furthermore, by using plates of different spectral sensitivity and coloured filters, he discovered that the two ellipticals and the centre of the spiral had red giants as their brightest stars rather than blue main-sequence stars, as in the case of the spiral arms. This finding led Baade to suggest that these galaxies, and also the Milky Way Galaxy, are made of two populations of stars that are distinct in their physical properties as well as their locations. He applied the term Population I to the stars that constitute the spiral arms of Andromeda and to most of the stars that are visible in the Milky Way system in the neighbourhood of the Sun. He found that these Population I objects were limited to the flat disk of the spirals and suggested that they were absent from the centres of such galaxies and from the ellipticals entirely. Baade designated as Population II the bright red giant stars that he discovered in the ellipticals and in the nucleus of Andromeda. Other objects that seemed to contain the brightest stars of this class were the globular clusters of the Galaxy. Baade further suggested that the high-velocity stars near the Sun (see below) were Population II objects that happened to be passing through the disk.

Population I and Population II

As a result of Baade's pioneering work on other galaxies in the Local Group (the cluster of star systems to which the Milky Way Galaxy belongs), astronomers immediately applied the notion of two stellar populations to the Galaxy. It is possible to segregate various components of the Galaxy into the two population types by applying both the idea of kinematics of different populations suggested by their position in the Andromeda system and the dynamical theories that relate galactic orbital properties with z distances (the distances above the plane of the Galaxy) for different stars. For many of these objects, the kinematic data on velocities are the prime source of population classification. The Population I component of the Galaxy, highly limited to the flat plane of the system, contains such objects as open star clusters, O and B stars, Cepheid variables, emission nebulas, and neutral hydrogen. Its Population II component, spread over a more nearly spherical volume of space, includes globular clusters, RR Lyrae variables, high-velocity stars, and certain other rarer objects (Figure 5).

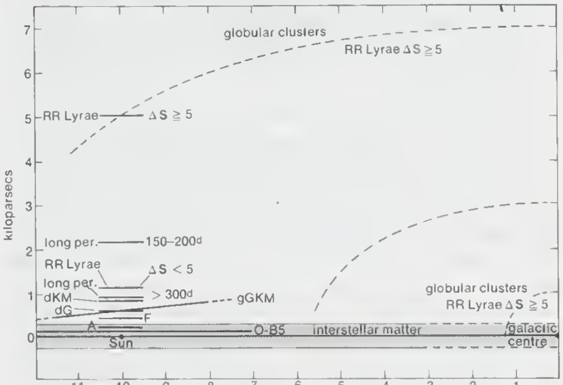

Figure 5: The space distribution of representative objects for various star populations projected on a plane perpendicular to the galactic plane and passing through the centre and the Sun. The horizontal lines indicate the distance from the galactic plane at which the density has fallen to one-tenth of that in the plane. *R* is the distance from the galactic centre. The RR Lyrae stars with high "ΔS" values have lowest metal content. The dashed lines indicate schematic (tentative) distributions (see text).

As time progressed, it was possible for astronomers to subdivide the different populations in the Galaxy further. Table 3 summarizes the properties and membership of the five subdivisions that were accepted at the time of the Vatican Conference on stellar populations in 1957. These subdivisions ranged from the nearly spherical "halo Population II" system to the very thin "extreme Population I" system, and each of the subgroups was found to contain (though not exclusively) characteristic types of stars. It was even possible to divide some of the variable-star types into subgroups according to their population subtype. The RR Lyrae variables of type ab, for example, could be separated into different groups by their spectral classifications and their mean periods. Those with mean periods longer than 0.4 days were classified as "halo Population II," while those with periods less than 0.4 days were placed in the "disk population." Similarly, long-period variables were divided into different subgroups, such that those with periods of less than 250 days and of relatively early spectral type (earlier than M 5e) were considered "intermediate Population II," whereas the longer period variables fell into the "older Population I" category.

An understanding of the physical differences in the stellar populations became increasingly clearer during the 1950s with improved calculations of stellar evolution. Evolving-star models showed that giants and supergiants are evolved objects recently derived from the main sequence after the exhaustion of hydrogen in the stellar core. As this became better understood, it was found that the luminosity of such giants was not only a function of the masses of the initial main-sequence stars from which they evolved but was also dependent on the chemical composition of the stellar atmosphere. Therefore, not only was the existence of giants in the different stellar populations understood but differences among the giants with relation to the main sequence of star groups came to be understood in terms of the chemistry of the stars.

At the same time, progress was made in determining the abundances of stars of the different population types by means of high-dispersion spectra obtained with large reflecting telescopes having a coudé focus arrangement. A curve of growth analysis demonstrated beyond a doubt that the two population types exhibited very different chemistries. In 1959 H. Lawrence Helfer, George Wallerstein, and Jesse L. Greenstein of the United States showed that the giant stars in globular clusters have chemical abundances quite different from those of Population I stars such as typified by the Sun. Population II stars have considerably lower abundances of the heavy elements—by amounts ranging from a factor of five or 10 up to a factor of several hundred. The total abundance of heavy elements, Z, for typical Population I stars is 0.04 (given in terms of the mass percent for all elements with atomic weights heavier than helium, a common practice in calculating stellar models). The values of Z for halo population globular clusters, on the other hand, were typically as small as 0.003.

Age estimates of stellar populations

A further difference between the two populations became clear as the study of stellar evolution advanced. It was found that Population II was exclusively made up of stars that are very old. Estimates of the age of Population II stars have varied over the years, depending on the degree of sophistication of the calculated models and the manner in which observations for globular clusters are fitted to these models. They have ranged from 10^9 years up to 2×10^{10} years. Recent comparisons of these data suggest that the halo globular clusters have ages of approximately 1.6×10^{10} years. The work of Sandage and his collaborators proved without a doubt that the range in age for globular clusters was relatively small and that the detailed characteristics of the giant branches of their colour-magnitude diagrams were correlated with age and small differences in chemical abundances. On the other hand, stars of Population I were found to have a wide range of ages. Stellar associations and galactic clusters with bright blue main-sequence stars have ages of a few million years (stars are still in the process of forming in some of them) to 10^{10} years or more. Studies of the stars nearest the Sun indicate a mixture of ages with a considerable number of stars of great age—on the order of 10^9 years. Careful searches, however, have shown that there are no stars in the solar neighbourhood and no galactic clusters whatsoever that are older than or even quite as old as the globular clusters. This is an indication that globulars, and thus Population II objects, formed first in the Galaxy and that Population I stars have been forming since.

In short, as the understanding of stellar populations grew, the division into Population I and Population II became understood in terms of three parameters: age, chemical composition, and kinematics. A fourth parameter, spatial distribution, appeared to be clearly another manifestation of kinematics. The correlations between these three parameters were not perfect but seemed to be reasonably good for the Galaxy, even though it was not yet known whether these correlations were applicable to other galaxies. Table 3 illustrates the close correlations, as formulated in the early 1960s, for the stars in the Galaxy and shows that there are many different combinations of these three parameters that seem to be excluded in nature. The many different physical manifestations of these parameters were gradually building up. Methods of determining the abundance of metals in objects by means other than laborious high-dispersion coudé spectroscopy became possible. For example, it was found that stars having a low abundance of heavy elements exhibited an easily measurable ultraviolet excess. This is demonstrated when the three colours U, B, and V of the Yerkes system are plotted in a three-colour diagram where the Population II stars all lie distinctly to the left of the normal star, three-colour relationship.

Understanding the evolution of the Galaxy's stellar population

Astronomers devised a graphic way to explain the evolution of the stellar population in the Milky Way Galaxy using a three-dimensional plot in which the age, the abundance of heavy elements, and the rate of star formation are all taken into account. Figure 6 is an example of such a three-dimensional plot. The volume shown in the figure indicates that the rate of star formation about the time the Galaxy originated was somewhat greater than at present but that it has not yet reached zero. As stars formed, the heavy elements were produced in the hot centres of the stars and in supernovas; thus the volume moves forward in the box until the present is reached, and the majority of stars that are now forming have heavy elements in approximately the same amount as the Sun. At any time, τ, there is a spread in the abundances of the stars formed, depending on the history of the interstellar material in the region.

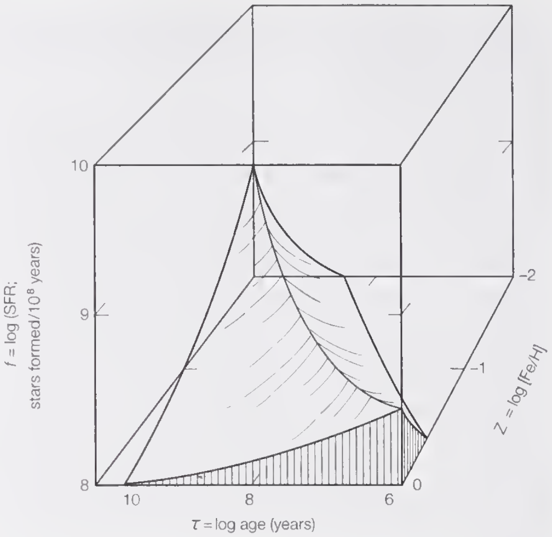

Figure 6: The star-formation history of the Milky Way Galaxy. The front axis is the age of the stars, the side axis is the heavy-element abundance of the stars (expressed in terms of the iron [Fe] abundance as compared with that of the Sun), and the vertical axis is the rate of stars that were being formed (SFR) at the corresponding time in the life of the Galaxy.

Complications in scientific understanding of stellar populations first became serious when detailed colour-magnitude diagrams were obtained for star clusters in the Magellanic Clouds during the late 1950s. Arp's work on the clusters of the Small Magellanic Cloud showed that the correlations between the properties of populations found in the Galaxy apparently broke down when other galaxies were examined carefully. Arp suggested that the star clusters of young age that he had observed in the SMC might be examples of young Population II stars—*i.e.,* young stars having a low abundance of heavy elements. No such stars were known in the Galaxy. Similarly, Arp found anomalous colour-magnitude diagrams for globular clusters in the SMC and proposed that perhaps this also was the result of abundance differences between the SMC and the Galaxy. At first it appeared that these conclusions were based on detailed comparisons with evolutionary models; however, because of the lack of such models at the time of Arp's observations, it seemed clear that the young star clusters of the SMC were anomalous in many details and that these peculiarities could not easily be accounted for other than by differences in chemical composition. In succeeding years, and as more star clusters in the Magellanic Clouds were measured, investigators were able to make detailed comparisons with models and to conclude that the chemical differences between the Galaxy and the Clouds must be rather small. Many of the star clusters have colour-magnitude diagrams that nearly conform to models calculated on the basis of solar-type abundances. It also is true, however, that many clusters, including those measured with high-detection-efficiency equipment such as the charge-coupled device (CCD), show real differences from colour-magnitude diagrams of galactic clusters, and these differences are still not completely understood. The Andromeda Galaxy has many globular clusters that can be observed with large instruments, and these also show a wider variety of properties than expected on the basis of the local sample. Surveys of the spectra and colours of the Andromeda globulars have demonstrated that there is a considerable spread in heavy-element abundance for these systems and that the close correlation between position and abundance found in the Galaxy fails to materialize in the case of Andromeda. Consequently, the segregation into stellar populations that works so well for the Galaxy is not necessarily a universal system. Moreover, it is possi-

Table 3: The Stellar Populations

	Population I		disk population	Population II	
	extreme Population I	older Population I		intermediate Population II	halo Population II
Members	gas young stars associated with the present spiral structure supergiants Cepheids T Tauri stars galactic clusters of Trumpler's class I	A-type stars strong-line stars Me dwarfs	stars of galactic nucleus planetary nebulas novas RR Lyrae stars with periods < 0.4 day weak-line stars	high-velocity stars with z-velocities > 30 km/sec long-period variables with periods < 250 days and spectral types earlier than M5e	subdwarfs globular clusters RR Lyrae stars with periods longer than 0.4 days
Average height over galactic plane (parsecs)	120	160	400	700	2,000

Total mass (10^9 suns)	2	5	47 (combined disk and intermediate)		16

ble that most of the correlations are connected specifically to the detailed history and evolution of the Galaxy rather than to fundamental properties that stars in general would be expected to possess.

The stellar luminosity function. The stellar luminosity function is a description of the relative number of stars of different absolute luminosities. It is often used to describe the stellar content of various parts of the Galaxy or other groups of stars, but it most commonly refers to the absolute number of stars of different absolute magnitudes in the solar neighbourhood. In this form it is usually called the van Rhijn function after the Dutch astronomer Pieter J. van Rhijn. The van Rhijn function is a basic datum for the local portion of the Galaxy, but it is not necessarily representative for an area larger than the immediate solar neighbourhood. Investigators have found that elsewhere in the Galaxy, and in the external galaxies (as well as in star clusters), the form of the luminosity function differs in various respects from the van Rhijn function.

The luminosity function of the solar neighbourhood

The detailed determination of the luminosity function of the solar neighbourhood is an extremely complicated process. Difficulties arise because of (1) the incompleteness of existing surveys of stars of all luminosities in any sample of space and (2) the uncertainties in the basic data (distances and magnitudes). In determining the van Rhijn function, it is normally preferable to specify exactly what volume of space is being sampled and to state explicitly the way in which problems of incompleteness and data uncertainties are handled.

In general there are four different methods for determining the local luminosity function. Most commonly, trigonometric parallaxes are employed as the basic sample. Alternative but somewhat less certain methods include the use of spectroscopic parallaxes, which can involve much larger volumes of space. A third method entails the use of mean parallaxes of a star of a given proper motion and apparent magnitude; this yields a statistical sample of stars of approximately known and uniform distance. The fourth method involves examining the distribution of proper motions and tangential velocities (the speeds at which stellar objects move at right angles to the line of sight) of stars near the Sun.

Because the solar neighbourhood is a mixture of stars of various ages and different types, it is difficult to interpret the van Rhijn function in physical terms without recourse to other sources of information, such as the study of star clusters of various types, ages, and dynamical families. Globular clusters are the best samples to use for determining the luminosity function of old stars having a low abundance of heavy elements (Population II stars).

Globular-cluster luminosity functions show a conspicuous peak at absolute magnitude $M_V = 0.5$, and this is clearly due to the enrichment of stars at that magnitude from the horizontal branch of the cluster. The height of this peak in the data is related to the richness of the horizontal branch, which is in turn related to the age and chemical composition of the stars in the cluster. A comparison of the observed M3 luminosity function with the van Rhijn function shows a depletion of stars, relative to fainter stars, for absolute magnitudes brighter than roughly $M_V = 3.5$. This discrepancy is important in the discussion of the physical significance of the van Rhijn function and luminosity functions for clusters of different ages, and so will be dealt with more fully below.

Luminosity functions of open clusters

Many studies of the component stars of open clusters have shown that the luminosity functions of these objects vary widely. The two most conspicuous differences are the overabundance of stars of brighter absolute luminosities and the underabundance or absence of stars of faint absolute luminosities. The overabundance at the bright end is clearly related to the age of the cluster (as determined from the main-sequence turnoff point) in the sense that younger star clusters have more of the highly luminous stars. This is completely understandable in terms of the evolution of the clusters and can be accounted for in detail by calculations of the rate of evolution of stars of different absolute magnitudes and mass. For example, the luminosity function for the young clusters h and χ Persei, when compared to the van Rhijn function, clearly shows a large overabundance of bright stars due to the extremely young age of the cluster, which is on the order of 10^6 years. Calculations of stellar evolution indicate that in an additional 10^9 or 10^{10} years all of these stars will have evolved away and disappeared from the bright end of the luminosity function.

In 1955 the first detailed attempt to interpret the shape of the general van Rhijn luminosity function was made by the Austrian-born astronomer Edwin E. Salpeter, who pointed out that the change in slope of this function near $M_V = +3.5$ is most likely the result of the depletion of the stars brighter than this limit. Salpeter noted that this particular absolute luminosity is very close to the turnoff point of the main sequence for stars of an age equal to the oldest in the solar neighbourhood—approximately 10^{10} years. Thus, all stars of the luminosity function with fainter absolute magnitudes have not suffered depletion of their numbers because of stellar evolution as there has not been enough time for them to have evolved from the main sequence. On the other hand, the ranks of stars of brighter absolute luminosity have been variously depleted by evolution, and so the form of the luminosity function in this range is a composite curve contributed by stars of

Formation function

ages ranging from 0 to 10^{10} years. Salpeter hypothesized that there might exist a time-independent function, the so-called formation function, which would describe the general initial distribution of luminosities, taking into account all stars at the time of formation. Then, by assuming that the rate of star formation in the solar neighbourhood has been uniform since the beginning of this process and by using available calculations of the rate of evolution of stars of different masses and luminosities, he showed that it is possible to apply a correction to the van Rhijn function in order to obtain the form of the initial luminosity function. Comparisons of open clusters of various ages have shown that these clusters agree much more closely with the initial formation function than with the van Rhijn function; this is especially true for the very young clusters. Consequently, investigators believe that the formation function, as derived by Salpeter, is a reasonable representation of the distribution of star luminosities at the time of formation, even though they are not certain that the assumption of a uniform rate of formation of stars can be precisely true or that the rate is uniform throughout a galaxy.

It was stated above that open-cluster luminosity functions show two discrepancies when compared with the van Rhijn function. The first is due to the evolution of stars from the bright end of the luminosity function such that young clusters have too many stars of high luminosity, as compared to the solar neighbourhood. The second discrepancy is that very old clusters such as the globulars have too few high-luminosity stars, as compared to the van Rhijn function, and this is clearly the result of stellar evolution away from the main sequence. Stars do not, however, disappear completely from the luminosity function; most become white dwarfs and reappear at the faint end. In his early comparisons of formation functions with luminosity functions of galactic clusters, Sandage calculated the number of white dwarfs expected in various clusters; present searches for these objects in a few of the clusters (*e.g.,* the Hyades) have supported his conclusions.

Open clusters also disagree with the van Rhijn function at the faint end—*i.e.,* for absolute magnitudes fainter than approximately $M_V = +6$. In all likelihood this is mainly due to a depletion of another sort, the result of dynamical effects on the clusters that arise because of internal and external forces. Stars of low mass in such clusters escape from the system under certain common conditions. The formation functions for these clusters may be different from the Salpeter function and may exclude faint stars. A further effect is the result of the finite amount of time it takes for stars to condense; very young clusters have few faint stars partly because there has not been sufficient time for them to have reached their main-sequence luminosity.

Star clusters and stellar associations. Although most stars in the Galaxy exist either as single stars like the Sun or as double stars, there are many conspicuous groups and clusters of stars that contain tens to thousands of members. These objects can be subdivided into three types: globular clusters, open clusters, and stellar associations. They differ primarily in age and in the number of member stars.

Principal types

Globular clusters. The largest and most massive star clusters are the globular clusters, so called because of their roughly spherical appearance (Figure 7). The Galaxy contains approximately 130 globular clusters (the exact number is uncertain because of obscuration by dust in the Milky Way band, which probably prevents some 10 or so globulars from being seen). They are arranged in a nearly spherical halo around the Milky Way, with relatively few toward the galactic plane but a heavy concentration toward the centre. The radial distribution, when plotted as a function of distance from the galactic centre, fits a mathematical expression of a form identical to the one describing the star distribution in elliptical galaxies, though there is an anomalous peak in the distribution at distances of about 40,000 light-years from the centre.

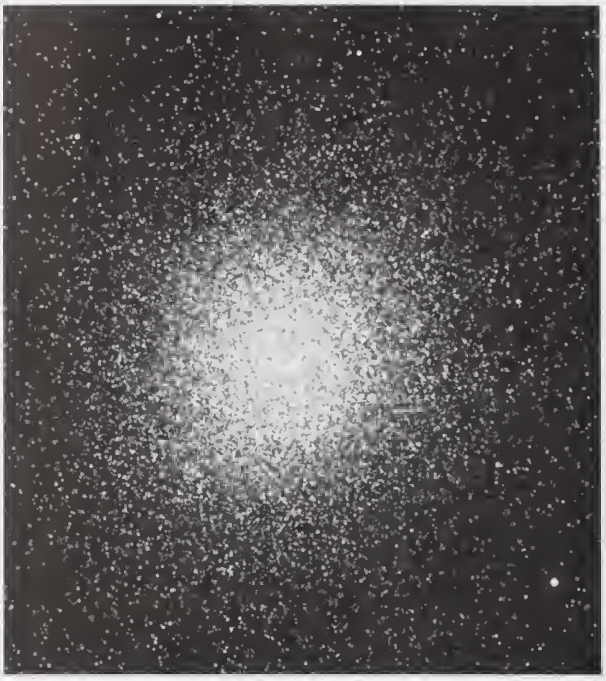

Figure 7: Omega Centauri (M3), the most imposing globular cluster in the Milky Way Galaxy.

By courtesy of the National Optical Astronomy Observatories

Globular clusters are extremely luminous objects. Their mean luminosity is the equivalent of approximately 25,000 suns. The most luminous are 50 times brighter. The masses of globular clusters, measured by determining the dispersion in the velocities of individual stars, range from a few thousand to more than 1,000,000 solar masses. The clusters are very large, with diameters measuring from 10 to as much as 300 light-years. Most globular clusters are highly concentrated at their centres, having stellar distributions that resemble isothermal gas spheres with a cutoff that corresponds to the tidal effects of the Galaxy. A precise model of star distribution within a cluster can be derived from stellar dynamics, which takes into account the kinds of orbits that stars have in the cluster, encounters between these member stars, and the effects of exterior influences. The American astronomer Ivan R. King, for instance, has derived dynamical models that fit observed stellar distributions very closely. He finds that a cluster's structure can be described in terms of two numbers: (1) the core radius, which measures the degree of concentration at the centre, and (2) the tidal radius, which measures the cutoff of star densities at the edge of the cluster.

A key distinguishing feature of globular clusters in the Galaxy is their uniformly old age. Determined by comparing the stellar population of globulars with stellar evolutionary models, the ages of all those so far measured range from 12 billion to 18 billion years. They are the oldest objects in the Galaxy and so must have been among the first formed when the system condensed out of the pregalactic gas. That this was the case is also indicated by the fact that the globulars tend to have much smaller amounts of heavy elements than do the stars in the plane of the Galaxy—*e.g.,* the Sun. Composed of stars belonging to the extreme Population II, as well as the high-latitude halo stars, these nearly spherical assemblages apparently formed before the material of the Galaxy flattened into the present thin disk. As their component stars evolved, they gave up some of their gas to interstellar space. This gas was enriched in the heavy elements produced in stars during the later stages of their evolution, so that the interstellar gas in the Galaxy is continually being changed. Hydrogen and helium have always been the major constituents, but heavy elements have gradually grown in importance. The present interstellar gas contains elements heavier than helium at a level of about 2 percent by mass, while the globulars contain as little as 0.02 percent of the same elements.

Open clusters. Clusters smaller and less massive than the globulars are found in the plane of the Galaxy intermixed with the majority of the system's stars, including the Sun. These objects are the open clusters, so called because they generally have a more open, loose appearance than typical globulars.

Open clusters are distributed in the Galaxy very similarly to young stars. They are highly concentrated along the plane of the Galaxy and slowly decrease in number outward from its centre. The large-scale distribution of these clusters cannot be learned directly because their existence in the Milky Way plane means that dust obscures those that are more than a few thousand light-years from the Sun. By analogy with open clusters in external galaxies similar to the Galaxy it is surmised that they follow the general distribution of integrated light in the Galaxy, except that there are probably fewer of them in the central areas. There is some evidence that the younger open clusters are more densely concentrated in the Galaxy's spiral arms, at least in the neighbourhood of the Sun where these arms can be discerned.

The brightest open clusters are considerably fainter than the brightest globular clusters. The peak absolute luminosity appears to be about 50,000 times the luminosity of the Sun, but the largest percentage of known open clusters has a brightness equivalent to 500 solar luminosities. Masses can be determined from the dispersion in the measured velocities of individual stellar members of clusters. Most open clusters have small masses—on the order of 50 solar masses. Their total populations of stars are small, ranging from tens to a few thousand.

Small mass of open clusters

Open clusters have diameters of only two or three to about 20 light-years, with the majority being less than five light-years across. In structure they look very different from globular clusters, though they can be understood in terms of similar dynamical models. The most important structural difference is their small total mass and relative looseness, which result from their comparatively large core radii. These two features have disastrous consequences as far as their ultimate fate is concerned, because open clusters are not sufficiently gravitationally bound to be able to withstand the disruptive tidal effects of the Galaxy (see STARS AND STAR CLUSTERS). Judging from the sample of open clusters within 3,000 light-years of the Sun, only half of them can withstand such tidal forces for more than 200,000,000 years, while a mere 2 percent have life expectancies as high as 1,000,000,000 years.

Measured ages of open clusters agree with the conclusions that have been reached about their life expectancies. They tend to be young objects; only a few are known to exceed 1,000,000,000 years in age. Most are younger than 200,000,000 years, and some are 1,000,000 or 2,000,000 years old. Ages of open clusters are determined by comparing their stellar membership with theoretical models of stellar evolution. Because all the stars in a cluster have very nearly the same age and chemical composition, the differences between the member stars are entirely the result of their different masses. As time progresses after the formation of a cluster, the massive stars, which evolve the fastest, gradually disappear from the cluster, becoming white dwarf stars or other underluminous stellar remnants. Theoretical models of clusters show how this effect changes the stellar content with time, and direct comparisons with real clusters give reliable ages for them. Astronomers use a diagram (the colour-magnitude diagram) that plots the temperatures of the stars against their luminosities to make this comparison. Colour-magnitude diagrams have been obtained for about 1,000 open clusters, and ages are thus known for this large sample.

Because open clusters are mostly young objects, they have chemical compositions that correspond to the enriched environment from which they formed. Most of them are like the Sun in their abundance of the heavy elements, and some are even richer. For instance, the Hyades, which compose one of the nearest clusters, have almost twice the abundance of heavy elements as the Sun.

Stellar associations. Even younger than open clusters, stellar associations are very loose groupings of stars that share a common place and time of origin but that are not generally tied closely enough together gravitationally to form a stable cluster. Stellar associations are limited strictly to the plane of the Galaxy and appear only in regions of the system where star formation is occurring, notably in the spiral arms. They are very luminous objects. The brightest are even brighter than the brightest globular clusters, but this is not because they contain more stars; instead it is the result of the fact that their constituent stars are very much brighter than the stars constituting globulars. The most luminous stars in stellar associations are very young stars of spectral types O and B. They have absolute luminosities as bright as any star in the Galaxy—on the order of 1,000,000 times the luminosity of the Sun. Such stars have very short lifetimes, only lasting a few million years. With luminous stars of this type there need not be very many to make up a highly luminous and conspicuous grouping. The total masses of stellar associations amount to only a few hundred solar masses, with the population of stars being in the hundreds or, in a few cases, thousands.

High luminosity of associations

The sizes of stellar associations are large; the average diameter of those in the Galaxy is about 700 light-years. Many are smaller, especially near the Sun, where they measure about 200 light-years across. In any case, stellar associations are so large and loosely structured that their self-gravitation is insufficient to hold them together, and in a matter of a few million years the members disperse into surrounding space, becoming separate and unconnected stars in the galactic field.

Moving groups. These objects are remote organizations of stars that share common measurable motions but do not form a noticeable cluster. This definition allows the term to be applied to a range of objects from the nearest gravitationally bound clusters to groups of widely spread stars with no apparent gravitational identity, which are discovered only by searching the catalogs for stars of common motion. Among the best known of the moving groups is the Hyades in the constellation Taurus. Also known as the Taurus moving cluster or the Taurus stream, this system is comprised of the relatively dense Hyades cluster, along with a few very distant members. It contains a total of about 350 stars, including several white dwarfs. Its centre lies about 150 light-years away. Other notable moving stellar groups include the Ursa Major, Scorpio-Centaurus, and Pleiades groups. Besides these remote organizations, investigators have observed what appears to be groups of high-velocity stars near the Sun. One of these, called the Groombridge 1830 group, consists of a number of subdwarfs and the star RR Lyrae after which the RR Lyrae variables were named.

Hyades moving cluster

Recent advances in the study of moving groups have had an impact on the investigation of the kinematic history of stars and on the absolute calibration of the distance scale of the Galaxy. Moving groups have proved particularly useful with respect to the latter because their commonality of motion enables astronomers to determine accurately (for the nearer examples) the distance of each individual member. Together with nearby parallax stars, moving-group parallaxes provide the basis for the galactic distance scale. Astronomers have found the Hyades moving cluster well suited for their purpose: it is close enough to permit the reliable application of the method, and it has enough members for deducing an accurate main-sequence position.

Moving-group parallaxes

One of the basic problems of using moving groups for distance determination is the selection of members. In the case of the Hyades this has been done very carefully but not without considerable dispute. The members of a moving group (and its actual existence) are established by the degree to which their motions define a common convergent point in the sky. One technique is to determine the coordinates of the poles of the great circles defined by the proper motions and positions of individual stars. The positions of the poles will define a great circle, and one of its poles will be the convergent point for the moving group. Membership of stars can be established by criteria applied to the distances of proper-motion poles of individual stars from the mean great circle. The reliability of the existence of the group itself can be measured by the dispersion of the great circle points about their mean.

As radial velocities will not have been used for the preliminary selection of members, they can be subsequently examined to eliminate further nonmembers. The final list of members should contain only a very few nonmembers—either those that appear to agree with the group motion because of observational errors or those that happen to share the group's motion at the present time but are not related to the group historically.

The distances of individual stars in a moving group may be determined if their radial velocities and proper motions are known (see below *Stellar motions*) and if the exact position of the radiant is determined. If the angular distance of a star from the radiant is λ, and if the velocity of the cluster as a whole with respect to the Sun is V, then the radial velocity of the star, V_r, is

$$V_r = V \cos \lambda.$$

The transverse (or tangential) velocity, T, is given by

$$T = V \sin \lambda = 4.74\mu/p,$$

where p is the star's parallax in arc seconds. Thus, the parallax of a star is given by

$$p = 4.74\mu \cot \lambda/V_r.$$

The key to achieving reliable distances by this method is to locate the convergent point of the group as accurately as possible. The various techniques used (*e.g.*, Charlier's method) are capable of high accuracy providing that the measurements themselves are free of systematic errors. For the Taurus moving group, for example, it has been estimated that the accuracy for the best observed stars is on the order of 3 percent in the parallax, discounting any errors due to systematic problems in the proper motions. By comparison, the trigonometric parallaxes of the same stars have errors of about 30 percent.

Emission nebulas. A conspicuous component of the Galaxy is the collection of large, bright, diffuse gaseous objects generally called nebulas. The brightest of these cloudlike objects are the emission nebulas, large complexes of interstellar gas and stars in which the gas exists in an ionized and excited state (with the electrons of the atoms excited to a higher than normal energy level). This condition is produced by the strong ultraviolet light emitted from the very luminous, hot stars embedded in the gas. Because emission nebulas consist almost entirely of ionized hydrogen, they are usually referred to as H II regions.

H II regions

H II regions are found in the plane of the Galaxy intermixed with young stars, stellar associations, and the youngest of the open clusters. They are areas where very massive stars have recently formed, and many contain the uncondensed gas, dust, and molecular complexes commonly associated with ongoing star formation. The H II regions are concentrated in the spiral arms of the Galaxy, though some do exist between the arms. Many of them are found at intermediate distances from the centre of the Milky Way, with the largest number occurring at a distance of 10,000 light-years. This latter fact can be ascertained even though the H II regions cannot be seen clearly beyond a few thousand light-years from the Sun. They emit radio radiation of a characteristic type, with a thermal spectrum that indicates that their temperatures are about 10,000 kelvins (K). This thermal radio radiation enables astronomers to map the distribution of H II regions in distant parts of the Galaxy.

The largest and brightest H II regions in the Galaxy rival the brightest star clusters in total luminosity. Even though most of the visible radiation is concentrated in a few discrete emission lines, the total apparent brightness of the brightest is the equivalent of tens of thousands of solar luminosities. These H II regions are also remarkable in size, having diameters of about 1,000 light-years. More typically, common H II regions such as the Orion Nebula are about 50 light-years across. They contain gas that has a total mass ranging from one or two solar masses up to several thousand. H II regions consist primarily of hydrogen, but they also contain measurable amounts of other gases. Helium is second in abundance, and large amounts of carbon, nitrogen, and oxygen occur as well. Preliminary evidence indicates that the ratio of the abundance of the heavier elements among the detected gases to hydrogen decreases outward from the centre of the Galaxy, a tendency that has been observed in other spiral galaxies.

Planetary nebulas. The gaseous clouds known as planetary nebulas are only superficially similar to other types of nebulas. So called because the smaller varieties almost resemble planetary disks when viewed through a telescope, planetary nebulas represent a stage at the end of the stellar life cycle rather than one at the beginning. The distribution of such nebulas in the Galaxy is different from that of H II regions. Planetary nebulas belong to an intermediate population and are found throughout the disk and the inner halo. There are slightly more than 1,000 known planetary nebulas in the Galaxy, but many might be overlooked because of obscuration in the Milky Way region.

Supernova remnants. Another type of nebulous object found in the Galaxy is the remnant of the gas blown out from an exploding star that forms a supernova. Occasionally these objects look something like planetary nebulas, as in the case of the Crab Nebula, but they differ from the latter in three ways: (1) the total mass of their gas (they involve a larger mass, essentially all the mass of the exploding star), (2) their kinematics (they are expanding with higher velocities), and (3) their lifetimes (they last for a shorter time as visible nebulas). The best-known supernova remnants are those resulting from three historically observed supernovas: that of AD 1054, which made the Crab Nebula its remnant; that of AD 1572, called Tycho's Nova; and that of AD 1604, called Kepler's Nova. These objects and the many others like them in the Galaxy are detected at radio wavelengths. They release radio energy in a nearly flat spectrum due to the emission of radiation by charged particles moving spirally at nearly the speed of light in a magnetic field enmeshed in the gaseous remnant. Radiation generated in this way is called synchrotron radiation and is associated with various types of violent cosmic phenomena besides supernova remnants, as, for example, radio galaxies.

Synchrotron radiation

Dust clouds. The dust clouds of the Galaxy are narrowly limited to the plane of the Milky Way, though very low-density dust can be detected even near the galactic poles. Dust clouds beyond 2,000 to 3,000 light-years from the Sun cannot be detected optically, because intervening clouds of dust and the general dust layer obscure more distant views. Based on the distribution of dust clouds in other galaxies, it can be concluded that they are often most conspicuous within the spiral arms, especially along the inner edge of well-defined ones. The best observed dust clouds near the Sun have masses of several hundred solar masses and sizes ranging from a maximum of about 200 light-years to a fraction of a light-year. The smallest tend to be the densest, possibly due in part to evolution: as a dust complex contracts, it also becomes denser and more opaque. The very smallest dust clouds are the so-called Bok globules, named after the Dutch-American astronomer Bart J. Bok; these objects are about one light-year across and have masses of one to 20 solar masses.

More complete information on the dust in the Galaxy comes from infrared observations. While optical instruments can detect the dust when it obscures more distant objects or when it is illuminated by very nearby stars, infrared telescopes are able to register the long-wavelength radiation that the cool dust clouds themselves emit. A complete survey of the sky at infrared wavelengths made during the early 1980s by an unmanned orbiting observatory, the Infrared Astronomy Satellite (IRAS), revealed a large number of dense dust clouds in the Milky Way.

Thick clouds of dust in the Milky Way can be studied by still another means. Many such objects contain detectable amounts of molecules that emit radio radiation at wavelengths that allow them to be identified and analyzed. More than 50 different molecules, including carbon monoxide and formaldehyde, and radicals have been detected in dust clouds.

The general interstellar medium. The stars in the Galaxy, especially along the Milky Way, reveal the presence of a general, all-pervasive interstellar medium by the way in which they gradually fade with distance. This occurs primarily because of interstellar dust, which obscures and reddens starlight. On the average, stars near the Sun are dimmed by a factor of two for every 3,000 light-years. Thus, a star that is 6,000 light-years away in the plane of the Galaxy will appear four times fainter than it would otherwise were it not for the interstellar dust.

Another way in which the effects of interstellar dust become apparent is through the polarization of background starlight. Dust is aligned in space to some extent, and this results in selective absorption such that there is a preferred plane of vibration for the light waves. The electric vectors tend to lie preferentially along the galactic plane, though there are areas where the distribution is more complicated. It is likely that the polarization arises because the dust grains are partially aligned by the galactic magnetic field. If the dust grains are paramagnetic so that they act somewhat like a magnet, then the general magnetic field, though very weak, can in time line up the grains with their short axes in the direction of the field. As a consequence, the directions of polarization for stars in different parts of the sky make it possible to plot the direction of the magnetic field in the Milky Way.

Interstellar neutral hydrogen

The dust is accompanied by gas, which is thinly dispersed among the stars, filling the space between them. This interstellar gas consists mostly of hydrogen in its neutral form. Radio telescopes can detect neutral hydrogen because it emits radiation at a wavelength of 21 centimetres. Such radio wavelength is long enough to penetrate interstellar dust and so can be detected from all parts of the Galaxy. Most of what astronomers have learned about the large-scale structure and motions of the Galaxy has been derived from the radio waves of interstellar neutral hydrogen. The distance to the gas detected is not easily determined. Statistical arguments must be used in many cases, but the velocities of the gas, when compared with the velocities found for stars and those anticipated on the basis of the dynamics of the Galaxy, provide useful clues as to the location of the different sources of hydrogen radio emission. Near the Sun the average density of interstellar gas is 10^{-21} gm/cm^3, which is the equivalent of about one hydrogen atom per cubic centimetre.

Even before they first detected the emission from neutral hydrogen in 1951, astronomers were aware of interstellar gas. Minor components of the gas, such as sodium and calcium, absorb light at specific wavelengths (see Table 4), and they thus cause the appearance of absorption lines in the spectra of the stars that lie beyond the gas. Since the lines originating from stars are usually different, it is possible to distinguish the lines of the interstellar gas and to measure both the density and velocity of the gas. Frequently it is even possible to observe the effects of several concentrations of interstellar gas between the Earth and the background stars and thereby determine the kinematics of the gas in different parts of the Galaxy.

STRUCTURE AND DYNAMICS

The structure of the Galaxy. The Galaxy's structure is fairly typical of a large spiral system. It can be viewed as consisting of six separate parts: (1) nucleus, (2) central bulge, (3) disk, (4) spiral arms, (5) spherical component, and (6) massive halo. Some of these components blend into each other; their differences in stellar population have been discussed above.

Sagittarius A

The nucleus. At the very centre of the Galaxy lies a remarkable object—in all likelihood a massive black hole surrounded by an accretion disk of high-temperature gas. Neither the central object nor any of the material immediately around it can be observed at optical wavelengths because of the thick screen of intervening dust in the Milky Way. The object, however, is readily detectable at radio wavelengths and has been dubbed Sagittarius A by radio astronomers. Somewhat similar to the centres of active galaxies (see below), though on a lesser scale, the galactic nucleus is the site of a wide range of activity apparently powered by the black hole. Infrared radiation and X rays are emitted from the area, and rapidly moving gas clouds can be observed there. Data strongly indicate that material is being pulled into the black hole from outside the nuclear region, including some gas from the z direction (*i.e.,* perpendicular to the galactic plane). As the gas nears the black hole, its strong gravitational force squeezes the gas into a rapidly rotating disk, which extends outward about five to 30 light-years from the central object. Rotation measurements of the disk indicate that the black hole has a mass roughly 4,000,000 times that of the Sun.

The central bulge. Surrounding the nucleus is an extended bulge of stars that is nearly spherical in shape and that consists primarily of Population II stars, though they are comparatively rich in heavy elements. Mixed with the stars are several globular clusters of similar stars, and both the stars and clusters have nearly radial orbits around the nucleus. The bulge stars can be seen optically where they stick up above the obscuring dust of the galactic plane.

Table 4: Interstellar Absorption Features

atomic lines		molecular lines		diffuse lines
atom or ion	λ (Å)	molecule	λ (Å)	λ (Å)
Na I	3302.34	CH	4300.31	4430.6
	3302.94		3890.23	4760
	5889.95		3886.39	5780.5

The disk. From a distance the most conspicuous part of the Galaxy would be the disk, which extends from the nucleus out to distances of approximately 75,000 light-years. The Galaxy resembles other spiral systems, featuring as it does a bright, flat arrangement of stars and gas clouds that is spread out over its entirety and marked by a spiral structure. The disk can be thought of as being the underlying body of stars upon which the arms are superimposed. This body has a thickness that is roughly one-fifth its diameter, but different components have different characteristic thicknesses, as described below.

The spiral arms. Astronomers did not know that the Galaxy had a spiral structure until 1953, when the distances to stellar associations were first obtained reliably. Because of the obscuring interstellar dust and the interior location of the solar system, the spiral structure is very difficult to detect optically. This structure is easier to discern from radio maps of either neutral hydrogen or molecular clouds since both can be detected through the dust. Distances to the observed neutral hydrogen atoms must be estimated on the basis of measured velocities used in conjunction with a rotation curve for the Galaxy, which can be built up from measurements made at different galactic longitudes (see Figure 8).

From W. Becker and G. Contopoulos (eds.) *The Spiral Structure of the Galaxy* (1970) © Reidel Publishing Co. Dordrecht Holland

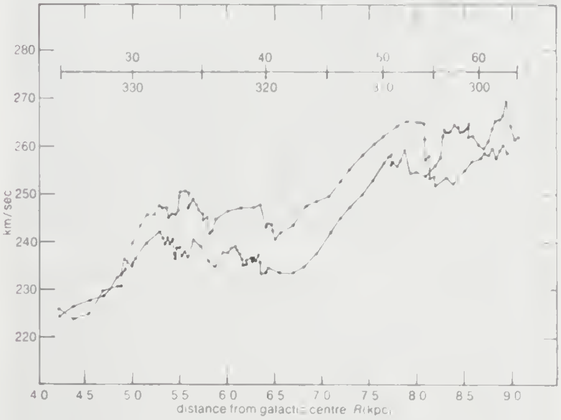

Figure 8: Galactic rotation curves from the 21-cm hydrogen emission line observations. Top curve refers to the gas north of (above) the galactic plane, bottom curve to points south of (below) the plane. The scale is set by the Sun's distance from the centre of the Galaxy, here taken as 10 kiloparsecs. The quantities *l* indicated above the curves are galactic longitudes.

From studies of other galaxies it can be shown that spiral arms generally follow a logarithmic spiral form such that

$$\log r = a - b\varphi,$$

where φ is a position angle measured from the centre to the outermost part of the arm, r is the distance from the centre of the galaxy, and a and b are constants. The range in pitch angles for galaxies is from about 50° to approximately 85°. The pitch angle is constant for any given galaxy if it follows a true logarithmic spiral. The pitch angle for the spiral arms of the Galaxy is difficult to determine from the limited optical data, but most measurements indicate a value of about 75°. There are five optically identified spiral arms in the part of the Milky Way wherein the solar system is located (see Table 5).

Table 5: Galactic Spiral Arms

arm number	name	galactic longitudes	distance
+I	Perseus	103–190°	10,000 light-years at 120°
0	Orion	60–250°	1,500 light-years at 180°
−I	Sagittarius	275–30°	5,000 light-years at 330°
−II	Norma	300–330°	10,000 light-years at 330°
−III	3kpc Arm	330–30°	20,000 light-years at 0°

Density-wave theory

Theoretical understanding of the Galaxy's spiral arms has progressed greatly in the 1980s, but there is still no complete understanding of the relative importance of the various effects thought to determine their structure. The overall pattern is almost certainly the result of a general dynamical effect known as a density-wave pattern. The Chinese-American astronomers Chia Chiao Lin and Frank H. Shu showed that a spiral shape is a natural result of any large-scale disturbance of the density distribution of stars in a galactic disk. When the interaction of the stars with one another is calculated, it is found that the resulting density distribution takes on a spiral pattern that does not rotate with the stars but rather moves around the nucleus more slowly as a fixed pattern. Individual stars in their orbits pass in and out of the spiral arms, slowing down in the arms temporarily and thereby causing the density enhancement. For the Galaxy, comparison of neutral hydrogen data with the calculations of Lin and Shu have shown that the pattern speed is 4 km/sec per 1,000 light-years.

Other effects that can influence a galaxy's spiral shape have been explored. It has been demonstrated, for example, that a general spiral pattern will result simply from the fact that the galaxy has differential rotation—*i.e.,* the rotation speed is different at different distances from the galactic centre. Any disturbance, such as a sequence of stellar formation events that are sometimes found drawn out in a near-linear pattern, will eventually take on a spiral shape simply because of the differential rotation. Distortions that also can be included are the results of massive explosions such as supernova events. These, however, tend to have only fairly local effects.

The spherical component. The space above and below the disk of the Galaxy is occupied by a thinly populated extension of the central bulge. Nearly spherical in shape, this region is populated by the outer globular clusters, but it also contains many individual field stars of extreme Population II, such as RR Lyrae variables and dwarf stars deficient in the heavy elements. Structurally, the spherical component resembles an elliptical galaxy, following the same simple mathematical law of density with distance from the centre.

The massive halo. The most controversial and least understood component of the Galaxy is the presumed giant massive halo that is exterior to the entire visible part. As explained above, the existence of the massive halo is demonstrated by its effect on the outer rotation curve of the Galaxy. All that can be said with any certainty is that the halo extends considerably beyond a distance of 100,000 light-years from the centre and that its mass is five or 10 times greater than the mass of the rest of the Galaxy taken together. It is not known what its shape is, what its constituents are, or how far into intergalactic space it extends.

Density distribution. *The stellar density near the Sun.* The density distribution of stars near the Sun can be used to calculate the mass density of material (in the form of stars) at the Sun's distance within the Galaxy. It is therefore of interest not only from the point of view of stellar statistics but also in relation to galactic dynamics. In principle, the density distribution can be calculated by integrating the stellar luminosity function. In practice, because of uncertainties in the luminosity function at the faint end and because of variations at the bright end, the local density distribution is not simply derived nor is there agreement between different studies in the final result.

Stellar density determinations

In the vicinity of the Sun, stellar density can be determined from the various surveys of nearby stars and from estimates of their completeness. For example, Peter van de Kamp's investigation of stars within 17 light-years can be used to determine the density of stars in this volume of space. Similarly, Wilhelm Gliese's catalog of stars closer than 65 light-years can be used for a larger volume of space and a larger sampling of stars.

The result of van de Kamp's determination of star density shows that even in his extremely close sample, incompleteness remains a problem in the surveys. The 60 stars that he includes fill a volume of space equal to 20,000 cubic light-years. Therefore, it is possible to calculate that the stellar density is 0.003 stars per cubic light-year. This figure, however, includes double and multiple star systems in addition to single stars, and if only the number of the systems is used stellar density is reduced to 0.002 objects per cubic light-year.

From Gliese's catalog, which contains 1,049 stars in a volume with a radius of 65 light-years, the average calculated density is less than one-third the calculated density for stars within 17 light-years. Thus, this catalog is incomplete, and its incompleteness is probably attributable to the fact that it is more difficult to detect the faintest stars and faint companions in the more distant systems.

In short, the true density of stars in the solar neighbourhood is difficult to establish. The value most commonly quoted is 0.003 stars per cubic light-year, a value obtained by integrating the van Rhijn luminosity function with a cutoff taken $M = 14.3$. This is, however, distinctly smaller than the true density as calculated for the most complete sampling volume discussed above and is therefore an underestimate. Gliese has estimated that when incompleteness of the catalogs is taken into account, the true stellar density is on the order of 0.004 stars per cubic light-year, which includes the probable number of unseen companions of multiple systems.

The density distribution of stars can be combined with the luminosity–mass relationship to obtain the mass density in the solar neighbourhood, which includes only stars and not interstellar material. This mass density is 4×10^{-24}g/cm^3.

Density distribution of various types of stars. To examine what kinds of stars contribute to the overall density distribution in the solar neighbourhood, various statistical sampling arguments can be applied to catalogs and lists of stars. The result of such a procedure is summarized in Table 6, which lists some of the kinds of objects and gives the calculated mean density over an appropriate volume centred on the Sun. For rare objects such as globular clusters, the volume of the sample must of course be rather large compared to that required to calculate the density for more common stars. Note that the figures are given in terms of mass density rather than number density. Number density for clusters obviously is very much smaller than mass densities.

The predominance of dwarf M stars

The most common stars and those that contribute the most to the local stellar mass density are the dwarf M stars, which provide a total of 0.0008 solar mass per cubic light-year. It is interesting to note that RR Lyrae variables and planetary nebulas—though many are known and thoroughly studied—contribute almost imperceptibly to the local star density. At the same time, white dwarfs, which are difficult to observe and of which very few are known, are among the more significant contributors.

Variations in the stellar density. The star density in the solar neighbourhood is not perfectly uniform. The most

Table 6: Space Densities of Stars

object	density (solar mass per cubic light-year)
O, B stars	0.00003
A, F stars	0.0001
dG, dK stars	0.0004
dM stars	0.0008
gG, gK stars	0.00003
gM stars	0.0000003
Dark companions	0.00014
White dwarfs	0.0002
Long-period variables	0.00000003
RR Lyrae stars	0.000000003
Cepheids	0.00000003
Planetary nebulas	0.0000000015
Open clusters	0.0000011
Globular clusters	0.00000003

conspicuous variations occur in the *z* direction, above and below the plane of the Galaxy, where the number density falls off rapidly. This will be considered separately below. The more difficult problem of variations within the plane is dealt with here.

Density variations are conspicuous for early type stars (*i.e.*, stars of higher temperatures) even after allowance has been made for interstellar absorption. For the stars earlier than type B3, for example, large stellar groupings in which the density is abnormally high are conspicuous in several galactic longitudes. The Sun in fact appears to be in a somewhat lower density region than the immediate surroundings where early B stars are relatively scarce. There is a conspicuous grouping of stars, sometimes called the Cassiopeia–Taurus Group, that has a centroid at approximately 600 light-years distance. A deficiency of early type stars is readily noticeable, for instance, in the direction of the constellation Perseus at distances beyond 600 light-years. Of course, the nearby stellar associations are striking density anomalies for early type stars in the solar neighbourhood. The early type stars within 2,000 light-years are significantly concentrated at negative galactic latitudes. This is a manifestation of a phenomenon referred to as "Gould's Belt," a tilt of the nearby bright stars in this direction with respect to the galactic plane. First noted by the English astronomer John Herschel in 1847, such anomalous behaviour is true only for the immediate neighbourhood of the Sun; faint B stars are strictly concentrated along the galactic equator.

Generally speaking, the large variations in stellar density near the Sun are less conspicuous for the late type dwarf stars (those of lower temperatures) than for the earlier types. This fact is explained as the result of the mixing of stellar orbits over long time intervals available for the older stars, which are primarily those stars of later spectral types. The young stars (O, B, and A types) are still close to the areas of star formation and show a common motion and common concentration due to initial formation distributions. In this connection it is interesting to note that the concentration of A-type stars at galactic longitudes 160° to 210° is coincident with a similar concentration of hydrogen detected by means of 21-centimetre line radiation. Correlations between densities of early type stars on the one hand and interstellar hydrogen on the other are conspicuous but not fixed; there are areas where neutral-hydrogen concentrations exist but for which no anomalous star density is found.

The variations discussed above are primarily small-scale fluctuations in star density rather than the large-scale phenomena so strikingly apparent in the structure of other galaxies. Sampling is too difficult and too limited to detect the spiral structure from the variations in the star densities for normal stars, although a hint of the spiral structure can be seen in the distribution in the earliest type stars and stellar associations. In order to determine the true extent in the star-density variations corresponding to these large-scale structural features, it is necessary to turn either to theoretical representations of the spiral structures or to other galaxies. From the former it is possible to find estimates of the ratio of star densities in the centre of spiral arms and in the interarm regions. The most commonly accepted theoretical representation of spiral structure, that of the density-wave theory, suggests that this ratio is on the order of 0.6, but for a complicated and distorted spiral structure such as apparently occurs in the Galaxy, there is no confidence that this figure corresponds very accurately with reality. On the other hand, fluctuations in other galaxies can be estimated from photometry of the spiral arms and the interarm regions provided that some indication of the nature of this stellar luminosity function at each position is available from colours or spectrophotometry. Estimates of the star density measured across the arms of spiral galaxies and into the interarm regions show that the large-scale spiral structure of a galaxy of this type is, at least in many cases, represented by only a relatively small fluctuation in star density.

Extremes in star density

It is clear from studies of the external galaxies that the range in star densities existing in nature is immense. For example, the density of stars at the centre of the nearby Andromeda spiral galaxy has been determined to equal 100,000 solar masses per cubic light-year, while the density at the centre of the Ursa Minor dwarf elliptical galaxy is only 0.00003 solar mass per cubic light-year.

Variation of star density with z distances. For all stars, variation of star density above and below the galactic plane rapidly decreases with height. Stars of different types, however, exhibit widely differing behaviour in this respect, and this tendency is one of the important clues as to the kinds of stars that occur in different stellar populations (see Table 3).

The luminosity function of stars is different at different galactic latitudes, and this is still another phenomenon connected with the *z* distribution of stars of different types. At a height of $z = 3{,}000$ light-years, stars of absolute magnitude 13 and fainter are nearly as abundant as at the galactic plane, while stars with absolute magnitude 0 are depleted by a factor of 100.

The values of the scale height for various kinds of objects given in Table 3 forms the basis for the segregation of these objects into different population types. Such objects as open clusters and Cepheid variables that have very small values of the scale height are the objects most restricted to the plane of the Galaxy, while globular clusters and other extreme Population II objects have scale heights of thousands of parsecs, indicating little or no concentration at the plane. Such data and the variation of star density with *z* distance bear on the mixture of stellar orbit types. They show the range from those stars having nearly circular orbits that are strictly limited to a very flat volume centred at the galactic plane to stars with highly elliptical orbits that are not restricted to the plane.

Basic elements of stellar motion

Stellar motions. A complete knowledge of a star's motion in space is possible only when both its proper motion and radial velocity can be measured. Proper motion is the motion of a star across an observer's line of sight and constitutes the rate at which the direction of the star changes in the celestial sphere. It is usually measured in seconds of arc per year. Radial velocity is the motion of a star along the line of sight and as such is the speed with which the star approaches or recedes from the observer. It is expressed in kilometres per second and given as either a positive or negative figure, depending on whether the star is moving away from or toward the observer.

Astronomers are able to measure both the proper motions and radial velocities of stars lying near the Sun. They can, however, determine only the radial velocities of stellar objects in more distant parts of the Galaxy and so must use these data, along with the information gleaned from the local sample of nearby stars, to ascertain the large-scale motions of stars in the Milky Way system.

Proper motions. The proper motions of the stars in the immediate neighbourhood of the Sun are usually very large, as compared to those of most other stars. Those of stars within 17 light-years of the Sun, for instance, range from 0.49 to 10.31 arc seconds per year. The latter value is that of Barnard's star, which is the star with the largest known proper motion. The tangential velocity of Barnard's star is 90 km/sec and, from its radial velocity (−108 km/sec) and distance (six light-years), astronomers have found that its space velocity (total velocity with respect to the Sun) is 140 km/sec. The distance to this star is rapidly decreasing; it will reach a minimum value of 3.5 light-years in about the year AD 11,800.

Radial velocities. Radial velocities, measured along the line of sight spectroscopically using the Doppler effect, are not known for all of the recognized stars near the Sun. Of the 45 systems within 17 light-years, only 40 have well-determined radial velocities. The radial velocities of the rest are not known either because of faintness or because of problems resulting from the nature of their spectrum. For example, radial velocities of white dwarfs are often very difficult to obtain because of the extremely broad and faint spectral lines in some of these objects. Moreover, the radial velocities that are determined for such stars are subject to further complication because a gravitational redshift generally affects the positions of their spectral lines. The average gravitational redshift for white dwarfs has been shown to be the equivalent of a velocity of −51 km/sec. To study the true motions of these objects it is necessary to make such a correction to the observed shifts of their spectral lines.

Radial velocities of nearby stars

For nearby stars, radial velocities are with very few exceptions rather small. For stars closer than 17 light-years, radial velocities range from −119 km/sec to +245 km/sec. Most values are on the order of ±20 km/sec, with a mean value of −6 km/sec.

Space motions. Space motions comprise a three-dimensional determination of stellar motion. They may be divided into a set of components related to directions in the Galaxy: *U*, directed away from the galactic centre; *V*, in the direction of galactic rotation; and *W*, toward the north galactic pole. For the nearby stars the average values for these galactic components are as follows: $U = -8$ km/sec, $V = -28$ km/sec, and $W = -12$ km/sec. These values are fairly similar to those for the galactic circular velocity components, which give $U = -9$ km/sec, $V = -12$ km/sec, and $W = -7$ km/sec. Note that the largest difference between these two sets of values is for the average *V*, which shows an excess of 16 km/sec for the nearby stars as compared to the circular velocity. Since *V* is the velocity in the direction of galactic rotation, this can be understood as resulting from the presence of stars in the local neighbourhood that have significantly elliptical orbits for which the apparent velocity in this direction is much less than the circular velocity. This fact was noted long before the kinematics of the Galaxy was understood and is referred to as the asymmetry of stellar motion.

Stream motion

The average components of the velocities of the local stellar neighbourhood also can be used to demonstrate the so-called stream motion. Calculations based on van de Kamp's table of stars within 17 light-years, excluding the star of greatest anomalous velocity, reveal that dispersions in the *V* direction and the *W* direction are approximately half the size of the dispersion in the *U* direction. This is an indication of a commonality of motion for the nearby stars; *i.e.*, these stars are not moving entirely at random but show a preferential direction of motion—the stream motion—confined somewhat to the galactic plane and to the direction of galactic rotation.

High-velocity stars. One of the nearest 45 stars, called Kapteyn's star, is an example of the high-velocity stars that lie near the Sun. Its observed radial velocity is −245 km/sec, and the components of its space velocity are $U = 19$ km/sec, $V = -288$ km/sec, $W = -52$ km/sec. The very large value for *V* indicates that with respect to circular velocity this star has practically no motion in the direction of galactic rotation at all. As the Sun's motion in its orbit around the Galaxy is estimated to be approximately 250 km/sec in this direction, the value *V* of −288 km/sec is primarily just a reflection of the solar orbital motion.

Solar motion. Solar motion is defined as the calculated motion of the Sun with respect to a specified reference frame. In practice, calculations of solar motion provide information not only on the Sun's motion with respect to its neighbours in the Galaxy but also on the kinematic properties of various kinds of stars within the system. These properties in turn can be used to deduce information on the dynamical history of the Galaxy and of its stellar components. Because accurate space motions can be obtained only for individual stars in the immediate vicinity of the Sun (within about 100 light-years), solutions for solar motion involving many stars of a given class are the prime source of information on the patterns of motion for that class. Furthermore, astronomers obtain information on the large-scale motions of galaxies in the neighbourhood of the Galaxy from solar motion solutions because it is necessary to know the space motion of the Sun with respect to the centre of the Galaxy (its orbital motion) before such velocities can be calculated.

The Sun's motion can be calculated by reference to any of three stellar motion elements: (1) the radial velocities of stars, (2) the proper motions of stars, or (3) the space motions of stars.

Solutions for solar motion based on radial velocities

Solar motion calculations from radial velocities. For objects beyond the immediate neighbourhood of the Sun, only radial velocities can be measured. Initially it is necessary to choose a standard of rest (the reference frame) from which the solar motion is to be calculated. This is usually done by selecting a particular kind of star or a portion of space. To solve for solar motion, two assumptions are made. The first is that the stars that form the standard of rest are symmetrically distributed over the sky, and the second is that the peculiar motions—the motions of individual stars with respect to that standard of rest—are randomly distributed. Considering the geometry then provides a mathematical solution for the motion of the Sun through the average rest frame of the stars being considered.

In astronomical literature where solar motion solutions are published, there is often employed a "K-term," a term that is added to the equations to account for systematic errors, the stream motions of stars, or the expansion or contraction of the member stars of the reference frame. Recent determinations of solar motion from high-dispersion radial velocities have suggested that most previous K-terms (which averaged a few kilometres per second) were the result of systematic errors in stellar spectra caused by blends of spectral lines. Of course, the K-term that arises when a solution for solar motions is calculated for galaxies results from the expansion of the system of galaxies and is very large if galaxies at great distances from the Milky Way Galaxy are included.

Solar motion calculations from proper motions. Solutions for solar motion based on the proper motions of the stars in proper motion catalogs can be carried out even when the distances are not known and the radial velocities are not given. It is necessary to consider groups of stars of limited dispersion in distance so as to have a well-defined and reasonably spatially-uniform reference frame. This can be accomplished by limiting the selection of stars according to their apparent magnitudes. The procedure is the same as the above except that the proper motion components are used instead of the radial velocities. The average distance of the stars of the reference frame enters into the solution of these equations and is related to the term often referred to as the secular parallax. The secular parallax is defined as $0.24h/r$, where h is the solar motion in astronomical units per year and r is the mean distance for the solar motion solution.

Solar motion calculations from space motions. For nearby well-observed stars, it is possible to determine complete space motions and to use these for calculating the solar motion. One must have six quantities: α (the right ascension of the star); δ (the declination of the star); μ_α (the proper motion in right ascension); μ_δ (the proper motion in declination); ρ (the radial velocity as reduced to the Sun); and r (the distance of the star). To find the solar motion, one calculates the velocity components of each star of the sample and the averages of all of these.

Solar motion solutions give values for the Sun's motion in terms of velocity components, which are normally reduced to a single velocity and a direction. The direction in which the Sun is apparently moving with respect to the reference frame is called the apex of solar motion. In addition, the calculation of the solar motion provides dispersion in velocity. Such dispersions are as intrinsically interesting as the solar motions themselves because a dispersion is an indication of the integrity of the selection of stars used as a reference frame and of its uniformity of kinematic properties. It is found, for example, that dispersions are very small for certain kinds of stars (*e.g.*, A-type stars, all of which apparently have nearly similar, almost circular orbits in the Galaxy) and are very large for some other kinds of objects (*e.g.*, the RR Lyrae variables, which show a dispersion of almost 100 km/sec due to the wide variation in the shapes and orientations of orbits for these stars).

The standard solar motion

Solar motion solutions. The motion of the Sun with respect to the nearest common stars is of primary interest. If stars within about 80 light-years of the Sun are used exclusively, the result is often called the standard solar motion. This average, taken for all kinds of stars, leads to a velocity $V_{\odot} = 19.5$ km/sec. The apex of this solar motion is in the direction of $\alpha = 270°$, $\delta = +30°$. The exact values depend on the selection of data and method of solution. These values suggest that the Sun's motion with respect to its neighbours is moderate but certainly not zero. The velocity difference is larger than the velocity dispersions for common stars of the earlier spectral types, but it is very similar in value to the dispersion for stars of a spectral type similar to the Sun. The solar velocity for, say, G5 stars, is 10 km/sec and the dispersion is 21 km/sec. Thus the Sun's motion can be considered fairly typical for its class in its neighbourhood. The peculiar motion of the Sun is a result of its relatively large age and a somewhat noncircular orbit. It is generally true that stars of later spectral types show both greater dispersions and greater values for solar motion, and this characteristic is interpreted to be the result of a mixture of orbital properties for the later spectral types, with increasingly large numbers of stars having more highly elliptical orbits.

The term basic solar motion has been used by some astronomers to define the motion of the Sun relative to stars moving in its neighbourhood in perfectly circular orbits around the galactic centre. The basic solar motion differs from the standard solar motion because of the noncircular motion of the Sun and because of the contamination of the local population of stars by the presence of older stars in noncircular orbits within the limits of the reference frame. The most commonly quoted value for the basic solar motion is a velocity of 16.5 km/sec toward an apex with a position $\alpha = 265°$, $\delta = 25°$.

When the solutions for solar motion are determined according to the spectral class of the stars, there is a correlation between the result and the spectral class. Table 7 summarizes values obtained from various sources and illustrates this fact. The apex of the solar motion, the solar motion velocity, and its dispersion are all correlated with spectral type. Generally speaking (with the exception of the very early type stars), the solar motion velocity increases with decreasing temperature of the stars, ranging from 16 km/sec for late B-type and early A-type stars to 24 km/sec for late K-type and early M-type stars. The dispersion similarly increases from a value near 10 km/sec to a value of 22 km/sec. The reason for this is related to the dynamical history of the Galaxy and the mean age and mixture of ages for stars of the different spectral types. It is quite clear, for example, that stars of early spectral type are all young, whereas stars of late spectral type are a mixture of young and old. Connected with this is the fact that the solar motion apex shows a trend for the latitude to decrease and the longitude to increase with later spectral types.

The solar motion can be based on reference frames defined by various kinds of stars and clusters of astrophysical interest. Data of this sort are interesting because of the way in which they make it possible to distinguish between objects with different kinematic properties in the Galaxy. For example, it is clear that interstellar calcium lines have relatively small solar motion and extremely small dispersion because they are primarily connected with the dust that is limited to the galactic plane and with objects that are decidedly of the Population I class. On the other hand, RR Lyrae variables and globular clusters have very large values of solar motion and very large dispersions, indicating that they are extreme Population II objects that do not all equally share in the rotational motion of the Galaxy. The solar motion of these various objects is an important consideration in determining to what population the objects belong and what their kinematic history has been.

Table 7: Adopted Components of the Solar Motion and Velocity Dispersions

type	solar motion (km/sec)			spread in velocities (km/sec)

When some of these classes of objects are examined in greater detail, it is possible to separate them into subgroups and find correlations with other astrophysical properties. Take, for example, globular clusters, for which the solar motion is correlated with the spectral type of the clusters. The clusters of spectral types G0–G5 (the more metal-rich clusters) have a mean solar motion of 80 ± 82 km/sec (corrected for the standard solar motion). The earlier type globular clusters of types F2–F9, on the other hand, have a mean velocity of 162 ± 36 km/sec, suggesting that they partake much less extensively in the general rotation of the Galaxy. Similarly, the most distant globular clusters have a larger solar motion than the ones closer to the galactic centre. Studies of RR Lyrae variables also show correlations of this sort. The period of an RR Lyrae variable, for example, is correlated with its motion with respect to the Sun. For type ab RR Lyrae variables, periods frequently vary from 0.3 to 0.7 day, and the range of solar motion for this range of period extends from 30 to 205 km/sec, respectively. This condition is believed to be primarily the result of the effects of the spread in age and composition for the RR Lyrae variables in the field, which is similar to but larger than the spread in the properties of the globular clusters.

The solar velocity of rotation

Since the direction of the centre of the Galaxy is well established by radio measurements and since the galactic plane is clearly established by both radio and optical studies, it is possible to determine the motion of the Sun with respect to a fixed frame of reference centred at the Galaxy and not rotating (*i.e.*, tied to the external galaxies). The value for this motion is generally accepted to be 225 km/sec in the direction $\ell^{\text{II}} = 90°$. It is not a firmly established number, but it is used by convention in most studies.

In order to arrive at a clear idea of the Sun's motion in the Galaxy as well as the motion of the Galaxy with respect to neighbouring systems, solar motion has been studied with respect to the Local Group galaxies and those in nearby space. Hubble determined the Sun's motion with respect to the galaxies beyond the Local Group and found the value of 300 km/sec in the direction toward galactic longitude 120°, latitude +35°. This velocity includes the Sun's motion in relation to its proper circular velocity, its circular velocity around the galactic centre, the motion of the Galaxy with respect to the Local Group, and the latter's motion with respect to its neighbours.

The magnetic field of the Galaxy. It was once thought that the spiral structure of galaxies might be controlled by a strong magnetic field. However, when the general magnetic field was detected by radio techniques, it was found to be too weak to have large-scale effects on galactic structure. The strength of the galactic field is only about 0.000001 times the strength of the Earth's field at its surface, a value that is much too low to have dynamical effects on the interstellar gas that could account for the order represented by the spiral-arm structure. This is, however, sufficient strength to cause a general alignment of the dust grains in interstellar space, a feature that is detected by measurements of the polarization of starlight. In the prevailing model of interstellar dust grains, the particles are shown to be rapidly spinning and to contain small amounts of metal (probably iron), though the primary constituents are ice and carbon. The magnetic field of the Galaxy can gradually act on the dust particles and cause their rotational axes to line up in such a way that their short axes are parallel to the direction of the field. The field itself is aligned along the Milky Way band, so that the short axes of the particles also become aligned along the galactic plane. Polarization measurements of stars at low galactic latitudes confirm this pattern.

The rotation of the Galaxy. As discussed above, the motions of stars in the local stellar neighbourhood can be understood in terms of a general population of stars that have circular orbits of rotation around the distant galactic nucleus, with an admixture of stars that have more highly elliptical orbits and that appear to be high-velocity stars to a terrestrial observer as the Earth moves with the Sun in its circular orbit. The general rotation of the disk stars was first detected through studies made in the 1920s, notably those of the Swedish astronomer Bertil Lindblad, who correctly interpreted the apparent asymmetries in stellar motions as the result of this multiple nature of stellar orbital characteristics.

Differential rotation and its effect

The disk component of the Galaxy rotates around the nucleus in a manner similar to the pattern for the planets of the solar system, which have nearly circular orbits around the Sun. Because the rotation rate is different at different distances from the centre of the Galaxy, the measured velocities of disk stars in different directions along the Milky Way exhibit different patterns. The Dutch astronomer Jan H. Oort first interpreted this effect in terms of galactic rotation motions, employing the radial velocities and proper motions of stars. He demonstrated that differential rotation leads to a systematic variation of the radial velocities of stars with galactic longitude following the mathematical expression:

$$\text{radial velocity} = Ar \sin 2l,$$

where A is called Oort's constant and is approximately 15 km/sec/kpc, r is the distance to the star, and l is the galactic longtitude (Figure 9).

A similar expression can be derived for measured proper motions of stars. The agreement of observed data with Oort's formulas was a landmark demonstration of the correctness of Lindblad's ideas about stellar motions. It led to the modern understanding of the Galaxy as a giant rotating disk.

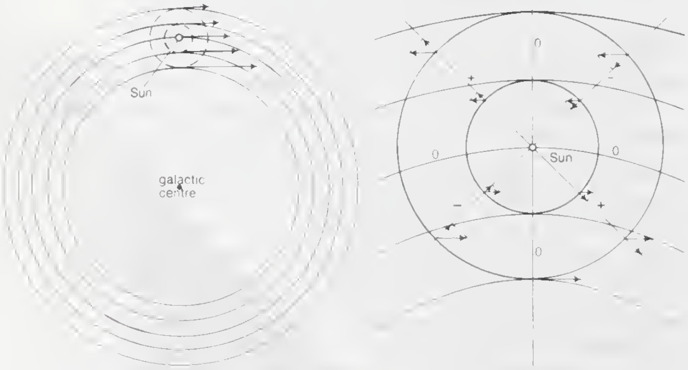

Figure 9: The effect of galactic rotation on the radial velocities (speeds in the line of sight). (Left) The arrows represent the variation of rotational velocity with the distance from the centre. (Right) The arrows represent the velocities as observed. The radial velocity components are also shown (see text).

The external galaxies

THE EXTRAGALACTIC DISTANCE SCALE

Before astronomers could establish the existence of galaxies, they had to develop a way to measure their distances. In an earlier section, it was explained how astronomers first accomplished this exceedingly difficult task for the nearby galaxies during the 1920s. Since that time, progress has been slow and the results far from satisfactory. Distance determinations for the nearest galaxies still remain uncertain by as much as 10 percent, and the scale of distances beyond the Local Group of galaxies is even more unsure, with an uncertainty of possibly a factor of two. The reason for this unfortunate situation is the great difficulty of observing distant galaxies in sufficient detail to recognize the necessary distance criteria accurately, to measure their characteristics, and to make certain that their characteristics are correctly interpreted.

From Paul W Hodge, *The Physics and Astronomy of Galaxies and Cosmology* (1966)

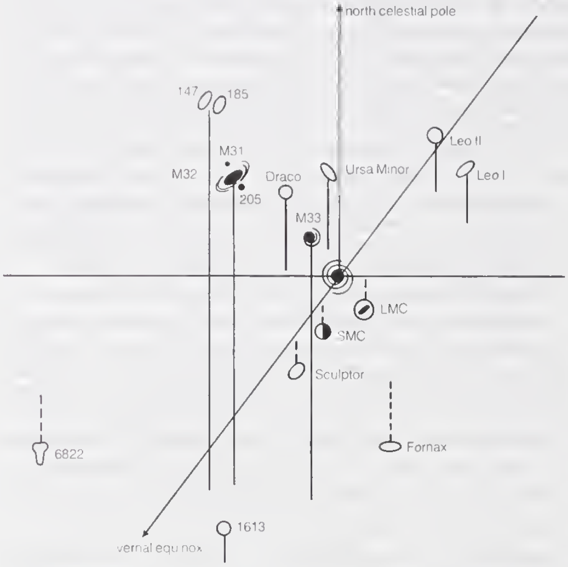

Figure 10: Three-dimensional schematic diagram of the principal galaxies of the Local Group. Galaxy images are not to scale.

The process involved is one of many successive steps that are all closely tied to one another. Distances are first determined for a number of galaxies close to the Milky Way Galaxy, specifically those in the Local Group and a few in other nearby groups. For this step, criteria are used that have been calibrated within the Galaxy, where checks can be made between different methods and where the ultimate criterion is a geometrical one (basically involving trigonometric parallaxes and the moving-cluster method). Next, the nearby galaxies are used to set up new, brighter distance criteria that can be employed in more distant realms where only the brightest stars and other objects are discernible in galaxies. These in turn can be used to establish criteria based on the properties of whole galaxies so that distances can be found for systems so far away that no individual objects can be resolved within them. These last criteria then are applied to extend scientific knowledge to the most distant galaxies that can be detected—those at the very edge of the visible universe. Considering the magnitude of the task, it is no surprise that the answers obtained are not yet highly certain. Astronomers have done remarkably well to measure such vast distances even with an uncertainty of a factor of two.

The Local Group of galaxies is a concentration of approximately 35 galaxies, dominated by two large spirals, the Milky Way system and the Andromeda galaxy (Table 8 and Figure 10). For many of these galaxies, distances can be measured using the Cepheid period–luminosity law, which has been refined and made more accurate since Hubble first used it. For instance, the nearest ex-

ternal galaxy, the Large Magellanic Cloud, contains more than 2,000 Cepheid variables, which can be compared to Cepheids of known distance in the Galaxy to yield a distance determination of 150,000 light-years. This method has been employed for 10 galaxies of the Local Group (Figure 11). Most of the rest of the members are elliptical galaxies, which do not have Cepheid variables; their distances are measured by using Population II stars, such as RR Lyrae variables.

Beyond the Local Group are two nearby groups for which the period–luminosity relation has been used: the Sculptor group and the M81 group. Both of these are small clusters of galaxies that are similar in size to the Local Group. They lie at a distance of from 10,000,000 to 15,000,000 light-years.

Distance-determining techniques

While the period–luminosity relation is the primary distance criterion in this realm, others also are used. One of these is main-sequence fitting, a technique that compares the temperatures of individual stars (those in their normal, stable main-sequence phase) with similar stars in steller clusters in the Galaxy. Main-sequence fitting became effective in the 1980s, when powerful new detectors allowed accurate measurements of very faint stars in the few nearest galaxies.

Also in the 1980s, astronomers developed a new method of effectively measuring distances to galaxies in the Local Group, in nearby groups, and even as far away as the Virgo cluster, lying at a distance of about 50,000,000 light-years. This method makes use of planetary nebulas, the ringlike shells that surround some stars in their late stages of evolution. Planetary nebulas have a variety of luminosities, depending on their age and other physical circumstances; however, it has been determined that the brightest planetary nebulas have an upper limit to their intrinsic brightnesses. This means that astronomers can measure the brightnesses of such nebulas in any given galaxy, find the upper limit to the apparent brightnesses, and then immediately calculate the distance of the galaxy. Another recent method involves the use of the nova phenomenon, which can be detected in galaxies in the Local Group and beyond—that is to say, as remote as the Virgo cluster.

From Paul W. Hodge, *The Physics and Astronomy of Galaxies and Cosmology* (1966)

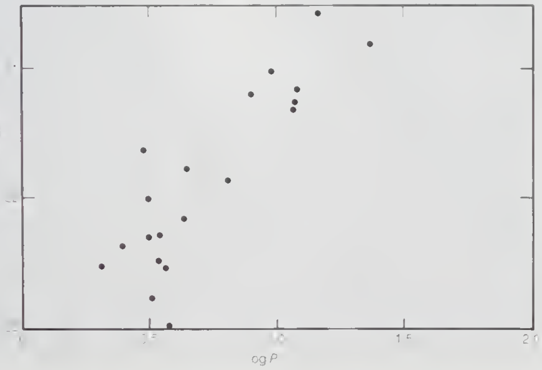

Figure 11: Period–luminosity relation for Cepheids in a portion of M31. Open circles are type II Cepheids.

Once distances have been established for these nearby galaxies and groups, new criteria are calibrated for extension to fainter galaxies. Examples of the many different criteria that have been tried are the luminosities of the brightest stars in the Galaxy, the diameters of the largest H II regions, supernova luminosities, the spread in the rotational velocities of stars and interstellar gas, and the luminosities of globular clusters. All of these criteria have difficulties in their application because of dependencies on galaxy type, composition, luminosity, and other characteristics, so that the results of several methods must be intercompared and cross-checked. Such distance criteria allow astronomers to measure the distances to galaxies out to a few hundred million light-years.

The Hubble constant

Beyond 100,000,000 light-years, another method becomes possible. The expansion of the universe, at least for the immediate neighbourhood of the Local Group (within 1,000,000,000 light-years or so), is linear enough that the radial velocity of a galaxy is à reliable distance indicator. The velocity is directly proportional to the distance in this interval, so that once a galaxy's radial velocity has been measured all that must be known is the constant of proportionality, which is called the Hubble constant. Although there still remains some uncertainty in the correct value of the Hubble constant, research in the 1990s has indicated that the constant has a value very near 25 km/sec per 1,000,000 light-years (see Figure 12). Radial velocity for nearby galaxies and groups is affected by the Local Group's motion with respect to the general background of galaxies toward a concentration of galaxies and groups of galaxies centred on the Virgo cluster, all of which make up a local supercluster. Radial velocities cannot give reliable distances beyond a few billion light-years because, in the case of such galaxies, astronomers are looking so far back in time that they do not know whether the expansion rate of the universe was then the same as it is now. The light that is observed today was emitted several billion years ago when the universe was much younger and smaller than it is at present.

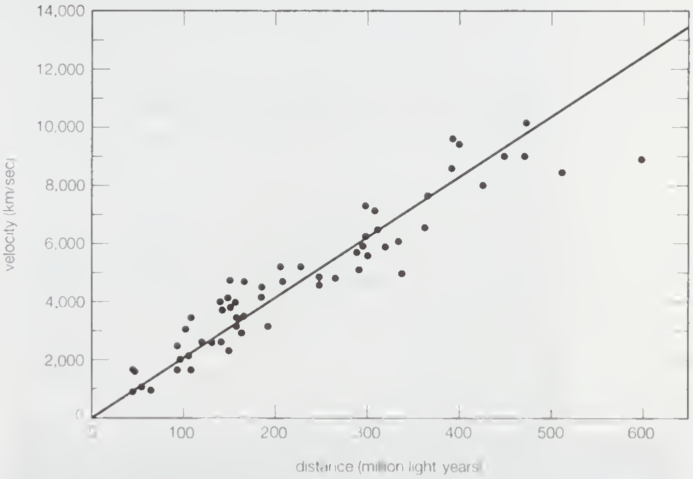

Figure 12: Hubble diagram for the brightest galaxies in clusters. The line is a fit that corresponds to a Hubble constant of 25 km/sec per 1,000,000 light-years.

To find the distances of very distant galaxies, astronomers have to avail themselves of methods that make use of the total properties of the very brightest galaxies. Most commonly it is assumed that the brightest galaxies in clusters all have the same true luminosity (this appears to be the case for relatively nearby clusters for which distances can be measured in other ways) and that therefore measuring the apparent brightness of the brightest galaxy in a distant cluster will give its distance. This method, as well as others that make use of the cluster environment, have yielded distance estimates as large as 10,000,000,000 to 20,000,000,000 light-years for the most distant galaxies detectable (Figure 13).

From Paul W. Hodge, *The Physics and Astronomy of Galaxies and Cosmology* (1966)

PHYSICAL PROPERTIES OF EXTERNAL GALAXIES

Size and mass. The range in intrinsic size for the external galaxies extends from the smallest systems, such as the nearby dwarf galaxy GR8 with a diameter of about 5,000 light-years, to giant radio galaxies, the extent of which (including their radio-bright lobes) is more than 3,000,000 light-years. Normal large spiral galaxies, such as the Andromeda galaxy, have diameters of 100,000 to 500,000 light-years.

The total masses of galaxies are not well known, largely because of the uncertain nature of the hypothesized invisible dark halos that surround many, or possibly all, galaxies. The total mass of material within the radius out to which the light of a galaxy can be detected is known for many hundreds of systems. The range is from about 100,000 to roughly 1,000,000,000,000 times the Sun's mass. The mass of a typical large spiral is about 500,000,-000,000 suns.

Luminosity. The external galaxies show an extremely large range in their total luminosities. The intrinsically faintest are the extreme dwarf elliptical galaxies, such as the Ursa Minor dwarf, which has a luminosity of approximately 100,000 suns. The most luminous galaxies are those that contain quasars at their centres. These remarkably bright, superactive nuclei can be as luminous as 2,000,000,000,000 suns. The underlying galaxies are often as much as 100 times fainter than their nuclei. Normal large spiral galaxies have a luminosity of a few hundred billion suns.

Super-
active
nuclei

Age. Even though different galaxies have had quite different histories, measurements tend to suggest that most, if not all, galaxies have very nearly the same age. The age of the Milky Way Galaxy, which is measured by determining the ages of the oldest stars found within it, is approximately 16,000,000,000 years. Nearby galaxies, even those such as the Large and Small Magellanic Clouds that contain a multitude of very young stars, also have at least a few very old stars of approximately that same age. When more distant galaxies are examined, their spectra and colours closely resemble those of the nearby galaxies, and it is inferred that they too must contain a population of similarly very old stars. Extremely distant galaxies, on the other hand, look younger, but that is because the "look-back" time for them is a significant fraction of their age; the light received from such galaxies was emitted when they were appreciably younger.

It seems likely that all of the galaxies began to form at about the same time when the universe had cooled down enough for matter to condense, and thus they all started forming stars during nearly the same epoch. Their large differences are not a matter of age but rather of how they proceeded to regulate the processing of their materials (gas and dust) into stars. The ellipticals formed almost all their stars during the first few billion years, while the spirals and the irregulars have been using up their materials more gradually.

Composition. The abundances of the chemical elements in stars and galaxies are remarkably uniform. The ratios of the amounts of the different elements that astronomers observe for the Sun is a reasonably good approximation for those of other stars in the Galaxy and also for stars in other galaxies. The main difference found is in the relative amount of the primordial gases, hydrogen and helium. As noted earlier, the heavier elements are formed by stellar evolutionary processes, and they are relatively more abundant in areas where extensive star formation has been taking place. Thus, in such small elliptical galaxies as the Draco system where almost all of the stars were formed at the beginning of its lifetime, the component stars are nearly pure hydrogen and helium, while in such large galaxies as the Andromeda Galaxy, there are areas where star formation has been active for a long time (right up to the present in fact), and here investigators find that the heavier elements are more abundant. In some external galaxies as well as in some parts of the Milky Way system, heavy elements are even more abundant than in the Sun but rarely by more than a factor of two or so. Even in such cases, hydrogen and helium make up most of the constituent materials, accounting for at least 90 percent of the mass.

STRUCTURE

The spheroidal component. Most and perhaps all galaxies have a spheroidal component of very old stars. In the ellipticals this component comprises all or most of any given system. In the spirals it represents about half of the constituent stars (this fraction varies greatly according to galaxy type). In the irregulars the spheroidal component is very inconspicuous or, possibly in a few cases, entirely absent. The structure of the spheroidal component of all galaxies is similar, as if the spirals and irregulars possess a skeleton of old stars arranged in a structure that resem-

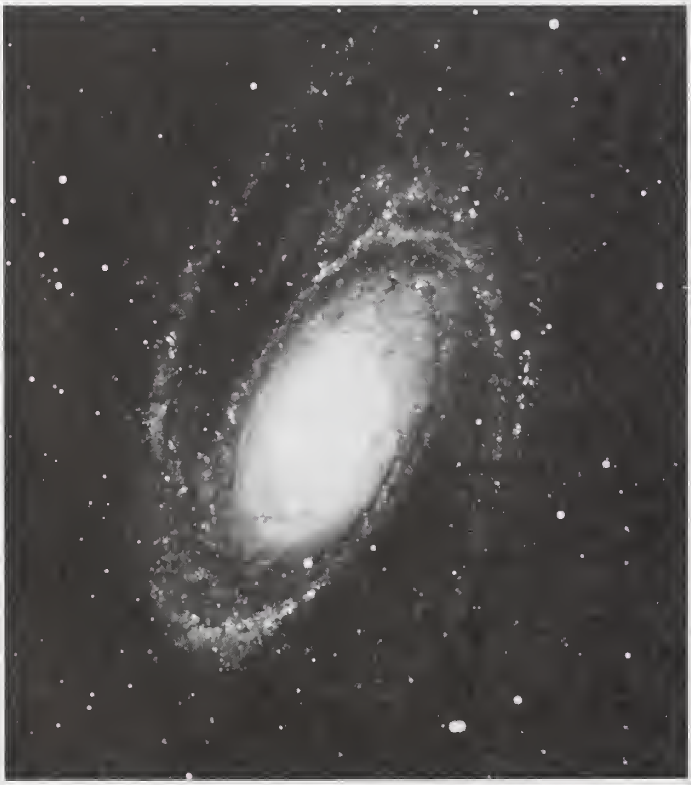

Figure 14: M81, a large spiral galaxy in the constellation Ursa Major.

bles an elliptical. The radial distribution of stars follows a law of the form

$$I = I_e 10^{(-3.33([r/r_e]^{1/4}-1))},$$

where I is the surface brightness (or the stellar density) at position r, r is the radial distance from the centre, and I_e and r_e are constants. This expression, advocated by de Vaucouleurs, is an empirical formula that works remarkably well in describing the spheroidal components of almost all galaxies. An alternative formula, put forth by Hubble, is of the form

$$I = I_0(r/a + 1)^{-2},$$

where I is the surface brightness, I_0 is the central brightness, r is the distance from the centre, and a is a scaling constant. Either of these formulas describes the structure well, but neither explains it.

A somewhat more complicated set of equations can be derived on the basis of the mutual gravitational attraction of stars for one another and the long-term effects of close encounters between stars. These models of the spheroidal component (appropriately modified in the presence of other galactic components) fit the observed structures well. Rotation is not an important factor, since elliptical galaxies and the spheroidal component of spiral systems (*e.g.*, the Milky Way Galaxy) rotate slowly. One of the open questions about the structure of these objects is why they have as much flattening as some of them do. In most cases, the measured rotation rate is inadequate to explain the flattening on the basis of a model of an oblate spheroid that rotates around its short axis. It has been suggested that some elliptical galaxies may instead be prolate spheroids that rotate around their long axis.

Slow rotation rate

The disk component. Except for such early type galaxies as S0, SB0, Sa, and SBa systems, spirals and irregulars have a flat component of stars that emits most of their brightness. The disk component has a thickness that is approximately one-fifth its diameter (this varies, depending on the type of stars being considered, as explained above for the Galaxy). The stars show a radial distribution that obeys an exponential decrease outward; *i.e.*, the brightness obeys a formula of the form

$$\log I = -kr,$$

where I is the surface brightness, r is the distance from the centre, and k is a scaling constant. This constant is dependent both on the type of the galaxy and on its intrinsic luminosity. The steepness of the outward slope is greatest for the early Hubble types (Sa and SBa) and for the least luminous galaxies.

Spiral arms. The structure of the arms of spiral galaxies depends on the galaxy type, and there is also a great deal of variability within each type. Generally the early Hubble types have smooth, indistinct spiral arms with small pitch angles. The later types have more open arms (larger pitch angles; Figure 14). Within a given type there can be found galaxies that have extensive arms (extending around the centre for two or more complete rotations) and those that have a chaotic arm structure made up of many short fragments that extend only 20° or 30° around the centre. All spiral arms fit reasonably well to a logarithmic spiral of the form described above for the Milky Way Galaxy.

Gas distribution. If one were to look at galaxies at wavelengths that show only neutral hydrogen gas, they would look rather different from their optical appearance. Normally the gas, as detected at radio wavelengths for neutral hydrogen atoms, is more widely spread out, with the size of the gas component often extending to twice the size of the optically visible image. Also, in some galaxies a hole exists in the centre of the system where almost no neutral hydrogen occurs. There is, however, enough molecular hydrogen to make up for the lack of atomic hydrogen. Molecular hydrogen is difficult to detect, but it is accompanied by other molecules, such as carbon monoxide, which can be observed at radio wavelengths.

Neutral hydrogen

CLUSTERS OF GALAXIES

Galaxies tend to cluster together, sometimes in small groups and sometimes in enormous complexes. Most galaxies have companions, either a few nearby objects or a large-scale cluster; isolated galaxies, in other words, are quite rare (Table 9).

Table 9: Properties of Some Well-Known Clusters of Galaxies

name	distance	diameter	description
	(millions of light-years)		
Local group	—	3	small loose group
M81 group	7	1	loose group
Virgo cluster	50	7	large complex cluster
Fornax cluster	50	3	complex cluster
Coma cluster	150	23	large compact cluster
Hercules cluster	240	7	large loose cluster
Corona Borealis cluster	700	7	compact cluster

Types of clusters. There are several different classification schemes for galaxy clusters, but the simplest is the most useful. This scheme divides clusters into three classes: groups, irregulars, and sphericals.

Groups. The groups class is composed of small, compact groups of 10 to 50 galaxies of mixed types, spanning roughly 5,000,000 light-years. An example of such an entity is the Local Group, which includes the Milky Way Galaxy, the Magellanic Clouds, the Andromeda Galaxy, and 18 other systems mostly of the dwarf variety.

Irregular clusters. Irregular clusters are large, loosely structured assemblages of mixed galaxy types (mostly spirals and ellipticals), totaling perhaps 1,000 or more systems and extending out 10,000,000 to 50,000,000 light-years. The Virgo and Hercules clusters are representative of this class (Figure 15).

Spherical clusters. Spherical clusters are dense and consist almost exclusively of elliptical and S0 galaxies. They are enormous, having a linear diameter of up to 50,000,000 light-years. Spherical clusters may contain as many as 10,000 galaxies, which are concentrated toward the cluster centre.

Distribution. Clusters of galaxies are found all over the sky. They are difficult to detect along the Milky Way,

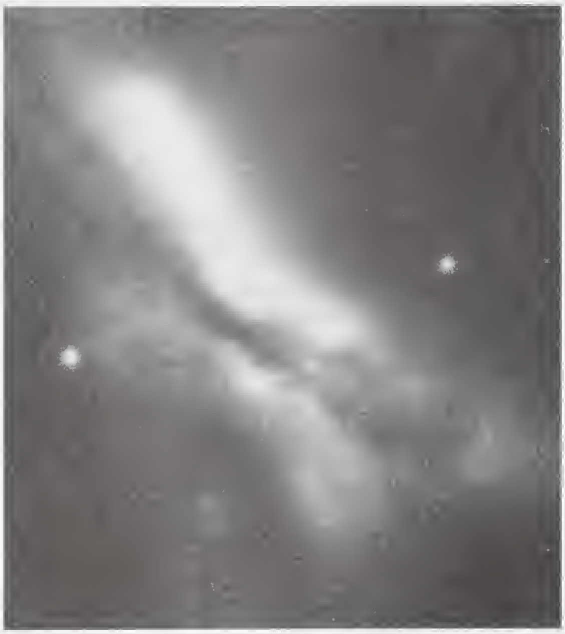

Figure 16: NGC 520, an example of an interacting pair of galaxies, in which the shapes of the galaxies and the motions of the constituent stars and interstellar material are grossly distorted.

Lick Observatory, Mount Hamilton, California

where high concentrations of the Galaxy's dust and gas obscure virtually everything at optical wavelengths. However, even there clusters can be found in a few galactic "windows," the random holes in the dust that permit optical observations.

Superclusters

The clusters are not evenly spaced in the sky; instead, they are arranged in a way that suggests a certain amount of organization. Clusters are frequently associated with other clusters, forming giant superclusters. These superclusters typically consist of three to 10 clusters and span as many as 200,000,000 light-years. There also are immense areas between clusters that are nearly empty, forming "voids." Large-scale surveys made in the 1980s of the radial velocities of galaxies revealed an even larger kind of structure. It was discovered that galaxies and galaxy clusters tend to fall in position along large planes and curves, almost like giant walls, with relatively empty spaces between them. A related large-scale structure was found to exist where there occur departures from the velocity–distance relation in certain directions, indicating that the otherwise uniform expansion is being perturbed by large concentrations of mass. One of these, discovered in 1988, has been dubbed "The Great Attractor."

Interactions between cluster members. Galaxies in clusters exist in a part of the universe that is much denser than average, and the result is that they have several unusual features. In the inner parts of dense clusters there are very few, if any, normal spiral galaxies. This condition is probably the result of fairly frequent collisions between the closely packed galaxies, as such violent interactions tend to sweep out the interstellar gas, leaving behind only the spherical component and a gasless disk. What remains, in effect, is an S0 galaxy.

A second and related effect of galaxy interactions is the presence of gas-poor spiral systems at the centres of large irregular clusters. A significant number of the members of such clusters have anomalously small amounts of neutral hydrogen, and their gas components are smaller on the average than those for more isolated galaxies. This is thought to be the result of frequent distant encounters between such galaxies involving the disruption of their outer parts (Figure 16).

A third effect of the dense cluster environment is the presence in some clusters—usually rather small, dense clusters—of an unusual type of galaxy called a cD galaxy. These objects are somewhat similar in structure to S0 galaxies, but they are considerably larger, having envelopes that extend out to radii as large as 1,000,000 light-years. Many of them have multiple nuclei, and most are strong sources of radio waves. The most likely explanation for cD galaxies is that they are massive, central galactic systems that have captured smaller cluster members because of their dominating gravitational fields and have absorbed the other galaxies into their own structures. Astronomers refer to this process as galactic cannibalism. In this sense, the outer extended disks of cD systems, as well as their multiple nuclei, represent the remains of past, partly digested "meals" (Figure 17).

Galactic cannibalism

By courtesy of the National Optical Astronomy Observatories

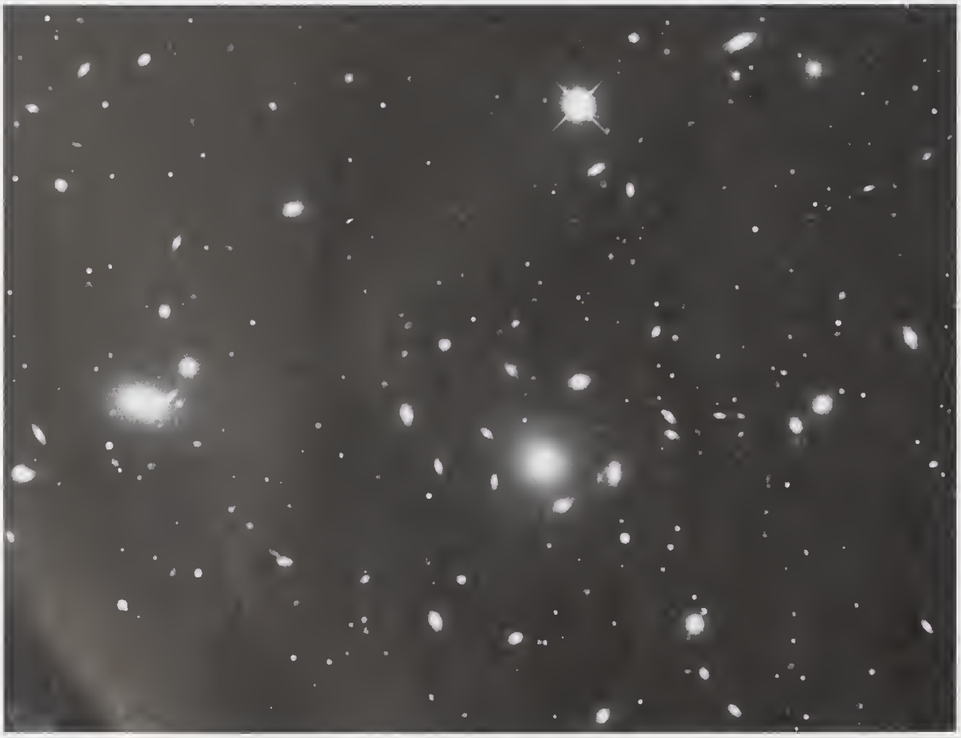

Figure 17: Coma cluster, a spherically symmetrical group of galaxies with a high concentration of ellipticals toward its centre.

One more effect that can be traced to the cluster environment is the presence of strong radio and X-ray sources, which tend to occur in or near the centres of clusters of galaxies. These will be discussed in detail in the next section.

EXTRAGALACTIC RADIO AND X-RAY SOURCES

Radio galaxies. Some of the strongest radio sources in the sky are galaxies (Table 10). Most of them have a peculiar morphology that is related to the cause of their radio radiation. Some are relatively isolated galaxies, but most galaxies that emit unusually large amounts of radio energy are found in large clusters.

The basic characteristics of radio galaxies and the variations that exist among them can be made clear with two examples. The first is Centaurus A, a giant radio structure surrounding a bright, peculiar galaxy of remarkable morphology designated NGC 5128. It exemplifies a type of radio galaxy that consists of an optical galaxy located at the centre of an immensely larger two-lobed radio source. In the particular case of Centaurus A, the extent of the radio structure is so great that it is almost 100 times the size of the central galaxy, which is itself a giant galaxy. This radio structure includes, besides the pair of far-flung radio lobes, two other sets of radio sources: one that is approximately the size of the optical galaxy and that resembles the outer structure in shape; and a second that is an intense, small source at the galaxy's nucleus (Figure 18). Optically, NGC 5128 appears as a giant elliptical galaxy with two notable characteristics: it has an unusual disk of dust and gas surrounding it and thin jets of interstellar gas and young stars radiating outward (Figure 19). The most plausible explanation currently offered for this whole array is that a series of explosive events in the nucleus of the galaxy expelled hot, ionized gas from the centre at relativistic velocities (*i.e.*, those at nearly the speed of light) in two opposite directions. These clouds of relativistic particles generate synchrotron radiation, which is detected at radio (and X-ray) wavelengths. In this model the very large structure is associated with an old event, while the inner lobes are the result of a more recent explosion. The centre is still active, as evidenced by the presence of the nuclear radio source.

Centaurus A

Virgo A

The other notable example of a radio galaxy is Virgo A, a powerful radio source that corresponds to a bright elliptical galaxy in the Virgo cluster designated as M87. In this type of radio galaxy, most of the radio radiation is emitted from an appreciably smaller area than in the case of Centaurus A. This area coincides in size with the optically visible object (Figure 20). Virgo A is not particularly unusual except for one peculiarity: it has a bright jet of gaseous material that appears to emanate from the nucleus of the galaxy, extending out approximately halfway to its faint outer parts. This gaseous jet can be detected at optical, radio, and other (*e.g.*, X-ray) wavelengths; its spectrum suggests strongly that it shines by means of the synchrotron mechanism.

About the only condition that can account for the immense amounts of energy emitted by radio galaxies is the capture of material (interstellar gas and stars) by a supermassive object at their centre. Such an object would resemble the one thought to be in the nucleus of the Milky Way Galaxy but far more massive. In short, the most probable type of supermassive object for explaining the details of strong radio sources would be a black hole. Large amounts of energy can be released when material is captured by a black hole. An extremely hot, high-density accretion disk is first formed around the supermassive object from the material, and then some of the material seems to be ejected explosively from the area, giving rise to the various radio jets and lobes observed.

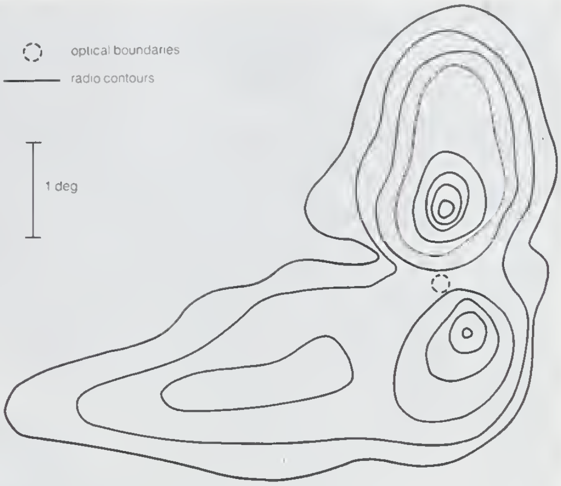

Figure 18: Continuum radio emission from the immense radio source Centaurus A (NGC 5128 is the optical galaxy at the centre of the source).

From Paul W. Hodge, *The Physics and Astronomy of Galaxies and Cosmology* (1966)

X-ray galaxies. Synchrotron radiation is characteristically emitted at virtually all wavelengths at almost the same intensity. A synchrotron source therefore ought to be detectable at optical and radio wavelengths, as well as at others (*e.g.*, infrared, ultraviolet, X-ray, and gamma-ray wavelengths). For radio galaxies this does seem to be the case, at least in circumstances where the radiation is not screened by absorbing material in the source or in intervening space.

X rays are absorbed by the Earth's atmosphere. Consequently, X-ray galaxies could not be detected until it became possible to place telescopes above the atmosphere, first with balloons and sounding rockets and later with orbiting observatories specially designed for X-ray studies. For example, the Einstein Observatory, which was in operation during the early 1980s, made a fairly complete search for X-ray sources across the sky and studied several of them in detail. Many of the sources turned out to be distant galaxies and quasars, while others were relatively nearby objects, including neutron stars (extremely dense stars composed almost exclusively of neutrons) in the Milky Way Galaxy.

A substantial number of the X-ray galaxies so far detected are also well-known radio galaxies. Some X-ray sources, such as certain radio sources, are much too large to be individual galaxies, consisting rather of a whole cluster of galaxies.

Clusters of galaxies as radio and X-ray sources. Some clusters of galaxies contain a widespread intergalactic cloud of hot gas that can be detected as a diffuse radio source or

Table 10: Some Strong Radio Sources

name	optical description	radio luminosity (ergs/sec)	radio diameter	optical diameter	distance (millions of light-years)
Virgo A (M87)	elliptical galaxy with "jet" from nucleus	5×10^{41}	10′ (and 30″ jet)	10′ (and 20″ jet)	50
Fornax A (NGC 1316)	S0 galaxy with dust lanes and outer ring	6×10^{41}	30′ (double)	15′	50
Centaurus A (NGC 5128)	peculiar spiral	8×10^{41}	10° (multiple)	20′	15
Perseus A (NGC 1275)	complex S0 galaxy	10^{42}	4′ (with 10″ core)	2′	230
Hydra A	large S0 galaxy	2×10^{43}	50″	0′5	680
Hercules A	large S0 galaxy with dust lanes and outer wisps	1.5×10^{44}	110′ (double)	0′2	2,000
Cygnus A	double galaxy	5×10^{44}	106″ (double)	2″	710
3C 48	quasi-stellar source, fluctuations in brightness	5×10^{44}	<1″	<0″5	3,600

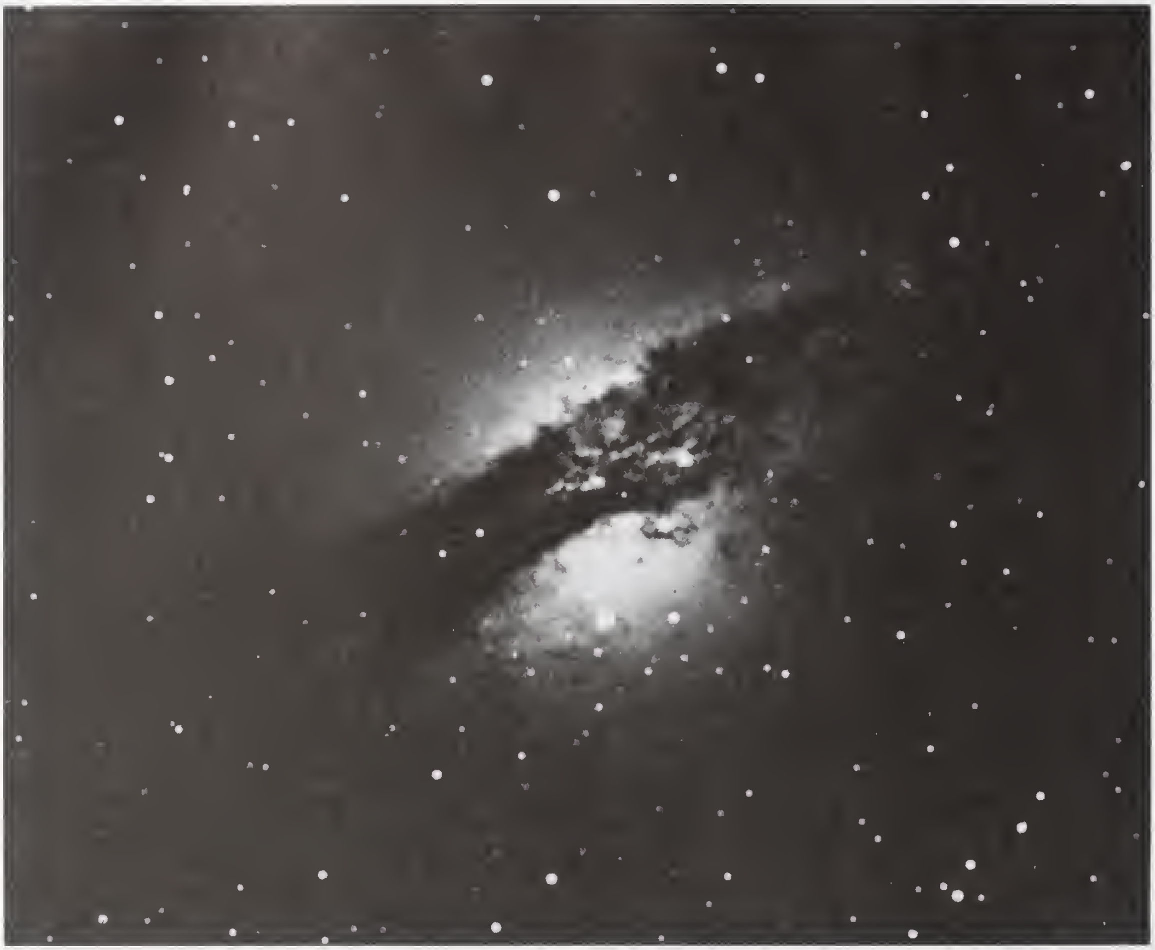

Figure 19: Centaurus A, when viewed at visible wavelengths, appears as a bright ellipse in the middle of which lies a disk-shaped absorption lane composed largely of dust and ionized atomic hydrogen.

as a large-scale source of X rays. The gaseous cloud has a low density but a very high temperature, having been heated by the passage of the galaxies of a cluster through it and by the emission of high-energy particles from active galaxies within it.

"Head–tail" galaxies

The form of certain radio galaxies in clusters points rather strongly to the presence of intergalactic gas. These are the "head–tail" galaxies, systems that have a bright source accompanied by a tail or tails that appear swept back by their interaction with the cooler, more stationary intergalactic gas. These tails are radio lobes of ejected gas whose shape has been distorted by collisions with the cluster medium.

From Paul W Hodge, *The Physics and Astronomy of Galaxies and Cosmology* (1966)

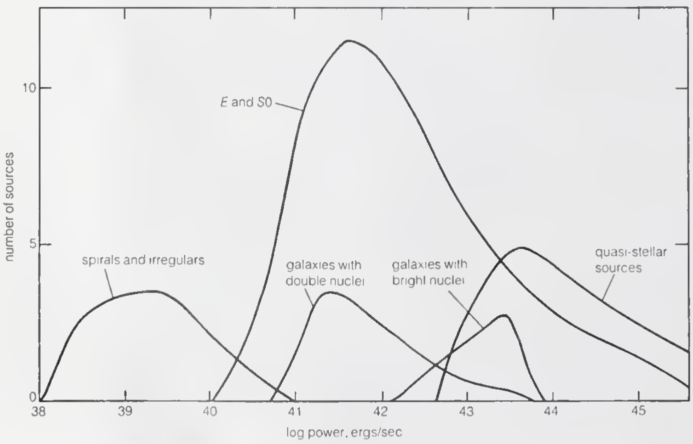

Figure 20: Distribution of radio sources according to radiated power and optical type.

Quasars. An apparently new kind of radio source was discovered in the early 1960s when radio astronomers identified a very small but powerful radio object designated 3C 48 with a stellar optical image. When they obtained the spectrum of the optical object, they found unexpected and at first unexplainable emission lines superimposed on a flat continuum. This object remained a mystery until another similar but optically brighter object, 3C 273, was examined in 1963 (Figure 21). Investigators noticed that 3C 273 had a normal spectrum with the same emission lines as observed in radio galaxies, though greatly redshifted (*i.e.,* the spectral lines are displaced to longer wavelengths), as by the Doppler effect. If the redshift were to be ascribed to velocity, however, it would imply an immense velocity of recession. In the case of 3C 48, the redshift had been so large as to shift familiar lines so far that they were not recognized. Many more such objects were found, and they came to be known as quasi-stellar radio sources, abbreviated as quasars.

Large redshifts of quasars

Although the first 20 years of quasar studies were noted more for controversy and mystery than for progress in understanding, the 1980s finally saw a solution to the questions raised by these strange objects. It is now clear that quasars are extreme examples of energetic galaxy nuclei. The amount of radiation emitted by such a nucleus overwhelms the light from the rest of the galaxy so that only very special observational techniques can reveal the galaxy's existence.

A quasar has many remarkable properties. Although it is extremely small (only the size of the solar system), it emits up to 100 times as much radiation as an entire galaxy. It is a complex mixture of very hot gas, cooler gas and dust, and particles that emit synchrotron radiation. Its brightness often varies over short periods—days or even hours. The galaxy underlying the brilliant image of a quasar is

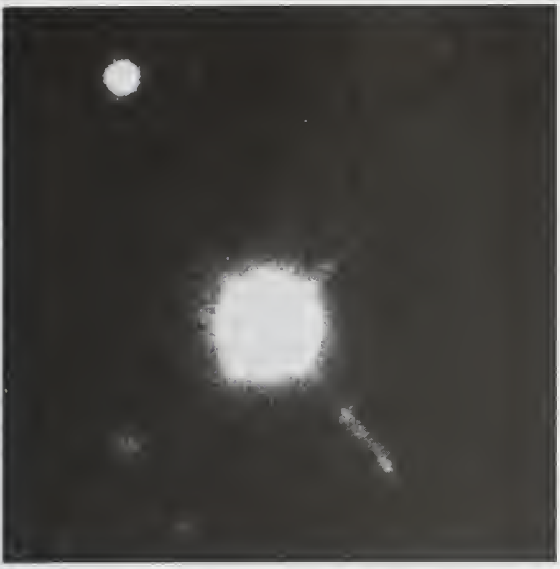

Figure 21: Quasar 3C 273, the brightest and closest of the quasi-stellar radio sources.

By courtesy of the National Optical Astronomy Observatories

probably fairly normal in its properties except for the superficial large-scale effects of the quasar at its centre. Quasars apparently are powered by the same mechanism attributed to radio galaxies. They demonstrate in an extreme way what a supermassive object at the centre of a galaxy can do.

With the gradual recognition of the causes of the quasar phenomenon has come an equally gradual realization that they are simply extreme examples of a process that can be observed in more familiar objects. The black holes that are thought to inhabit the cores of the quasar galaxies are similar to, though more explosive than, those that appear to occur in certain unusual nearer galaxies known as Seyfert Galaxies (see above *Types of galaxies: Principal schemes of classification*). The radio galaxies fall in between. The reason for the differences in the level of activity is apparently related to the source of the gas and stars that are falling into the centres of such objects, providing the black holes with fuel. In the case of quasars, evidence suggests that an encounter with another galaxy, which causes the latter to be tidally destroyed and its matter to fall into the centre of the more massive quasar galaxy, is the cause of its activity. As the material approaches the black hole, it is greatly accelerated, and some of it is expelled by the prevailing high temperatures and drastically rapid motions. This process probably also explains the impressive but lower-level activity in the nuclei of radio and Seyfert galaxies. The captured mass may be of lesser amount—*i.e.*, either a smaller galaxy or a portion of the host galaxy itself. Quasars are more common in that part of the universe observed to have high redshifts, meaning that they were more common about 10 or so billion years ago than they are now, in all probability a result of the higher density of galaxies at that time.

Evolution of galaxies and quasars

The study of the origin and evolution of galaxies and the quasar phenomenon has only just begun. Many models of galaxy formation and evolution have been constructed on the basis of assumptions about conditions in the early universe, which are in turn based on models of the expansion of the Cosmos after the "big bang"—the primordial explosion from which the Cosmos is thought to have originated. Prevailing theory has it that at crucial points in time there condensed from the expanding matter smaller clouds (protogalaxies) that could collapse under their own gravitational field and eventually form galaxies. At the time when the mass of such a stable perturbation in the cloud was approximately 10^{12} solar masses, the galaxies formed. It is still not known whether the clusters of galaxies emerged first or whether they resulted as accumulations of already formed galaxies. Following the separation of mass into individual galaxies, the next step probably depended on the characteristics of the particular clump of matter involved, especially on its mass and angular momentum. The latter quantity was the most likely determinant of the form of the galaxy that eventually evolved. It is thought that a protogalaxy with a large amount of angular momentum tended to form a flat, rapidly rotating system (a spiral galaxy), whereas one with very little angular momentum developed into a more nearly spherical system (an elliptical galaxy).

Significance of angular momentum

Calculations show that a galaxy very gradually becomes dimmer and redder as time progresses and its constituent stars evolve. There is some evidence from very distant galaxies—those whose light was emitted billions of years ago when they were younger—that the effects of this kind of slow evolution can actually be seen.

A more spectacular example of galaxy evolution is provided by quasars. From the statistics of the frequency of different redshifts, which represent different distances and different epochs in the past, it has been determined that the quasar phenomenon occurred most frequently a few billion years after the big bang (the exact amount of time is uncertain because astronomers do not as yet know enough about the geometry or the age of the universe). It appears that conditions did not become suitable for quasar formation until after the galaxies had formed and separated. Today quasars are quite rare, but many galaxies have miniature versions of them in their nuclei in the form of less massive yet remarkably energetic objects.

BIBLIOGRAPHY

The Galaxy: BART J. BOK and PRISCILLA F. BOK, *The Milky Way*, 5th ed. (1981), contains a comprehensive and up-to-date account, without mathematics, of modern galactic research. DIMITRI MIHALAS and JAMES BINNEY, *Galactic Astronomy: Structure and Kinematics*, 2nd ed. (1981), is a thorough, mathematically replete textbook on the Milky Way Galaxy and other galaxies, with emphasis on structure and dynamics. Two collections are HUGO VAN WOERDEN, RONALD J. ALLEN, and W. BUTLER BURTON (eds.), *The Milky Way Galaxy* (1985), symposium articles written at a technical level; and ADRIAAN BLAAUW and MAARTEN SCHMIDT (eds.), *Galactic Structure* (1965), a group of fundamental articles, most of which are still useful sources of basic data, methods, and approaches.

External galaxies: EDWIN HUBBLE, *The Realm of the Nebulae* (1936, reprinted 1982), is a classic account of the early history of extragalactic research written by one of the principal investigators. ALLAN SANDAGE, *The Hubble Atlas of Galaxies* (1961), discusses galaxy classification and includes marvelous full-page illustrations of different types of galaxies. Galileo

Galileo Galilei, Italian natural philosopher, astronomer, and mathematician, made fundamental contributions to the sciences of motion and astronomy and to the development of the scientific method. His formulation of circular inertia, the law of falling bodies, and parabolic trajectories marked the beginning of a fundamental change in the study of motion. His insistence that the book of nature was written in the language of mathematics changed natural philosophy from a verbal, qualitative account to a mathematical one in which experimentation became a recognized method for discovering the facts of nature. Finally, his discoveries with the telescope revolutionized astronomy and paved the way for the acceptance of the Copernican heliocentric system—though his advocacy of that system eventually resulted in an Inquisition process against him.

Galileo, oil painting by Justus Sustermans, *c.* 1637; in the Uffizi, Florence.

Early life and career. Galileo was born in Pisa, Tuscany, on February 15, 1564, the oldest son of Vincenzo Galilei, a musician who made important contributions to the theory and practice of music and who may have performed some experiments with Galileo in 1588–89 on the relationship between pitch and the tension of strings. In the early 1570s the family moved to Florence, where the Galilei family had lived for generations. In his middle teens Galileo attended the monastery school at Vallombrosa, near Florence, and then in 1581 matriculated at the University of Pisa, where he was to study medicine. However, he became enamoured of mathematics and decided to make the mathematical subjects and philosophy his profession, against the protests of his father. Galileo then began to prepare himself to teach Aristotelian philosophy and mathematics, and several of his lectures have survived. In 1585 Galileo left the university without having obtained a degree, and for several years he gave private lessons in the mathematical subjects in Florence and Siena. During this period he designed a new form of hydrostatic balance for weighing small quantities and wrote a short treatise, *La bilancetta* ("The Little Balance"), that circulated in manuscript form. He also began his studies on motion, which he pursued steadily for the next two decades.

In 1588 Galileo applied for the chair of mathematics at the University of Bologna but was unsuccessful. His reputation was, however, increasing, and later that year he was asked to deliver two lectures to the Florentine Academy, a prestigious literary group, on the arrangement of the world in Dante's *Inferno*. He also found some ingenious theorems on centres of gravity (again, circulated in manuscript) that brought him recognition among mathematicians and the patronage of Guidobaldo del Monte (1545–1607), a nobleman and author of several important works on mechanics. As a result, he obtained the chair of mathematics at the University of Pisa in 1589. There, according to his first biographer, Vincenzo Viviani (1622–1703), Galileo demonstrated, by dropping bodies of different weights from the top of the famous Leaning Tower, that the speed of fall of a heavy object is not proportional to its weight, as Aristotle had claimed. The manuscript tract *De motu* (*On Motion*), finished during this period, shows that Galileo was abandoning Aristotelian notions about motion and was instead taking an Archimedean approach to the problem. But his attacks on Aristotle made him unpopular with his colleagues, and in 1592 his contract was not renewed. His patrons, however, secured him the chair of mathematics at the University of Padua, where he taught from 1592 until 1610.

The experiments at Pisa

Although Galileo's salary was considerably higher there, his responsibilities as the head of the family (his father had died in 1591) meant that he was chronically pressed for money. His university salary could not cover all his expenses, and he therefore took in well-to-do boarding students whom he tutored privately in such subjects as fortification. He also sold a proportional compass, or sector, of his own devising, made by an artisan whom he employed in his house. Perhaps because of these financial problems, he did not marry, but he did have an arrangement with a Venetian woman, Marina Gamba, who bore him two daughters and a son. In the midst of his busy life he continued his research on motion, and by 1609 he had determined that the distance fallen by a body is proportional to the square of the elapsed time (the law of falling bodies) and that the trajectory of a projectile is a parabola, both conclusions that contradicted Aristotelian physics.

Telescopic discoveries. At this point, however, Galileo's career took a dramatic turn. In the spring of 1609 he heard that in the Netherlands an instrument had been invented that showed distant things as though they were nearby. By trial and error, he quickly figured out the secret of the invention and made his own three-powered spyglass from lenses for sale in spectacle makers' shops. Others had done

© Scala/Art Resource, New York City

Two of Galileo's first telescopes; in the Museum of Science, Florence.

the same; what set Galileo apart was that he quickly figured out how to improve the instrument, taught himself the art of lens grinding, and produced increasingly powerful telescopes. In August of that year he presented an eight-powered instrument to the Venetian Senate (Padua was in the Venetian republic). He was rewarded with life tenure and a doubling of his salary. Galileo was now one of the highest-paid professors at the university. In the fall of 1609 Galileo began observing the heavens with instruments that magnified up to 20 times. In December he drew the Moon's phases as seen through the telescope, showing that the Moon's surface is not smooth, as had been thought, but is rough and uneven. In January 1610 he discovered four moons revolving around Jupiter. He also found that the telescope showed many more stars than are visible with the naked eye. These discoveries were earthshaking, and Galileo quickly produced a little book, *Sidereus Nuncius* (*The Sidereal Messenger*), in which he described them. He dedicated the book to Cosimo II de Medici (1590–1621), the grand duke of his native Tuscany, whom he had tutored in mathematics for several summers, and he named the moons of Jupiter after the Medici family: the Sidera Medicea, or "Medicean Stars." Galileo was rewarded with an appointment as mathematician and philosopher of the grand duke of Tuscany, and in the fall of 1610 he returned in triumph to his native land.

Galileo's illustrations of the Moon, from his *Sidereus Nuncius* (1610; *The Sidereal Messenger*).

The Sun at the centre of the universe

Galileo was now a courtier and lived the life of a gentleman. Before he left Padua he had discovered the puzzling appearance of Saturn, later to be shown as caused by a ring surrounding it, and in Florence he discovered that Venus goes through phases just as the Moon does. Although these discoveries did not prove that the Earth is a planet orbiting the Sun, they undermined Aristotelian cosmology: the absolute difference between the corrupt earthly region and the perfect and unchanging heavens was proved wrong by the mountainous surface of the Moon, the moons of Jupiter showed that there had to be more than one centre of motion in the universe, and the phases of Venus showed that it (and, by implication, Mercury) revolves around the Sun. As a result, Galileo was confirmed in his belief, which he had probably held for decades but which had not been central to his studies, that the Sun is the centre of the universe and that the Earth is a planet, as Copernicus had argued. Galileo's conversion to Copernicanism would be a key turning point in the scientific revolution.

After a brief controversy about floating bodies, Galileo again turned his attention to the heavens and entered a debate with Christoph Scheiner (1573–1650), a German Jesuit and professor of mathematics at Ingolstadt, about the nature of sunspots (of which Galileo was an independent discoverer). This controversy resulted in Galileo's *Istoria e dimostrazioni intorno alle macchie solari e loro accidenti* ("History and Demonstrations Concerning Sunspots and Their Properties," or "Letters on Sunspots"), which appeared in 1613. Against Scheiner, who, in an effort to save the perfection of the Sun, argued that sunspots are satellites of the Sun, Galileo argued that the spots are on or near the Sun's surface, and he bolstered his argument with a series of detailed engravings of his observations.

Galileo's Copernicanism. Galileo's increasingly overt Copernicanism began to cause trouble for him. In 1613 he wrote a letter to his student Benedetto Castelli (1528–1643) in Pisa about the problem of squaring the Copernican theory with certain biblical passages. Inaccurate copies of this letter were sent by Galileo's enemies to the Inquisition in Rome, and he had to retrieve the letter and send an accurate copy. Several Dominican fathers in Florence lodged complaints against Galileo in Rome, and Galileo went to Rome to defend the Copernican cause and his good name. Before leaving, he finished an expanded version of the letter to Castelli, now addressed to the grand duke's mother and good friend of Galileo, the dowager Christina. In his *Letter to the Grand Duchess Christina*, Galileo discussed the problem of interpreting biblical passages with regard to scientific discoveries but, except for one example, did not actually interpret the Bible. That task had been reserved for approved theologians in the wake of the Council of Trent (1545–63) and the beginning of the Catholic Counter-Reformation. But the tide in Rome was turning against the Copernican theory, and in 1615, when the cleric Paolo Antonio Foscarini (*c.* 1565–1616) published a book arguing that the Copernican theory did not conflict with scripture, Inquisition consultants examined the question and pronounced the Copernican theory heretical. Foscarini's book was banned, as were some more technical and nontheological works, such as Johannes Kepler's *Epitome of Copernican Astronomy*. Copernicus's own 1543 book, *De revolutionibus orbium coelestium libri vi* ("Six Books Concerning the Revolutions of the Heavenly Orbs"), was suspended until corrected. Galileo was not mentioned directly in the decree, but he was admonished by Robert Cardinal Bellarmine (1542–1621) not to "hold or defend" the Copernican theory. An improperly prepared document placed in the Inquisition files at this time states that Galileo was admonished "not to hold, teach, or defend" the Copernican theory "in any way whatever, either orally or in writing."

Galileo was thus effectively muzzled on the Copernican issue. Only slowly did he recover from this setback. Through a student, he entered a controversy about the nature of comets occasioned by the appearance of three comets in 1618. After several exchanges, mainly with Orazio Grassi (1583–1654), a professor of mathematics at the Collegio Romano, he finally entered the argument under his own name. *Il saggiatore* (*The Assayer*), published in 1623, was a brilliant polemic on physical reality and an exposition of the new scientific method. Galileo here discussed the method of the newly emerging science, arguing:

The language of nature is mathematics

> Philosophy is written in this grand book, the universe, which stands continually open to our gaze. But the book cannot be understood unless one first learns to comprehend the language and read the letters in which it is composed. It is written in the language of mathematics, and its characters are triangles, circles, and other geometric figures without which it is humanly impossible to understand a single word of it.

He also drew a distinction between the properties of external objects and the sensations they cause in us—*i.e.*, the distinction between primary and secondary qualities. Publication of *Il saggiatore* came at an auspicious moment, for Maffeo Cardinal Barberini (1568–1644), a friend, admirer, and patron of Galileo for a decade, was named Pope Urban VIII as the book was going to press. Galileo's friends quickly arranged to have it dedicated to the new pope. In 1624 Galileo went to Rome and had six interviews with Urban VIII. Galileo told the pope about his theory of the tides (developed earlier), which he put forward as proof of the annual and diurnal motions of the Earth. The pope gave Galileo permission to write a book about theories of the universe but warned him to treat the Copernican theory only hypothetically. The book, *Dialogo sopra i due massimi sistemi del mondo, tolemaico e copernicano* (*Dialogue Concerning the Two Chief World Systems, Ptolemaic & Copernican*), was finished in 1630, and Galileo sent it to the Roman censor. Because of an outbreak of the plague, communications between Florence and Rome were interrupted, and Galileo asked for the censoring to be done instead in Florence. The Roman censor had a number of serious criticisms of the book and forwarded these to his colleagues in Florence. After writing a preface in which he professed that what followed was written hypothetically, Galileo had little trouble getting the book through the Florentine censors, and it appeared in Florence in 1632.

Galileo before the Inquisition. In the *Dialogue*'s witty conversation between Salviati (representing Galileo), Sagredo (the intelligent layman), and Simplicio (the dyed-in-the-wool Aristotelian), Galileo gathered together all the arguments (mostly based on his own telescopic discoveries) for the Copernican theory and against the traditional geocentric cosmology. As opposed to Aristotle's, Galileo's approach to cosmology is fundamentally spatial and geometric: the Earth's axis retains its orientation in space as the Earth circles the Sun, and bodies not under a force retain their velocity (although this inertia is ultimately circular). But in giving Simplicio the final word, that God could have made the universe any way he wanted to and still made it appear to us the way it does, he put Pope Urban VIII's favourite argument in the mouth of the person who had been ridiculed throughout the dialogue. The reaction against the book was swift. The pope convened a special commission to examine the book and make recommendations; the commission found that Galileo had not really treated the Copernican theory hypothetically and recommended that a case be brought against him by the Inquisition. Galileo was summoned to Rome in 1633. During his first appearance before the Inquisition, he was confronted with the 1616 edict recording that he was forbidden to discuss the Copernican theory. In his defense Galileo produced a letter from Cardinal Bellarmine, by then dead, stating that he was admonished only not to hold or defend the theory. The case was at somewhat of an impasse, and, in what can only be called a plea bargain, Galileo confessed to having overstated his case. He was pronounced to be vehemently suspect of heresy and was condemned to life imprisonment and was made to abjure formally. There is no evidence that at this time he whispered, "Eppur si muove" ("And yet it moves"). It should be noted that Galileo was never in a dungeon or tortured; during the Inquisition process he stayed mostly at the house of the Tuscan ambassador to the Vatican and for a short time in a comfortable apartment in the Inquisition building. After the process he spent six months at the palace of Ascanio Piccolomini (*c.* 1590–1671), the archbishop of Siena and a friend and patron, and then moved into a villa near Arcetri, in the hills above Florence. He spent the rest of his life there. Galileo's daughter Sister Maria Celeste, who was in a nearby nunnery, was a great comfort to her father until her untimely death in 1634.

Under house arrest

Galileo was then 70 years old. Yet he kept working. In Siena he had begun a new book on the sciences of motion and strength of materials. There he wrote up his unpublished studies that had been interrupted by his interest in the telescope in 1609 and pursued intermittently since. The book was spirited out of Italy and published in Leiden, Netherlands, in 1638 under the title *Discorsi e dimostrazioni matematiche intorno a due nuove scienze attenenti alla meccanica* (*Dialogues Concerning Two New Sciences*). Galileo here treated for the first time the bending and breaking of beams and summarized his mathematical and experimental investigations of motion, including the law of falling bodies and the parabolic path of projectiles as a result of the mixing of two motions, constant speed and uniform acceleration. By then Galileo had become blind, and he spent his time working with a young student, Vincenzo Viviani, who was with him when he died at Arcetri on January 8, 1642.

BIBLIOGRAPHY. The standard edition of Galileo's works is *Le opere di Galileo Galilei*, 20 vol. in 21, ed. by ANTONIO FAVARO (1890–1909, reissued 1968). There are now several English translations of *Sidereus Nuncius* (1610): *The Sidereal Messenger of Galileo Galilei and a Part of the Preface to Kepler's Dioptrics Containing the Original Account of Galileo's Astronomical Discoveries*, trans. by EDWARD STAFFORD CARLOS (1880, reprinted 1959); *Sidereus Nuncius; or, The Sidereal Messenger*, trans. by ALBERT VAN HELDEN (1989); and STILLMAN DRAKE, *Telescopes, Tides, and Tactics: A Galilean Dialogue About the Starry Messenger and Systems of the World* (1983), which contains a complete translation interspersed in the dialogue. *Discorso…intorno alle cose, che stanno iǹ sù l'acqua, ò che in quella si muovono* (1612) appears in English as *Discourse on Bodies in Water*, trans. by THOMAS SALUSBURY and ed. by STILLMAN DRAKE (1960); and is interspersed in a dialogue in STILLMAN DRAKE, *Cause, Experiment, and Science: A Galilean Dialogue, Incorporating a New English Translation of Galileo's Bodies That Stay Atop Water, or Move in It* (1981). Galileo's letter to the grand duchess Christina on the relationship of science to religion, written in 1615, was published in Latin in Strasbourg in 1636 without Galileo's permission; English translations are "Letter to Madame Christina…," in *Discoveries and Opinions of Galileo*, trans. by STILLMAN DRAKE (1957, reissued 1990), pp. 175–216, which also includes abridged translations of *Sidereus Nuncius*, the letters on sunspots (*Istoria e dimostrazioni intorno alle macchie solari e loro accidenti*, 1613), and *Il saggiatore;* and "Galileo's Letter to the Grand Duchess Christina (1615)," in MAURICE A. FINOCCHIARO (ed. and trans.), *The Galileo Affair: A Documentary History* (1989), pp. 87–118, which also includes the translated documents of Galileo's trial. The standard translation of *Dialogo sopra i due massimi sistemi del mondo tolemaico, e copernicano* (1632) is *Dialogue Concerning the Two Chief World Systems, Ptolemaic & Copernican*, trans. by STILLMAN DRAKE, 2nd ed. (1967). Galileo's *Discorsi e dimostrazioni matematiche, intorno à due nuove scienze . . .* (1638) appears as *Dialogues Concerning Two New Sciences*, trans. by HENRY CREW and ALFONSO DE SALVIO (1914, reissued 1968); and *Two New Sciences*, trans. by STILLMAN DRAKE, rev. ed. (1989). The correspondence between Galileo and one of his daughters is available in MARY ALLAN-OLNEY (compiler), *The Private Life of Galileo: Compiled Principally from his Correspondence and That of His Eldest Daughter, Sister Maria Celeste* (1870).

Several biographies of Galileo have been written by STILLMAN DRAKE: *Galileo at Work: His Scientific Biography* (1978, reissued 1995), *Galileo: Pioneer Scientist* (1990), and *Galileo* (1980). JAMES RESTON, JR., *Galileo* (1994), is a well-documented popular biography. Portraits and other depictions of Galileo can be found in J.J. FAHIE, *Memorials of Galileo Galilei, 1564–1642* (1929).

Studies of various aspects of Galileo's life and career include MAURICE A. FINOCCHIARO, *Galileo and the Art of Reasoning: Rhetorical Foundations of Logic and Scientific Method* (1980); SILVIO A. BEDINI, *The Pulse of Time: Galileo Galilei, the Determination of Longitude, and the Pendulum Clock* (1991); MICHAEL SEGRE, *In the Wake of Galileo* (1991); VICTOR COELHO (ed.), *Music and Science in the Age of Galileo* (1992); JOSEPH C. PITT, *Galileo, Human Knowledge, and the Book of Nature: Method Replaces Metaphysics* (1992); MARIO BIAGIOLI, *Galileo, Courtier: The Practice of Science in the Culture of Absolutism* (1993); JEAN DIETZ MOSS, *Novelties in the Heavens: Rhetoric and Science in the Copernican Controversy* (1993); and Cesare S. Maffioli, *Out of Galileo: The Science of Waters, 1628–1718* (1994).

Works specifically treating Galileo and the Roman Catholic church include KARL VON GEBLER, *Galileo Galilei and the Roman Curia* (1879, reprinted 1977; originally published in German, 2 vol., 1876–77); GIORGIO DE SANTILLANA, *The Crime of Galileo* (1955, reprinted 1981); JEROME J. LANGFORD, *Galileo, Science, and the Church*, 3rd ed. (1992); PIETRO REDONDI, *Galileo Heretic* (1987; originally published in Italian, 1983); RICHARD S. WESTFALL, *Essays on the Trial of Galileo* (1989); RICHARD J. BLACKWELL, *Galileo, Bellarmine, and the Bible* (1991); RIVKA FELDHAY, *Galileo and the Church: Political Inquisition or Critical Dialogue?* (1995); and ANNIBALE FANTOLI, *Galileo: For Copernicanism and for the Church*, 2nd ed., rev. and corrected (1996; originally published in Italian, 1993).

(A.V.H.)

Game Theory

Game theory is a branch of applied mathematics that provides tools for analyzing situations in which parties, called players, make decisions that are interdependent. This interdependence causes each player to consider the other player's possible decisions, or strategies, in formulating his own strategy. A solution to a game describes the optimal decisions of the players, who may have similar, opposed, or mixed interests, and the outcomes that may result from these decisions.

Although game theory can be and has been used to analyze parlour games, its applications are much broader. In fact, game theory was originally developed by the Hungarian-born American mathematician John von Neumann and his Princeton University colleague Oskar Morgenstern, a German-born American economist, to solve problems in economics. In their book *Theory of Games and Economic Behavior* (1944), von Neumann and Morgenstern asserted that the mathematics developed for the physical sciences, which describes the workings of a disinterested nature, was a poor model for economics. They observed that economics is much like a game, wherein players anticipate each other's moves, and therefore requires a new kind of mathematics, which they called game theory.

Game theory has been applied to a wide variety of situations in which the choices of players interact to affect the outcome. In stressing the strategic aspects of decision making, the theory both supplements and goes beyond the classical theory of probability. It has been used, for example, to determine what political coalitions or business conglomerates are likely to form, the optimal price at which to sell products or services in the face of competition, the best site for a manufacturing plant, and the behaviour of certain life-forms in their struggle for survival. It has even been used to challenge the legality of certain voting systems.

It would be surprising if any one theory could address such an enormous range of "games," and in fact there is no single game theory. A number of theories have been proposed, each applicable to different situations and each with its own concepts of what constitutes a solution. This article describes some simple games, discusses different theories, and outlines principles underlying game theory.

The article is divided into the following sections:

CLASSIFICATION OF GAMES

Games can be classified according to certain significant features, the most obvious of which is the number of players. Thus, a game can be designated as being a one-person, two-person, or *n*-person (with *n* greater than two) game, with games in each category having their own distinctive features. In addition, a player need not be an individual; it may be a nation, a corporation, or a team comprising many people with shared interests.

In games of perfect information, such as chess, each player knows everything about the game at all times. Poker, on the other hand, is a game of imperfect information because players do not know all of their opponents' cards.

Constant-sum games

The extent to which the goals of the players coincide or conflict is another basis for classifying games. Constant-sum games are games of total conflict, which are also called games of pure competition. Poker, for example, is a constant-sum game because the combined wealth of the players remains constant.

Players in constant-sum games have completely opposed interests, whereas in variable-sum games they may all be winners or losers. In a labour-management dispute, for example, the two parties certainly have some conflicting interests, but both will benefit if a strike is averted.

Variable-sum games

Variable-sum games can be further distinguished as being either cooperative or noncooperative. In cooperative games players can communicate and make binding agreements; in noncooperative games players may communicate, but they cannot make binding agreements, such as an enforceable contract. An automobile salesperson and a potential customer will be engaged in a cooperative game if they agree on a price and sign a contract. However, the dickering that they do to reach this point will be noncooperative. Similarly, when people bid independently at an auction they are playing a noncooperative game, even though the high bidder agrees to complete the purchase.

Finally, a game is said to be finite when each player has a finite number of options, the number of players is finite, and the game cannot go on indefinitely. Chess, checkers, poker, and most parlour games are finite. Infinite games are more subtle and will only be touched upon in this article.

A game can be described in extensive, normal, or characteristic-function form. Most parlour games, which progress one move at a time, can be modeled as games in extensive form. Extensive-form games can be described by a "game tree," in which each turn is a vertex of the tree, with each branch indicating the players' successive choices.

The normal (strategic) form is primarily used to describe two-person games. In this form a game is represented by a payoff matrix, wherein each row describes the strategy of one player and each column describes the strategy of the other player. The matrix entry at the intersection of each row and column gives the outcome of each player choosing the corresponding strategy. The payoffs to each player associated with this outcome are the basis for determining whether the strategies are "in equilibrium," or stable.

The characteristic-function form is generally used to analyze games with more than two players. It indicates the minimum value that each coalition of players—including single-player coalitions—can guarantee for itself when playing against a coalition made up of all the other players.

ONE-PERSON GAMES

With no opponents, the player only needs to list available options and then choose the optimal outcome in one-person games. When chance is involved the game might seem to be more complicated, but in principle the decision is still relatively simple. For example, a person deciding whether to carry an umbrella weighs the costs and benefits of carrying or not carrying it. While this person may make the wrong decision, there does not exist a conscious opponent. That is, nature is presumed to be completely indifferent to the player's decision, and the person can base his decision on simple probabilities. One-person games hold little interest for game theorists.

TWO-PERSON CONSTANT-SUM GAMES

Strictly determined

Games of perfect information. The simplest game of any real theoretical interest is a two-person constant-sum game of perfect information. Examples of such games include chess, checkers, and the Japanese game of go. In 1912 the German mathematician Ernst Zermelo proved that such games are strictly determined; by making use of all available information, the players can deduce strategies that are optimal, which makes the outcome preordained. In chess, for example, exactly one of three outcomes must occur if the players make optimal choices: (1) White wins (has a strategy that wins against any strategy of Black); (2) Black wins; or (3) White and Black draw. In principle, a sufficiently powerful computer could determine which of the three outcomes will occur. However, considering that there are some 10^{43} distinct 40-move games of chess possible, there seems no possibility that such a computer will be developed in the foreseeable future.

Games of imperfect information. A "saddlepoint" in a two-person constant-sum game is the outcome that rational players would choose. (Its name derives from its being the minimum of a row that is also the maximum of a column in a payoff matrix—to be illustrated shortly—which corresponds to the shape of a saddle.) A saddlepoint always exists in games of perfect information but may not exist in games of imperfect information. By choosing a strategy associated with this outcome, each player obtains an amount at least equal to his payoff at that outcome, no matter what the other player does. This payoff is called the value of the game; as in perfect-information games, it is preordained by the players' choices of strategies associated with the saddlepoint, making such games strictly determined.

Value of the game

The normal-form game in Table 1 is used to illustrate the calculation of a saddlepoint. Two political parties, A and B, must each decide how to handle a controversial issue in a certain election. Each party can either support the issue, oppose it, or evade it by being ambiguous. The decisions by A and B on this issue determine the percentage of the vote that each party receives. The entries in the payoff matrix represent party A's percentage of the vote (the remaining percentage goes to B). When, for example, A supports the issue and B evades it, A gets 80 percent and B 20 percent of the vote.

Assume that each party wants to maximize its vote. A's decision seems difficult at first because it depends on B's choice of strategy. A does best to support if B evades, oppose if B supports, and evade if B opposes. A must therefore consider B's decision before making its own. Note that no matter what A does, B obtains the largest percentage of the vote (smallest percentage for A) by opposing the issue rather than supporting it or evading it. Once A recognizes this, its strategy obviously should be to evade, settling for 30 percent of the vote. Thus, a 30 to 70 percent division of the vote, to A and B respectively, is the game's saddlepoint.

Maximin and minimax value

A more systematic way of finding a saddlepoint is to determine the so-called maximin and minimax values. A first determines the minimum percentage of votes it can obtain for each of its strategies; it then finds the maximum of these three minimum values, giving the maximin. The minimum percentages A will get if it supports, opposes, or evades are, respectively, 20, 25, and 30. The largest of these, 30, is the maximin value. Similarly, for each strategy B chooses, it determines the maximum percentage of votes A will win (and thus the minimum that it can win). In this case, if B supports, opposes, or evades, the maximum A will get is 80, 30, and 80, respectively. B will obtain its largest percentage by minimizing A's maximum percent of the vote, giving the minimax. The smallest of A's maximum values is 30, so 30 is B's minimax value. Because both the minimax and the maximin values coincide, 30 is a saddlepoint. The two parties might as well announce their strategies in advance, because the other party cannot gain from this knowledge.

Payoff matrix with saddlepoint

		party B		
		support	oppose	evade
party A	support	A 60% B 40%	A 20% B 80%	A 80% B 20%
	oppose	A 80% B 20%	A 25% B 75%	A 75% B 25%
	evade	A 35% B 65%	A 30% B 70% saddlepoint	A 40% B 60%

Table 1.

Mixed strategies and the minimax theorem. When saddlepoints exist, the optimal strategies and outcomes can be easily determined. However, when there is no saddlepoint the calculation is more elaborate, as illustrated in Table 2.

Payoff matrix without saddlepoint

		guard	
		protect $S1$	protect $S2$
safecracker	rob $S1$	$0 stolen	$10,000 stolen
	rob $S2$	$100,000 stolen	$0 stolen

Table 2.

A guard is hired to protect two safes in separate locations: $S1$ contains \$10,000 and $S2$ contains \$100,000. The guard can protect only one safe at a time. A safecracker and the guard must decide in advance, without knowing what the other party will do, which safe to try to rob and which safe to protect. When they go to the same safe, the safecracker gets nothing; when they go to different safes, the safecracker gets the contents of the unprotected safe.

In such a game, game theory does not indicate that any one particular strategy is best. Instead, it prescribes that a strategy be chosen in accordance with a probability distribution, which in this simple example is quite easy to calculate. In larger and more complex games, finding this strategy involves solving a problem in linear programming, which can be considerably more difficult.

To calculate the appropriate probability distribution in this example, each player adopts a strategy that makes him indifferent to what his opponent does. Assume that the guard protects $S1$ with probability p and $S2$ with probability $1 - p$. Thus, if the safecracker tries $S1$, he will be successful whenever the guard protects $S2$. In other words, he will get \$10,000 with probability $1 - p$ and \$0 with probability p for an average gain of $\$10,000(1 - p)$. Similarly, if the safecracker tries $S2$, he will get \$100,000 with probability p and \$0 with probability $1 - p$ for an average gain of $\$100,000p$.

The guard will be indifferent to which safe the safecracker chooses if the average amount stolen is the same in both cases—that is, if $\$10,000(1 - p) = \$100,000p$. Solving for p gives $p = 1/11$. If the guard protects $S1$ with probability $1/11$ and $S2$ with probability $10/11$, he will lose, on average, no more than about \$9,091 whatever the safecracker does.

Using the same kind of argument, it can be shown that the safecracker will get an average of at least \$9,091 if he tries to steal from $S1$ with probability $10/11$ and from $S2$ with probability $1/11$. This solution in terms of mixed strategies, which are assumed to be chosen at random with the indicated probabilities, is analogous to the solution of the game with a saddlepoint (in which a pure, or single best, strategy exists for each player).

Transparent strategies

The safecracker and the guard give away nothing if they announce the probabilities with which they will randomly choose their respective strategies. On the other hand, if they make themselves predictable by exhibiting any kind of pattern in their choices, this information can be exploited by the other player.

The minimax theorem, which von Neumann proved in 1928, states that every finite, two-person constant-sum game has a solution in pure or mixed strategies. Specifically, it says that for every such game between players A and B, there is a value v and strategies for A and B such that, if A adopts its optimal (maximin) strategy, the outcome will be at least as favourable to A as v; if B adopts its optimal (minimax) strategy, the outcome will be no more favourable to A than v. Thus, A and B have both the incentive and the ability to enforce an outcome that gives an (expected) payoff of v.

Utility theory. In the previous example it was tacitly assumed that the players were maximizing their average profits, but in practice players may consider other factors. For example, few people would risk a sure gain of $1,000,000 for an even chance of winning either $3,000,000 or $0, even though the expected (average) gain from this bet is $1,500,000. In fact, many decisions that people make, such as buying insurance policies, playing lotteries, and gambling at a casino, indicate that they are not maximizing their average profits. Game theory does not attempt to state what a player's goal should be; instead, it shows how a player can best achieve his goal, whatever that goal is.

Rational axioms

Von Neumann and Morgenstern understood this distinction; to accommodate all players, whatever their goals, they constructed a theory of utility. They began by listing certain axioms that they thought all rational decision makers would follow (for example, if a person likes tea better than coffee, and coffee better than milk, then that person should like tea better than milk). They then proved that it was possible to define a utility function for such decision makers that would reflect their preferences. In essence, a utility function assigns a number to each player's alternatives to convey their relative attractiveness. Maximizing someone's expected utility automatically determines a player's most preferred option. In recent years, however, some doubt has been raised about whether people actually behave in accordance with these axioms, and alternative axioms have been proposed.

TWO-PERSON VARIABLE-SUM GAMES

Much of the early work in game theory was on two-person constant-sum games because they are the easiest to treat mathematically. The players in such games have diametrically opposed interests, and there is a consensus about what constitutes a solution (as given by the minimax theorem). Most games that arise in practice, however, are variable-sum games; the players have both common and opposed interests. For example, a buyer and a seller are engaged in a variable-sum game (the buyer wants a low price and the seller a high one, but both want to make a deal), as are two hostile nations (they may disagree about numerous issues, but both gain if they avoid going to war).

Some "obvious" properties of two-person constant-sum games are not valid in variable-sum games. In constant-sum games both players cannot gain (they may or may not lose, but they cannot both gain) if they are deprived of some of their strategies. In variable-sum games, however, players may gain if some of their strategies are no longer available. This might not seem possible at first. One would think that if a player benefited from not using certain strategies, the player would simply avoid those strategies and choose more advantageous ones, but this is not always the case. For example, in a region with high unemployment a worker may be willing to accept a lower salary to obtain or keep a job, but if a minimum wage law makes that option illegal, the worker may be "forced" to accept a higher salary.

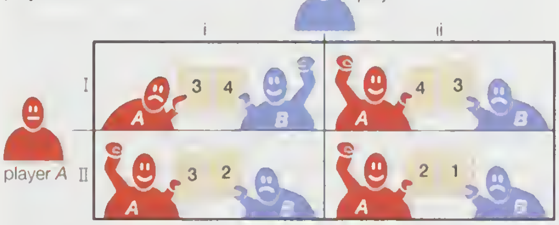
Effect of open communications

The effect of communication is particularly revealing of the difference between constant-sum and variable-sum games. In constant-sum games it never helps a player to give an adversary information, and it never hurts a player to learn an opponent's optimal strategy (pure or mixed) in advance. However, these properties do not necessarily hold in variable-sum games. Indeed, a player may want an opponent to be well-informed. In a labour-management dispute, for example, if the labour union is prepared to strike, it behooves the union to inform management and thereby possibly achieve its goal without a strike. In this example, management is not harmed by the advance information (it, too, benefits by avoiding a costly strike). In other variable-sum games, knowing an opponent's strategy can sometimes be disadvantageous. For example, a blackmailer can only benefit if he first informs his victim that he will harm him—generally by disclosing some sensitive and secret details of the victim's life—if his terms are not met. For such a threat to be credible, the victim must fear the disclosure and believe that the blackmailer is capable of executing the threat. (The credibility of threats is a question that game theory studies.) Although a blackmailer may be able to harm a victim without any communication taking place, a blackmailer cannot extort a victim unless he first adequately informs the victim of his intent and its consequences. Thus, the victim's knowledge of the blackmailer's strategy, including his ability and will to carry out the threat, works to the blackmailer's advantage.

Cooperative versus noncooperative games. Communication is pointless in constant-sum games because there is no possibility of mutual gain from cooperating. In variable-sum games, on the other hand, the ability to communicate, the degree of communication, and even the order in which players communicate can have a profound influence on the outcome.

In the variable-sum game shown in Table 3, each matrix entry consists of two numbers. (Because the combined wealth of the players is not constant, it is impossible to deduce one player's payoff from the payoff of the other; consequently, both players' payoffs must be given.) The first number in each entry is the payoff to the row player (player A), and the second number is the payoff to the column player (player B).

Variable-sum payoff matrix



player B
player A
A
B

player A \ player B	i	ii
I	3 4	4 3
II	3 2	2 1

Table 3.

In this example it will be to player B's advantage if the game is cooperative and to player A's advantage if the game is noncooperative. Without communication, assume each player applies the "sure-thing" principle: it maximizes its minimum payoff by determining the minimum it will receive whatever its opponent does. Thereby, A determines that it will do best to choose strategy I no matter what B does: if B chooses i, A will get 3 regardless of what A does; if B chooses ii, A will get 4 rather than 3. B similarly determines that it will do best to choose i no matter what A does. Selecting these two strategies, A will get 3 and B will get 4 at (3, 4).

Credible threats

In a cooperative game, however, A can threaten to play II unless B agrees to play ii. If B agrees, its payoff will be reduced to 3 while A's payoff will rise to 4 at (4, 3); if B does not agree and A carries out its threat, A will neither gain nor lose at (3, 2) compared to (3, 4), but B will get a payoff of only 2. Clearly, A will be unaffected if B does not agree and thus has a credible threat; B will be affected and obviously will do better at (4, 3) than at (3, 2) and should comply with the threat.

Sometimes both players can gain from the ability to communicate. Two pilots trying to avoid a midair collision clearly will benefit if they can communicate, and the degree of communication allowed between them may even determine whether or not they will crash. Generally, the more two players' interests coincide, the more important and advantageous communication becomes.

The solution to a cooperative game in which players have a common goal involves coordinating the players' decisions effectively. This is relatively straightforward, as is finding the solution to constant-sum games with a saddle-point. For games in which the players have both common and conflicting interests—in other words, in most variable-sum games, whether cooperative or noncooperative—what constitutes a solution is much harder to define and make persuasive.

The Nash solution. Sometimes solutions to variable-sum games seem inequitable or are not enforceable. One well-known cooperative solution to two-person variable-sum games was proposed by the American mathematician John F. Nash, who received the Nobel Prize for Economics in 1994 for this and related work he did in game theory.

Pareto-optimality

Given a game with a set of possible outcomes and associated utilities for each player, Nash showed that there is a unique outcome that satisfies four conditions: (1) The outcome is independent of the choice of a utility function (that is, if a player prefers x to y, the solution will not change if one function assigns x a utility of 10 and y a utility of 1 or a second function assigns the values of 20 and 2). (2) Both players cannot do better simultaneously (a condition known as Pareto-optimality). (3) The outcome is independent of irrelevant alternatives (in other words, if unattractive options are added to or dropped from the list of alternatives, the solution will not change). (4) The outcome is symmetrical (that is, if the players reverse their roles, the solution will remain the same, except that the payoffs will be reversed).

In some cases the Nash solution seems inequitable because it is based on a balance of threats—the possibility that no agreement will be reached, so that both players will suffer losses—rather than a "fair" outcome. When, for example, a rich person and a poor person are to receive $10,000 provided they can agree on how to divide the money (if they fail to agree, they receive nothing), most people assume that the fair solution would be for each person to get half, or even that the poor person should get more than half. According to the Nash solution, however, there is a utility for each player associated with all possible outcomes. Moreover, the specific choice of utility functions should not affect the solution (condition 1) as long as they reflect each person's preferences. In this example, assume that the rich person's utility is equal to one-half the money received and that the poor person's utility is equal to the money received. These different functions reflect the fact that additional income is more precious to the poor person. Under the Nash solution, the threat of reaching no agreement induces the poor person to accept one-third of the $10,000, giving the rich person two-thirds. In general, the Nash solution finds an outcome such that each player gains the same amount of utility.

The Prisoners' Dilemma. To illustrate the kinds of difficulties that arise in two-person noncooperative variable-sum games, consider the celebrated Prisoners' Dilemma (PD), originally formulated by the American mathematician Albert W. Tucker. Two prisoners, A and B, suspected of committing a robbery together, are isolated and urged to confess. Each is concerned only with getting the shortest possible prison sentence for himself; each must decide whether to confess without knowing his partner's decision. Both prisoners, however, know the consequences of their decisions: (1) if both confess, both go to jail for five years; (2) if neither confesses, both go to jail for one year (for carrying concealed weapons); and (3) if one confesses while the other does not, the confessor goes free (for turning state's evidence) and the silent one goes to jail for 20 years. The normal form of this game is shown in Table 4.

Code of silence

Superficially, the analysis of PD is very simple. Although A cannot be sure what B will do, he knows that he does best to confess when B confesses (he gets five years rather than 20) and also when B remains silent (he serves no time rather than a year); analogously, B will reach the same conclusion. So the solution would seem to be that each prisoner does best to confess and go to jail for five years. Paradoxically, however, the two robbers would do better if they both adopted the apparently irrational strategy of remaining silent; each would then serve only one year in jail. The irony of PD is that when each of two (or more) parties acts selfishly and does not cooperate with the other (that is, when he confesses), they do worse than when they act unselfishly and cooperate together (remain silent).

PD is not just an intriguing hypothetical problem; similar real-life situations have often been observed. For example, two shopkeepers engaged in a price war may well be caught up in a PD. Each shopkeeper knows that if he has lower prices than his rival, he will attract his rival's customers and thereby increase his own profits. Each therefore decides to lower his prices, with the result that neither gains any customers and both earn smaller profits. Similarly, nations competing in an arms race and farmers increasing crop production can also be seen as manifestations of PD. When two nations keep buying more weapons in an attempt to achieve military superiority, neither gains an advantage and both are poorer than when they started. A single farmer can increase his profits by increasing production, but when all farmers increase their output a market glut ensues, with lower profits for all.

It might seem that the paradox inherent in PD could be resolved if the game were played repeatedly. Players would learn that they do best when both act unselfishly and cooperate. Indeed, if one player failed to cooperate in one game, the other player could retaliate by not cooperating in the next game, and both would lose until they began to "see the light" and cooperated again. When the game is repeated a fixed number of times, however, this argument fails. To see this, suppose two shopkeepers set up their booths at a 10-day county fair. Furthermore, suppose that each maintains full prices, knowing that if he does not, his competitor will retaliate the next day. On the last day, however, each shopkeeper realizes that his competitor can no longer retaliate and so there is little reason not to lower their prices. But if each shopkeeper knows that his rival will lower his prices on the last day, he has no incentive to maintain full prices on the ninth day. Continuing this reasoning, one concludes that rational shopkeepers will have a price war every day. It is only when the game is played repeatedly, and neither player knows when the sequence will end, that the cooperative strategy can succeed.

"Nice" strategies

In 1980 the American political scientist Robert Axelrod engaged a number of game theorists in a round-robin tournament. In each match the strategies of two theorists, incorporated in computer programs, competed against one another in a sequence of PDs with no definite end. A "nice" strategy was defined as one in which a player always cooperates with a cooperative opponent. Also, if a player's opponent did not cooperate during one turn, most strategies prescribed noncooperation on the next turn, but a player with a "forgiving" strategy reverted rapidly to cooperation once its opponent started cooperating again. In this experiment it turned out that every nice strategy outperformed every strategy that was not nice. Furthermore, of the nice strategies, the forgiving ones performed best.

		prisoner B	
		confess	remain silent
prisoner A	confess	5 years 5 years	0 year 20 years
	remain silent	20 years 0 year	1 year 1 year

Table 4.

Theory of moves. Another approach to inducing cooperation in variable-sum games is the theory of moves (TOM). Proposed by the American political scientist Steven J. Brams, TOM allows players, starting at any outcome in a payoff matrix, to move and countermove within the matrix, thereby capturing the changing strategic nature of games as they evolve over time. In particular, TOM assumes that players think ahead about the consequences of all of the participants' moves and countermoves when formulating plans. Thereby, TOM embeds extensive-form calculations within the normal form, deriving advantages of both forms: the nonmyopic thinking of the extensive form disciplined by the economy of the normal form.

To illustrate the nonmyopic perspective of TOM, consider what happens in PD as a function of where play starts:

When play starts noncooperatively, players are stuck, no matter how far ahead they look, because as soon as one player departs, the other player, enjoying his best outcome, will not move on. Outcome: The players stay at the noncooperative outcome.

When play starts cooperatively, neither player will defect, because if he does, the other player will also defect, and they both will end up worse off. Thinking ahead, therefore, neither player will defect. Outcome: The players stay at the cooperative outcome.

When play starts at one of the win-lose outcomes (best for one player, worst for the other), the player doing best will know that if he is not magnanimous, and consequently does not move to the cooperative outcome, his opponent will move to the noncooperative outcome, inflicting on the best-off player his next-worst outcome. Therefore, it is in the best-off player's interest, as well as his opponent's, that he act magnanimously, anticipating that if he does not, the noncooperative outcome (next-worst for both), rather than the cooperative outcome (next-best for both), will be chosen. Outcome: The best-off player will move to the cooperative outcome, where play will remain.

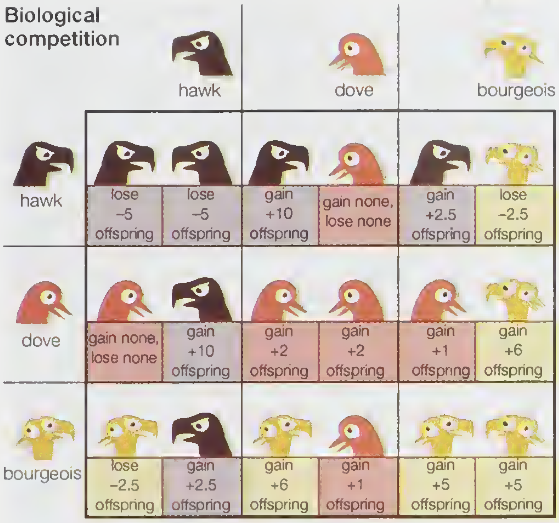
Rational moves

Such rational moves are not beyond the pale of most players. Indeed, they are frequently made by those who look beyond the immediate consequences of their own choices. Such far-sighted players can escape the dilemma in PD—and in other variable-sum games—provided play does not begin noncooperatively. Hence, TOM does not predict unconditional cooperation in PD but, instead, makes it a function of the starting point of play.

Biological applications. One fascinating and unexpected application of game theory in general, and PD in particular, occurs in biology. When two males confront each other, whether competing for a mate or for some disputed territory, they can behave either like "hawks"—fighting until one is maimed, killed, or flees—or like "doves"—posturing a bit but leaving before any serious harm is done. (In effect, the doves cooperate while the hawks do not.) Neither type of behaviour is ideal for survival: a species containing only hawks would have a high casualty rate; a species containing only doves would be vulnerable to an invasion by hawks or a mutation that produces hawks, because the population growth rate of the competitive hawks would be much higher initially than that of the doves.

"Bourgeois" behaviour

Thus, a species with males consisting exclusively of either hawks or doves is vulnerable. The English biologist John Maynard Smith showed that a third type of male behaviour, which he called "bourgeois," would be more stable than that of either pure hawks or pure doves. A bourgeois may act like either a hawk or a dove, depending on some external cues; for example, it may fight tenaciously when it meets a rival in its own territory but yield when it meets the same rival elsewhere. In effect, bourgeois animals submit their conflict to external arbitration to avoid a prolonged and mutually destructive struggle.



Biological competition

	hawk		dove		bourgeois	
hawk	lose −5 offspring	lose −5 offspring	gain +10 offspring	gain none, lose none	gain +2.5 offspring	lose −2.5 offspring
dove	gain none, lose none	gain +10 offspring	gain +2 offspring	gain +2 offspring	gain +1 offspring	gain +6 offspring
bourgeois	lose −2.5 offspring	gain +2.5 offspring	gain +6 offspring	gain +1 offspring	gain +5 offspring	gain +5 offspring

Table 5.

As shown in Table 5, Smith constructed a payoff matrix in which various possible outcomes (*e.g.*, death, maiming, successful mating), and the costs and benefits associated with them (*e.g.*, cost of lost time), were weighted in terms of the expected number of genes propagated. Smith showed that a bourgeois invasion would be successful against a completely hawk population by observing that when a hawk confronts a hawk it loses 5, whereas a bourgeois loses only 2.5. (Because the population is assumed to be predominantly hawk, the success of the invasion can be predicted by comparing the average number of offspring a hawk will produce when it confronts another hawk with the average number of offspring a bourgeois will produce when confronting a hawk.) Patently, a bourgeois invasion against a completely dove population would be successful as well, gaining the bourgeois 6 offspring. On the other hand, a completely bourgeois population cannot be invaded by either hawks or doves, because the bourgeois gets 5 against bourgeois, which is more than either hawks or doves get when confronting bourgeois. Note in this application that the question is not what strategy a rational player will choose—animals are not assumed to make conscious choices, though their types may change through mutation—but what combinations of types are stable and hence likely to evolve.

Smith gave several examples of the bourgeois strategy. For example, male speckled wood butterflies seek sunlit spots on the forest floor where females are often found. There is a shortage of such spots, however, and in a confrontation between a stranger and an inhabitant, the stranger yields after a brief duel in which the combatants circle one another. The dueling skills of the adversaries have little effect on the outcome. When one butterfly is forcibly placed on another's territory so that each considers the other the aggressor, the two butterflies duel with righteous indignation for a much longer time.

N-PERSON GAMES

Nash equilibriums

Theoretically, *n*-person games in which the players are not allowed to communicate and make binding agreements are not fundamentally different from two-person noncooperative games. In the two examples that follow, each involving three players, one looks for Nash equilibriums—that is, stable outcomes from which no player would normally depart because to do so would be disadvantageous.

Sequential and simultaneous truels. As an example of an *n*-person noncooperative game, imagine three players, *A*, *B*, and *C*, situated at the corners of an equilateral triangle. They engage in a truel, or three-person duel, in which each player has a gun with one bullet. Assume that each player is a perfect shot and can kill one other player at any time. There is no fixed order of play, but any shooting that occurs is sequential: no player fires at the same time as any other. Consequently, if a bullet is fired, the results are known to all players before another bullet is fired.

Suppose that the players order their goals as follows: (1) survive alone, (2) survive with one opponent, (3) survive with both opponents, (4) not survive, with no opponents alive, (5) not survive, with one opponent alive, and (6) not survive, with both opponents alive. Thus, surviving alone is best, dying alone is worst.

If a player can either fire or not fire at another player, who, if anybody, will shoot whom? It is not difficult to see that outcome (3), in which nobody shoots, is the unique Nash equilibrium—any player that departs from not shooting does worse. Suppose, on the contrary, that *A* shoots *B*, hoping for *A*'s outcome (2), whereby he and *C* survive. Now, however, *C* can shoot a disarmed *A*, thereby leaving himself as the sole survivor, or outcome (1). As this is *A*'s penultimate outcome (5), in which *A* and one opponent (*B*) are killed while the other opponent (*C*) lives, *A* should not fire the first shot; the same reasoning applies to the other two players. Consequently, nobody will shoot, resulting in outcome (3), in which all three players survive.

Now consider whether any of the players can do better through collusion. Specifically, assume that *A* and *B* agree not to shoot each other; if either shoots another player, they agree it would be *C*. Nevertheless, if *A* shoots *C* (for instance), *B* could now repudiate the agreement with impunity and shoot *A*, thereby becoming the sole survivor.

Thus, thinking ahead about the consequences of shooting first or colluding with another player to do so, nobody will shoot or collude. Thereby all players will survive if the players must act in sequence, giving outcome (3). Because no player can do better by shooting, or saying they will do so to another, these strategies yield a Nash equilibrium.

Next, suppose that the players act simultaneously; hence, they must decide in ignorance of each others' intended actions. This situation is common in life: people often must act before they find out what others are doing. While there is no "best" strategy in all situations, the possibilities of survival will increase if the number of rounds is unlimited. Outcome: There may be zero, one, or three survivors, but never two. To summarize, shooting is never rational in a sequential truel, whereas it is always rational in a simultaneous truel that goes only one round. Thus, "nobody shoots" and "everybody shoots" are the Nash equilibriums in these two kinds of truels. In simultaneous truels that go more than one round, by comparison, there are multiple Nash equilibriums. If the number of rounds is known, then there is one Nash equilibrium in which a player shoots, and one in which he does not, at the start, but in the end there will be only one or no survivors. When the number of rounds is unlimited, however, a new Nash equilibrium is possible in which nobody shoots on any round. Thus, like PD with an uncertain number of rounds, an unlimited number of rounds in a truel can lead to greater cooperation.

The von Neumann–Morgenstern theory. Von Neumann and Morgenstern were the first to construct a cooperative theory of *n*-person games. They assumed that various groups of players might join together to form coalitions, each of which has an associated value defined as the minimum amount that the coalition can ensure by its own efforts. (In practice, such groups might be blocs in a legislative body or business partners in a conglomerate.) They described these *n*-person games in characteristic-function form—that is, by listing the individual players (one-person coalitions), all possible coalitions of two or more players, and the values that each of these coalitions could ensure if a counter-coalition comprising all other players acted to minimize the amount that the coalition can obtain. They also assumed that the characteristic function is superadditive: the value of a coalition of two formerly separate coalitions is at least as great as the sum of the separate values of the two coalitions.

The sum of payments to the players in each coalition must equal the value of that coalition. Moreover, each player in a coalition must receive no less than what he could obtain playing alone; otherwise, he would not join the coalition. Each set of payments to the players describes one possible outcome of an *n*-person cooperative game and is called an imputation. Within a coalition *S*, an imputation *X* is said to dominate another imputation *Y* if each player in *S* gets more with *X* than with *Y* and if the players in *S* receive a total payment that does not exceed the coalition value of *S*. This means that players in the coalition prefer the payoff *X* to the payoff *Y* and have the power to enforce this preference.

Imputations

Von Neumann and Morgenstern defined the solution to an *n*-person game as a set of imputations satisfying two conditions: (1) no imputation in the solution dominates another imputation in the solution and (2) any imputation not in the solution is dominated by another one in the solution. A von Neumann–Morgenstern solution is not a single outcome but, rather, a set of outcomes, any one of which may occur. It is stable because, for the members of the coalition, any imputation outside the solution is dominated by—and is therefore less attractive than—an imputation within the solution. The imputations within the solution are viable because they are not dominated by any other imputations in the solution.

In any given cooperative game there are generally many—sometimes infinitely many—solutions. A simple three-person game that illustrates this fact is one in which any two players, as well as all three players, receive one unit, which they can divide between or among themselves in any way that they wish; individual players receive nothing. In such a case the value of each two-person coalition, and the three-person coalition as well, is 1.

One solution to this game consists of three imputations, in each of which one player receives 0 and the other two players receive ½ each. There is no self-domination within the solution, because if one imputation is substituted for another, one player gets more, one gets less, and one gets the same (for domination, each of the players forming a coalition must gain). In addition, any imputation outside the solution is dominated by one in the solution, because the two players with the lowest payoffs must each get less than ½; clearly, this imputation is dominated by an imputation in the solution in which these two players each get ½. According to this solution, at any given time one of its three imputations will occur, but von Neumann and Morgenstern do not predict which one.

A second solution to this game consists of all the imputations in which player *A* receives ¼ and players *B* and *C* share the remaining ¾. Although this solution gives a different set of outcomes from the first solution, it, too, satisfies von Neumann and Morgenstern's two conditions. For any imputation within the solution, player *A* always gets ¼ and therefore cannot gain. In addition, because players *B* and *C* share a fixed sum, if one of them gains in a proposed imputation, the other must lose. Thus, no imputation in the solution dominates another imputation in the solution.

For any imputation not in the solution, player *A* must get either more or less than ¼. When *A* gets more than ¼, players *B* and *C* share less than ¾ and, therefore, can do better with an imputation within the solution. When player *A* gets less than ¼, say ⅛, he always does better with an imputation in the solution. Players *B* and *C* now have more to share; but no matter how they split the new total of ⅞, there is an imputation in the solution that one of them will prefer. When they share equally, each gets 7/16; but player *B*, for example, can get more in the imputation (¼, ½, ¼), which is in the solution. When players *B* and *C* do not divide the ⅞ equally, the player who gets the smaller amount can always do better with an imputation in the solution. Thus, any imputation outside the solution is dominated by one inside the solution. Similarly, it can be shown that all of the imputations in which player *B* gets ¼ and players *A* and *C* share ¾, as well as the set of all imputations in which player *C* gets ¼ and players *A* and *B* share ¾, also constitute a solution to the game.

Although there may be many solutions to a game (each representing a different "standard of behaviour"), it was not apparent at first that there would always be at least one in every cooperative game. Von Neumann and Morgenstern found no game without a solution, and they deemed it important that no such game exists. However, in 1967 a fairly complicated 10-person game was discovered by the American mathematician William F. Lucas that did not have a solution. This and later counterexamples indicated that the von Neumann–Morgenstern solution is not universally applicable, but it remains compelling, especially since no definitive theory of *n*-person cooperative games exists.

Game without a solution

The Banzhaf value in voting games. Power defined as control over outcomes is not synonymous with control over resources. For example, in the paradox of the chair's position, the chair's extra tie-breaking vote may actually be a detriment because the strategic situation facing voters may intervene and cause them to reassess their strategies in light of the additional resources that the chair possesses. In

Paradox of the chair

doing so, they may be led to "gang up" against the chair. In effect, the chair's resources become a burden to bear, not power to relish.

When players' preferences are not known beforehand, though, it is useful to define power in terms of their ability to alter the outcome by changing their votes, as governed by a constitution, bylaws, or other rules of the game. Various measures of voting power have been proposed for simple games, in which every coalition has a value of 1 (if it has enough votes to win) or 0 (if it does not). The sum of the powers of all the players is 1. When a player has 0 power, his vote has no influence on the outcome; when a player has a power of 1, the outcome depends only on his vote. The key to calculating voting power is determining the frequency with which a player casts a critical vote.

Critical vote

American attorney John F. Banzhaf III proposed that all combinations in which any player is the critical voter—that is, in which a measure passes only with this voter's support—be considered equally likely. The Banzhaf value for each player is then the number of combinations in which this voter is critical divided by the total number of combinations in which each voter (including this one) is critical.

This view is not compatible with defining the voting power of a player to be proportional to the number of votes he casts, because votes per se may have little or no bearing on the choice of outcomes. For example, in a three-member voting body in which *A* has 4 votes, *B* 2 votes, and *C* 1 vote, members *B* and *C* will be powerless if a simple majority wins. The fact that members *B* and *C* together control $3/7$ of the votes is irrelevant in the selection of outcomes, so these members are called dummies. Member *A*, by contrast, is a dictator by virtue of having enough votes alone to determine the outcome. A voting body can have only one dictator, whose existence renders all other members dummies, but there may be dummies and no dictator.

Minimal winning coalition

A minimal winning coalition (MWC) is one in which the subtraction of at least one of its members renders it losing. To illustrate the calculation of Banzhaf values, consider a voting body with two 2-vote members (distinguished as 2a and 2b) and one 3-vote member, in which a simple majority wins. There are three distinct MWCs—(3, 2a), (3, 2b), and (2a, 2b)—or combinations in which some voter is critical; the grand coalition, comprising all three members, (3, 2a, 2b), is not an MWC because no single member's defection would cause it to lose.

As each member's defection is critical in two MWCs, each member's proportion of voting power is two-sixths, or one-third. Thus, the Banzhaf index, which gives the Banzhaf values for each member in vector form, is (⅓, ⅓, ⅓). Clearly, the voting power of the 3-vote member is the same as that of each of the two 2-vote members, although the 3-vote member has 50 percent greater weight (more votes) than each of the 2-vote members.

The discrepancy between voting weight and voting power is more dramatic in the voting body (50, 49, 1) where, again, a simple majority wins. The 50-vote member is critical in all three MWCs—(50, 1), (50, 49), and (50, 49, 1), giving him a veto because his presence is necessary for a coalition to be winning—whereas the 49-vote member is critical in only (50, 49) and the 1-vote member in only (50, 1). Thus, the Banzhaf index for (50, 49, 1) is (⅗, ⅕, ⅕), making the 49-vote member indistinguishable from the 1-vote member; the 50-vote member, with just one more vote than the 49-vote member, has three times as much voting power.

In 1958 six western European countries formed the European Economic Community (EEC). The three large countries (West Germany, France, and Italy) each had 4 votes on its Council of Ministers, the two medium-size countries (Belgium and The Netherlands) 2 votes each, and the one small country (Luxembourg) 1 vote. The decision rule of the Council was a qualified majority of 12 out of 17 votes, giving the large countries Banzhaf values of $5/21$ each, the medium-size countries ⅐ each, and—amazingly—Luxembourg no voting power at all. From 1958 to 1973—when the EEC admitted three additional members—Luxembourg was a dummy. Luxembourg might as well not have gone to Council meetings except to participate in the debate, because its 1 vote could never change the outcome. To see this without calculating the Banzhaf values of all the members, note that the votes of the five other countries are all even numbers. Therefore, an MWC with exactly 12 votes could never include Luxembourg's (odd) 1 vote; while a 13-vote MWC that included Luxembourg could form, Luxembourg's defection would never render such an MWC losing. It is worth noting that as the Council kept expanding with the addition of new countries and the formation of the European Union, Luxembourg never reverted to being a dummy, even though its votes became an ever smaller proportion of the total.

The Banzhaf and other power indices, rooted in cooperative game theory, have been applied to many voting bodies, not necessarily weighted, sometimes with surprising results. For example, the Banzhaf index has been used to calculate the power of the 5 permanent and 10 nonpermanent members of the United Nations Security Council. (The permanent members, all with a veto, have 83 percent of the power.) It has also been used to compare the power of representatives, senators, and the president in the U.S. federal system.

Game theory is now well established and widely used in a variety of disciplines. The foundations of economics, for example, are increasingly grounded in game theory; among game theory's many applications in economics is the design of Federal Communications Commission auctions of airwaves, which have netted the U.S. government billions of dollars. Game theory is being used increasingly in political science to study strategy in areas as diverse as campaigns and elections, defense policy, and international relations. In biology, business, management science, computer science, and law, game theory has been used to model a variety of strategic situations. Game theory has even penetrated areas of philosophy (*e.g.*, to study the equilibrium properties of ethical rules), religion (*e.g.*, to interpret Bible stories), and pure mathematics (*e.g.*, to analyze how to divide a cake fairly among *n* people). All in all, game theory holds out great promise not only for advancing the understanding of strategic interaction in very different settings but also for offering prescriptions for the design of better auction, bargaining, voting, and information systems that involve strategic choice. (M.D.D./S.J.B.)

BIBLIOGRAPHY. The seminal work in game theory is JOHN VON NEUMANN and OSKAR MORGENSTERN, *Theory of Games and Economic Behavior*, 3rd ed. (1953, reprinted 1980). AVINASH K. DIXIT and BARRY J. NALEBUFF, *Thinking Strategically: The Competitive Edge in Business, Politics, and Everyday Life* (1991), uses case studies, without formal mathematical analysis, to introduce the principles of game theory. Two introductions that require only high school algebra are AVINASH K. DIXIT and SUSAN SKEATH, *Games of Strategy* (1999); and PHILIP D. STRAFFIN, *Game Theory* (1993).

Applications of game theory are presented in NESMITH C. ANKENY, *Poker Strategy: Winning with Game Theory* (1981, reprinted 1982); ROBERT AXELROD, *The Evolution of Cooperation* (1984); DOUGLAS G. BAIRD, ROBERT H. GERTNER, and RANDAL C. PICKER, *Game Theory and the Law* (1994); STEVEN J. BRAMS, *Biblical Games: Game Theory and the Hebrew Bible*, 2nd ed. (2002); STEVEN J. BRAMS, *Theory of Moves* (1994); DAN S. Histories of game theory can be found in WILLIAM POUNDSTONE, *Prisoner's Dilemma: John von Neumann, Game Theory, and the Puzzle of the Bomb* (1992); and E. ROY WEINTRAUB (ed.), *Toward a History of Game Theory* (1992). (S.J.B.)

Gandhi

Mohandas Karamchand Gandhi, the preeminent leader of Indian nationalism and the prophet of nonviolence in the 20th century, was born, the youngest child of his father's fourth wife, on Oct. 2, 1869, at Porbandar, the capital of a small principality in Gujarāt in western India under British suzerainty. His father, Karamchand Gandhi, who was the dewan (chief minister) of Porbandar, did not have much in the way of a formal education but was an able administrator who knew how to steer his way between the capricious princes, their long-suffering subjects, and the headstrong British political officers in power.

Gandhi's mother, Putlibai, was completely absorbed in religion, did not care much for finery and jewelry, divided her time between her home and the temple, fasted frequently, and wore herself out in days and nights of nursing whenever there was sickness in the family. Mohandas grew up in a home steeped in Vaishnavism (Vaiṣṇavism)—worship of the Hindu god Vishnu (Viṣṇu)—with a strong tinge of Jainism, a morally rigorous Indian religion, whose chief tenets are nonviolence and the belief that everything in the universe is eternal. Thus he took for granted *ahiṁsā* (noninjury to all living beings), vegetarianism, fasting for self-purification, and mutual tolerance between adherents of various creeds and sects.

Youth. The educational facilities at Porbandar were rudimentary; in the primary school that Mohandas attended, the children wrote the alphabet in the dust with their fingers. Luckily for him, his father became dewan of Rājkot, another princely state. Though he occasionally won prizes and scholarships at the local schools, his record was on the whole mediocre. One of the terminal reports rated him as "good at English, fair in Arithmetic and weak in Geography; conduct very good, bad handwriting." A diffident child, he was married at the age of 13 and thus lost a year at school. He shone neither in the classroom nor on the playing field. He loved to go out on long solitary walks when he was not nursing his by now ailing father or helping his mother with her household chores.

Education

He had learned, in his words, "to carry out the orders of the elders, not to scan them." With such extreme passivity, it is not surprising that he should have gone through a phase of adolescent rebellion, marked by secret atheism, petty thefts, furtive smoking, and—most shocking of all for a boy born in a Vaishnava family—meat eating. His adolescence was probably no stormier than that of most children of his age and class. What was extraordinary was the way his youthful transgressions ended.

Margaret Bourke-White, LIFE MAGAZINE © TIME INC

Gandhi, 1946.

"Never again" was his promise to himself after each escapade. And he kept his promise. Beneath an unprepossessing exterior, he concealed a burning passion for self-improvement that led him to take even the heroes of Hindu mythology, such as Prahlāda and Hariścandra—legendary embodiments of truthfulness and sacrifice—as living models.

In 1887 Mohandas scraped through the matriculation examination of the University of Bombay and joined Samaldas College in Bhāvnagar (Bhaunagar). As he had suddenly to switch from his native language—Gujarātī—to English, he found it rather difficult to follow the lectures.

Meanwhile, his family was debating his future. Left to himself, he would have liked to be a doctor. But, besides the Vaishnava prejudice against vivisection, it was clear that, if he was to keep up the family tradition of holding high office in one of the states in Gujarāt, he would have to qualify as a barrister. This meant a visit to England, and Mohandas, who was not too happy at Samaldas College, jumped at the proposal. His youthful imagination conceived England as "a land of philosophers and poets, the very centre of civilization." But there were several hurdles to be crossed before the visit to England could be realized. His father had left little property; moreover, his mother was reluctant to expose her youngest child to unknown temptations and dangers in a distant land. But Mohandas was determined to visit England. One of his brothers raised the necessary money, and his mother's doubts were allayed when he took a vow that, while away from home, he would not touch wine, women, or meat. Mohandas disregarded the last obstacle—the decree of the leaders of the Modh Bania subcaste (Vaisya caste), to which the Gandhis belonged, who forbade his trip to England as a violation of the Hindu religion—and sailed in September 1888. Ten days after his arrival, he joined the Inner Temple, one of the four London law colleges.

Law studies

England. Gandhi took his studies seriously and tried to brush up on his English and Latin by taking the London University matriculation examination. But, during the three years he spent in England, his main preoccupation was with personal and moral issues rather than with academic ambitions. The transition from the half-rural atmosphere of Rājkot to the cosmopolitan life of London was not easy for him. As he struggled painfully to adapt himself to Western food, dress, and etiquette, he felt awkward. His vegetarianism became a continual source of embarrassment to him; his friends warned him that it would wreck his studies as well as his health. Fortunately for him he came across a vegetarian restaurant as well as a book providing a reasoned defense of vegetarianism, which henceforth became a matter of conviction for him, not merely a legacy of his Vaishnava background. The missionary zeal he developed for vegetarianism helped to draw the pitifully shy youth out of his shell and gave him a new poise. He became a member of the executive committee of the London Vegetarian Society, attending its conferences and contributing articles to its journal.

In the vegetarian restaurants and boarding houses of England, Gandhi met not only food faddists but some earnest men and women to whom he owed his introduction to the Bible and the *Bhagavadgītā*, the most popular expression of Hinduism in the form of a philosophical poem, which he read for the first time in its English translation by Sir Edwin Arnold. The English vegetarians were a motley crowd. They included socialists and humanitarians like Edward Carpenter, "the British Thoreau"; Fabians like George Bernard Shaw; and Theosophists like Annie Besant. Most of them were idealists; quite a few were rebels who rejected the prevailing values of the late Victorian

Establishment, denounced the evils of the capitalist and industrial society, preached the cult of the simple life, and stressed the superiority of moral over material values and of cooperation over conflict. These ideas were to contribute substantially to the shaping of Gandhi's personality and, eventually, to his politics.

Return to India

Painful surprises were in store for Gandhi when he returned to India in July 1891. His mother had died in his absence, and he discovered to his dismay that the barrister's degree was not a guarantee of a lucrative career. The legal profession was already beginning to be overcrowded, and Gandhi was much too diffident to elbow his way into it. In the very first brief he argued in a Bombay court, he cut a sorry figure. Turned down even for the part-time job of a teacher in a Bombay high school, he returned to Rājkot to make a modest living by drafting petitions for litigants. Even this employment was closed to him when he incurred the displeasure of a local British officer. It was, therefore, with some relief that he accepted the none-too-attractive offer of a year's contract from an Indian firm in Natal, South Africa.

Reaction to segregation

South Africa. Africa was to present to Gandhi challenges and opportunities that he could hardly have conceived. In a Durban court, he was asked by the European magistrate to take off his turban; he refused and left the courtroom. A few days later, while travelling to Pretoria, he was unceremoniously thrown out of a first-class railway compartment and left shivering and brooding at Pietermaritzburg Station; in the further course of the journey he was beaten up by the white driver of a stagecoach because he would not travel on the footboard to make room for a European passenger; and finally he was barred from hotels reserved "for Europeans only." These humiliations were the daily lot of Indian traders and labourers in Natal who had learned to pocket them with the same resignation with which they pocketed their meagre earnings. What was new was not Gandhi's experience but his reaction. He had so far not been conspicuous for self-assertion or aggressiveness. But something happened to him as he smarted under the insults heaped upon him. In retrospect the journey from Durban to Pretoria struck him as one of the most creative experiences of his life; it was his moment of truth. Henceforth he would not accept injustice as part of the natural or unnatural order in South Africa; he would defend his dignity as an Indian and as a man.

While in Pretoria, Gandhi studied the conditions in which his countrymen lived and tried to educate them on their rights and duties, but he had no intention of staying on in South Africa. Indeed, in June 1894, as his year's contract drew to a close, he was back in Durban, ready to sail for India. At a farewell party given in his honour he happened to glance through the *Natal Mercury* and learned that the Natal Legislative Assembly was considering a bill to deprive Indians of the right to vote. "This is the first nail in our coffin," Gandhi told his hosts. They professed their inability to oppose the bill, and indeed their ignorance of the politics of the colony, and begged him to take up the fight on their behalf.

Until the age of 18, Gandhi had hardly ever read a newspaper. Neither as a student in England nor as a budding barrister in India had he evinced much interest in politics. Indeed, he was overcome by a terrifying stage fright whenever he stood up to read a speech at a social gathering or to defend a client in court. Nevertheless, in July 1894, when he was barely 25, he blossomed almost overnight into a proficient political campaigner. He drafted petitions to the Natal legislature and the British government and had them signed by hundreds of his compatriots. He could not prevent the passage of the bill but succeeded in drawing the attention of the public and the press in Natal, India, and England to the Natal Indians' grievances. He was persuaded to settle down in Durban to practice law and to organize the Indian community. In 1894, he founded the Natal Indian Congress of which he himself became the indefatigable secretary. Through this common political organization, he infused a spirit of solidarity in the heterogeneous Indian community. He flooded the government, the legislature, and the press with closely reasoned statements of Indian grievances. Finally, he exposed to the view of the outside world the skeleton in the imperial cupboard, the discrimination practiced against the Indian subjects of Queen Victoria in one of her own colonies in Africa. It was a measure of his success as a publicist that such important newspapers as *The Times* of London and the *Statesman* and *Englishman* of Calcutta editorially commented on the Natal Indians' grievances.

In 1896 Gandhi went to India to fetch his wife Kasturbai and their children and to canvass support for the Indians overseas. He met prominent leaders and persuaded them to address public meetings in the country's principal cities. Unfortunately for him, garbled versions of his activities and utterances reached Natal and inflamed its European population. On landing at Durban in January 1897, he was assaulted and nearly lynched by a white mob. Joseph Chamberlain, the colonial secretary in the British Cabinet, cabled the government of Natal to bring the guilty men to book, but Gandhi refused to prosecute his assailants. It was, he said, a principle with him not to seek redress of a personal wrong in a court of law.

Role in the Boer War

Gandhi was not the man to nurse a grudge. On the outbreak of the Boer War in 1899, he argued that the Indians, who claimed the full rights of citizenship in the British crown colony of Natal, were in duty bound to defend it. He raised an ambulance corps of 1,100 volunteers, out of whom 300 were free Indians and the rest indentured labourers. It was a motley crowd: barristers and accountants, artisans and labourers. It was Gandhi's task to instill in them a spirit of service to those whom they regarded as their oppressors. The editor of the *Pretoria News* has left a fascinating pen portrait of Gandhi in the battle zone:

> After a night's work which had shattered men with much bigger frames, I came across Gandhi in the early morning sitting by the roadside eating a regulation army biscuit. Every man in (General) Buller's force was dull and depressed, and damnation was heartily invoked on everything. But Gandhi was stoical in his bearing, cheerful and confident in his conversation and had a kindly eye.

The British victory in the Boer War brought little relief to the Indians in South Africa. The new regime in South Africa was to blossom into a partnership, but only between Boers and Britons. Gandhi saw that, with the exception of a few Christian missionaries and youthful idealists, he had been unable to make a perceptible impression upon the South African Europeans. In 1906 the Transvaal government published a particularly humiliating ordinance for the registration of its Indian population. The Indians held a mass protest meeting at Johannesburg in September 1906 and, under Gandhi's leadership, took a pledge to defy the ordinance if it became law in the teeth of their opposition, and to suffer all the penalties resulting from their defiance. Thus was born *satyāgraha* ("devotion to truth"), a new technique for redressing wrongs through inviting, rather than inflicting, suffering, for resisting the adversary without rancour and fighting him without violence.

The struggle in South Africa lasted for more than seven years. It had its ups and downs, but under Gandhi's leadership, the small Indian minority kept up its resistance against heavy odds. Hundreds of Indians chose to sacrifice their livelihood and liberty rather than submit to laws repugnant to their conscience and self-respect. In the final phase of the movement in 1913, hundreds of Indians, including women, went to jail, and thousands of Indian workers who had struck work in the mines bravely faced imprisonment, flogging, and even shooting. It was a terrible ordeal for the Indians, but it was also the worst possible advertisement for the South African government, which, under pressure from the governments of Britain and India, accepted a compromise negotiated by Gandhi on the one hand and the South African statesman General Jan Christian Smuts on the other.

"The saint has left our shores," Smuts wrote to a friend on Gandhi's departure from South Africa for India, in July 1914, "I hope for ever." Twenty-five years later, he wrote that it had been his "fate to be the antagonist of a man for whom even then I had the highest respect." Once, during his not infrequent stays in jail, Gandhi had prepared a pair of sandals for Smuts, who recalled that there was no hatred and personal ill-feeling between them, and when the fight was over "there was the atmosphere in which a decent peace could be concluded."

As later events were to show, Gandhi's work did not provide an enduring solution for the Indian problem in South Africa. What he did to South Africa was indeed less important than what South Africa did to him. It had not treated him kindly, but, by drawing him into the vortex of its racial problem, it had provided him with the ideal setting in which his peculiar talents could unfold themselves.

The religious quest. Gandhi's religious quest dated back to his childhood, the influence of his mother and of his home at Porbandar and Rājkot, but it received a great impetus after his arrival in South Africa. His Quaker friends in Pretoria failed to convert him to Christianity, but they quickened his appetite for religious studies. He was fascinated by Tolstoy's writings on Christianity, read the Qu'rān in translation, and delved into Hindu scriptures and philosophy. The study of comparative religion, talks with scholars, and his own reading of theological works brought him to the conclusion that all religions were true and yet every one of them was imperfect because they were "interpreted with poor intellects, sometimes with poor hearts, and more often misinterpreted."

Return to Hinduism

Rajchandra, a brilliant young philosopher who became Gandhi's spiritual mentor, convinced him of "the subtlety and profundity" of Hinduism, the religion of his birth. And it was the *Bhagavadgītā,* which Gandhi had first read in London, that became his "spiritual dictionary" and exercised probably the greatest single influence on his life. Two Sanskrit words in the *Gītā* particularly fascinated him. One was *aparigraha* (nonpossession), which implied that man had to jettison the material goods that cramped the life of the spirit and to shake off the bonds of money and property. The other was *samabhava* (equability), which enjoined him to remain unruffled by pain or pleasure, victory or defeat, and to work without hope of success or fear of failure.

These were not merely counsels of perfection. In the civil case that had brought him to South Africa in 1893, he had persuaded the antagonists to settle their differences out of court. The true function of a lawyer seemed to him "to unite parties riven asunder." He soon regarded his clients not as purchasers of his services but as friends; they consulted him not only on legal issues but on such matters as the best way of weaning a baby or balancing the family budget. When an associate protested that clients came even on Sundays, Gandhi replied: "A man in distress cannot have Sunday rest."

Gandhi's legal earnings reached a peak figure of £5,000 a year, but he had little interest in moneymaking, and his savings were often sunk in his public activities. In Durban and later in Johannesburg, he kept an open table; his house was a virtual hostel for younger colleagues and political coworkers. This was something of an ordeal for his wife, without whose extraordinary patience, endurance, and self-effacement Gandhi could hardly have devoted himself to public causes. As he broke through the conventional bonds of family and property, their life tended to shade into a community life.

Gandhi felt an irresistible attraction to a life of simplicity, manual labour, and austerity. In 1904, after reading John Ruskin's *Unto This Last,* a critique of capitalism, he set up a farm at Phoenix near Durban where he and his friends could literally live by the sweat of their brow. Six years later another colony grew up under Gandhi's fostering care near Johannesburg; it was named Tolstoy Farm after the Russian writer and moralist, whom Gandhi admired and corresponded with. Those two settlements were the precursors of the more famous ashrams (*āśramas*) in India, at Sābarmati near Ahmedabad (Ahmadābād) and at Sevagram near Wardha.

South Africa had not only prompted Gandhi to evolve a novel technique for political action but also transformed him into a leader of men by freeing him from bonds that make cowards of most men. "Persons in power," Gilbert Murray prophetically wrote about Gandhi in the *Hibbert Journal* in 1918, "should be very careful how they deal with a man who cares nothing for sensual pleasure, nothing for riches, nothing for comfort or praise, or promotion, but is simply determined to do what he believes to be right. He is a dangerous and uncomfortable enemy, because his body which you can always conquer gives you so little purchase upon his soul."

Emergence as leader of nationalist India. From 1915 to 1918, Gandhi seemed to hover uncertainly on the periphery of Indian politics, declining to join any political agitation, supporting the British war effort in World War I, and even recruiting soldiers for the British Indian Army. At the same time, he did not flinch from criticizing the British officials for any acts of high-handedness or from taking up the grievances of the long-suffering peasantry in Bihār and Gujarāt. Not until February 1919, provoked by the British insistence on pushing through the Rowlatt Bills, which empowered the authorities to imprison without trial those suspected of sedition, in the teeth of Indian opposition, did Gandhi reveal a sense of estrangement from the British Raj. He announced a *satyāgraha* struggle. The result was a virtual political earthquake that shook the subcontinent in the spring of 1919. The violent outbreaks that followed—leading, among other incidents, to the killing by British-led soldiers of nearly 400 Indians attending a meeting at Amritsar in the Punjab and the enactment of martial law—prompted him to stay his hand. But within a year he was again in a militant mood, having in the meantime been irrevocably alienated by British insensitiveness to Indian feeling on the Punjab tragedy and Muslim resentment on the peace terms offered to Turkey following World War I.

Massacre at Amritsar

By the autumn of 1920, Gandhi was the dominant figure on the political stage, commanding an influence never attained by any political leader in India or perhaps in any other country. He refashioned the 35-year-old Indian National Congress into an effective political instrument of Indian nationalism: from a three-day Christmas-week picnic of the upper middle class in one of the principal cities of India, it became a mass organization with its roots in small towns and villages. Gandhi's message was simple; it was not British guns but imperfections of Indians themselves that kept their country in bondage. His program of nonviolent noncooperation with the British government included boycott not only of British manufactures but of institutions operated or aided by the British in India: legislatures, courts, offices, schools. This program electrified the country, broke the spell of fear of foreign rule, and led to arrests of thousands of *satyāgrahi*s, who defied laws and cheerfully lined up for prison. In February 1922 the movement seemed to be on the crest of a rising wave, but, alarmed by a violent outbreak in Chauri Chaura, a remote village in eastern India, Gandhi decided to call off mass civil disobedience. This was a blow to many of his followers, who feared that his self-imposed restraints and scruples would reduce the nationalist struggle to pious futility. Gandhi himself was arrested on March 10, 1922, tried for sedition, and sentenced to six years' imprisonment. He was released in February 1924, after an operation for appendicitis. The political landscape had changed in his absence. The Congress Party had split into two factions, one under Chitta Ranjan Das and Motilal Nehru (the father of Jawaharlal Nehru, India's first prime minister) favouring the entry of the party into legislatures and the other under C. Rajagopalachari and Vallabhbhai Jhaverbhai Patel opposing it. Worst of all, the unity between Hindus and Muslims of the heyday of the noncooperation movement of 1920–22 had dissolved. Gandhi tried to draw the warring communities out of their suspicion and fanaticism by reasoning and persuasion. And finally, after a serious communal outbreak, he undertook a three-week fast in the autumn of 1924 to arouse the people into following the path of nonviolence.

During the mid-1920s Gandhi took little interest in active politics and was considered a spent force. But in 1927 the British government appointed a constitutional reform commission under Sir John Simon, a prominent English lawyer and politician, that did not contain a single Indian. When the Congress and other parties boycotted the commission, the political tempo rose. After the Calcutta Congress in December 1928, where Gandhi moved the crucial resolution demanding dominion status from

Return to party leadership

the British government within a year under threat of a nation-wide nonviolent campaign for complete independence, Gandhi was back at the helm of the Congress Party. In March 1930, he launched the *satyāgraha* against the tax on salt, which affected the poorest section of the community. One of the most spectacular and successful campaigns in Gandhi's nonviolent war against the British Raj, it resulted in the imprisonment of more than 60,000 persons. A year later, after talks with Lord Irwin, Gandhi accepted a truce, called off civil disobedience, and agreed to attend the Round Table Conference in London as the sole representative of the Indian National Congress. The conference, which concentrated on the problem of the Indian minorities rather than on the transfer of power from the British, was a great disappointment to the Indian nationalists. Moreover, when Gandhi returned to India in December 1931 he found his party facing an all-out offensive from Lord Irwin's successor, Lord Willingdon, who unleashed the sternest repression in the history of the nationalist movement. Gandhi was once more imprisoned, and the government tried to insulate him from the outside world and to destroy his influence. This was not an easy task. Gandhi soon regained the initiative; in September 1932, while still a prisoner, he embarked on a fast to protest against the British government's decision to segregate the untouchables (the depressed classes) by allotting them separate electorates in the new constitution. The fast produced an emotional upheaval in the country; an alternative electoral arrangement was jointly and speedily devised by the leaders of the Hindu community and the untouchables and endorsed by the British government. The fast became the starting point of a vigorous campaign for the removal of the disabilities of the untouchables whom Gandhi renamed Harijans, "the children of God."

In 1934 Gandhi resigned not only as the leader but also as a member of the Congress Party. He had come to believe that its leading members had adopted nonviolence as a political expedient and not as the fundamental creed it was for him. In place of political activity he now concentrated on his "constructive programme" of building the nation "from the bottom up"—educating rural India, which accounted for 85 percent of the population; continuing his fight against untouchability; promoting handspinning, weaving, and other cottage industries to supplement the earnings of the underemployed peasantry; and evolving a system of education best suited to the needs of the people. Gandhi himself went to live at Sevagram, a village in central India, which became the centre of his program of social and economic uplift.

The last phase. With the outbreak of World War II, the nationalist struggle in India entered its last crucial phase. Gandhi hated fascism and all it stood for, but he also hated war. The Indian National Congress, on the other hand, was not committed to pacifism and was prepared to support the British war effort if Indian self-government was assured. Once more Gandhi became politically active. The failure of the mission of Sir Stafford Cripps, a British cabinet minister, who came to India in March 1942 with an offer that Gandhi found unacceptable, the British equivocation on the transfer of power to Indian hands, and the encouragement given by high British officials to conservative and communal forces promoting discord between Muslims and Hindus impelled him to demand in the summer of 1942 an immediate British withdrawal from India. The war against the Axis, particularly Japan, was in a critical phase; the British reacted sharply by imprisoning the entire Congress leadership and set out to crush the party once and for all. There were violent outbreaks that were sternly suppressed; the gulf between Britain and India became wider than ever.

A new chapter in Indo-British relations opened with the victory of the Labour Party in 1945. During the next two years, there were prolonged triangular negotiations between leaders of the Congress and the Muslim League under M.A. Jinnah and the British government culminating in the Mountbatten Plan of June 3, 1947, and the formation of the two new dominions of India and Pakistan in mid-August 1947.

Partition of British India

It was one of the greatest disappointments of Gandhi's life that Indian freedom was realized without Indian unity. Muslim separatism had received a great boost while Gandhi and his colleagues were in jail, and in 1946–47, as the final constitutional arrangements were being negotiated, the outbreak of communal riots between Hindus and Muslims unhappily created a climate in which Gandhi's appeals to reason and justice, tolerance and trust had little chance. When partition of the subcontinent was accepted—against his advice—he threw himself heart and soul into the task of healing the scars of the communal conflict, toured the riot-torn areas in Bengal and Bihār, admonished the bigots, consoled the victims, and tried to rehabilitate the refugees. In the atmosphere of that period, surcharged with suspicion and hatred, this was a difficult and heartbreaking task. Gandhi was blamed by partisans of both the communities. When persuasion failed, he went on a fast. He won at least two spectacular triumphs; in September 1947 his fasting stopped the rioting in Calcutta, and in January 1948, he shamed the city of Delhi into a communal truce. A few days later, on January 30, while he was on his way to his evening prayer meeting in Delhi, he was shot down by Nathuram Godse, a young Hindu fanatic.

Place in history. The British attitude to Gandhi was one of mingled admiration, amusement, bewilderment, suspicion, and resentment. Except for a tiny minority of Christian missionaries and radical socialists, the British tended to see in him at best a utopian visionary, at worst a cunning hypocrite whose professions of friendship for the British race were a mask for subversion of the British Raj. Gandhi was conscious of the existence of this wall of prejudice, and it was part of the strategy of *satyāgraha* to penetrate it.

His three major campaigns in 1920–22, 1930–34, and 1940–42 were well designed to engender that process of self-doubt and questioning that was to undermine the moral defences of his adversaries and to contribute, together with the objective realities of the postwar world, to producing the grant of dominion status in 1947. The British abdication in India was the first step in the liquidation of the British Empire on the continents of Asia and Africa. Gandhi's image as an archrebel died hard, but, as it had done to the memory of George Washington, Britain, in 1969, the centenary year of Gandhi's birth, erected a statue to his memory.

Gandhi had critics in his own country, and indeed in his own party. The liberal leaders protested that he was going too fast; the young radicals complained that he was not going fast enough; left-wing politicians alleged that he was not serious about evicting the British or liquidating such vested Indian interests as princes and landlords; the leaders of the untouchables doubted his good faith as a social reformer; and Muslim leaders accused him of partiality to his own community.

Recent research has established Gandhi's role as a great mediator and reconciler. His talents in this direction were applied to conflicts between the older moderate politicians and the young radicals, the political terrorists and the parliamentarians, the urban intelligentsia and the rural masses, the traditionalists and the modernists, the caste Hindus and the untouchables, the Hindus and the Muslims, and the Indians and the British.

Primacy of religion

It was inevitable that Gandhi's role as a political leader should loom larger in public imagination, but the mainspring of his life lay in religion, not in politics. And religion for him did not mean formalism, dogma, ritual, or sectarianism. "What I have been striving and pining to achieve these thirty years," he wrote in his autobiography, "is to see God face to face." His deepest strivings were spiritual, but unlike many of his countrymen with such aspirations, he did not retire to a cave in the Himalayas to meditate on the Absolute; he carried his cave, as he once said, within him. For him truth was not something to be discovered in the privacy of one's personal life; it had to be upheld in the challenging contexts of social and political life.

In the eyes of millions of his countrymen, he was the Mahatma (the great soul). The unthinking adoration of the huge crowds that gathered to see him all along his route made his tours a severe ordeal; he could hardly work during the day or rest at night. "The woes of the Mahatmas," he wrote, "are known only to the Mahatmas."

Gandhi won the affection and loyalty of gifted men and women, old and young, with vastly dissimilar talents and temperaments; of Europeans of every religious persuasion; and of Indians of almost every political line. Few of his political colleagues went all the way with him and accepted nonviolence as a creed; fewer still shared his food fads, his interest in mudpacks and nature cure, or his prescription of *brahmacarya,* complete renunciation of the pleasures of the flesh.

Gandhi's ideas on sex may sound quaint and unscientific. His marriage at the age of 13 seems to have complicated his attitude to sex and charged it with feelings of guilt, but it is important to remember that total sublimation, according to the best tradition of Hindu thought, is indispensable for those who seek self-realization, and *brahmacarya* was for Gandhi part of a larger discipline in food, sleep, thought, prayer, and daily activity designed to equip himself for service of the causes to which he was totally committed. What he failed to see was that his own unique experience was no guide for the common man.

It is probably too early to judge Gandhi's place in history. He was the catalyst if not the initiator of three of the major revolutions of the 20th century: the revolutions against colonialism, racism, and violence. He wrote copiously; the collected edition of his writings runs to more than 80 volumes.

Much of what he wrote was in response to the needs of his co-workers and disciples and the exigencies of the political situation, but on fundamentals, he maintained a remarkable consistency, as is evident from the *Hind Swaraj* ("Indian Home Rule") published in South Africa in 1909. The strictures on Western materialism and colonialism, the reservations about industrialism and urbanization, the distrust of the modern state, and the total rejection of violence that was expressed in this book seemed romantic, if not reactionary, to the pre-World War I generation in India and the West, which had not known the shocks of two global wars, experienced the phenomenon of Hitler, and the trauma of the atom bomb. Prime Minister Jawaharlal Nehru's objective of promoting a just and egalitarian order at home, and nonalignment with military blocs abroad doubtless owed much to Gandhi, but neither he nor his colleagues in the Indian nationalist movement wholly accepted the Gandhian models in politics and economics.

In recent years Gandhi's name has been invoked by the organizers of numerous demonstrations and movements, but with a few outstanding exceptions—such as those of his disciple the land reformer Vinoba Bhave in India and the black civil rights leader Martin Luther King, Jr., in the United States—these movements have been a travesty of the ideas of Gandhi.

Yet Gandhi will probably never lack champions. Erik H. Erikson, a distinguished American psychoanalyst, in his study of Gandhi senses "an affinity between Gandhi's truth and the insights of modern psychology." One of the greatest admirers of Gandhi was Albert Einstein, who saw in Gandhi's nonviolence a possible antidote to the massive violence unleashed by the fission of the atom. And Gunnar Myrdal, the Swedish economist, after his survey of the socioeconomic problems of the underdeveloped world, pronounced Gandhi "in practically all fields an enlightened liberal." In a time of deepening crisis in the underdeveloped world, of social malaise in the affluent societies, of the shadow of unbridled technology and the precarious peace of nuclear terror, it seems likely that Gandhi's ideas and techniques will become increasingly relevant. (B.R.N.)

BIBLIOGRAPHY. Gandhi's autobiography, *The Story of My Experiments with Truth,* 2 vol. (1927–29, reissued in 1 vol., 1983), tells the story of his life up to 1921; his *Satyagraha in South Africa,* 2nd ed. (1950, reprinted 1972), illuminates the formative two decades he spent in South Africa. The *Collected Works of Mahatma Gandhi,* 90 vol. (1958–84), includes all his writings, speeches, and letters.

A biography by PYARELAL, *Mahatma Gandhi,* 2nd ed., 2 vol. (1965–66), provides a richly documented chronicle of Gandhi's early and last years written by his former secretary. SUDHIR GHOSH, *Gandhi's Emissary* (1967), is an autobiographical memoir of Gandhi's informal agent to the British government in 1945–48. DINANATH G. TENDULKAR, *Mahatma,* rev. ed., 8 vol. (1960–63, reprinted 1969), tells the story of Gandhi's life mostly in Gandhi's own words extracted from his published writings. LOUIS FISCHER, *The Life of Mahatma Gandhi* (1950, reissued 1983), is based largely on printed sources but includes the author's vivid personal impressions of Gandhi and India in the 1940s; BAL R. NANDA, *Mahatma Gandhi: A Biography* (1958, reissued 1968), is a story of Gandhi's life as well as a critique of his thought and makes use of unpublished government records and correspondence of Gandhi. PENDEREL MOON, *Gandhi and Modern India* (1969), reflects a British administrator's views on Gandhi the politician. HENRY S.L. POLAK, HENRY M. BRAILSFORD, and FREDERICK W. PETHICK-LAWRENCE, *Mahatma Gandhi* (1949, reissued 1962), is a good introduction for Western readers. HORACE ALEXANDER, *Gandhi Through Western Eyes* (1969); and GEOFFREY ASHE, *Gandhi: A Study in Revolution* (1968), are sympathetic and analytical studies. ROBERT PAYNE, *The Life and Death of Mahatma Gandhi* (1969), is a well-researched biography, with emphasis on the personal rather than political aspect.

CHANDRAN D.S. DEVANESEN, *The Making of the Mahatma* (1969), covers Gandhi's childhood and youth in detail. ERIK H. ERIKSON, *Gandhi's Truth: On the Origins of Militant Nonviolence* (1969), illuminates Gandhi's life and technique by bringing to bear on them the insights of psychoanalysis. Another psychological biography is E. VICTOR WOLFENSTEIN, *The Revolutionary Personality: Lenin, Trotsky, Gandhi* (1967, reprinted 1971). See also JOSEPH J. DOKE, *M.K. Gandhi: An Indian Patriot in South Africa* (1909, reprinted 1967); CALVIN KYTLE, *Gandhi: Soldier of Nonviolence,* rev. ed. (1982); and GERALD GOLD, *Gandhi: A Pictorial Biography* (1983).

ROBERT A. HUTTENBACK, *Gandhi in South Africa: British Imperialism and the Indian Question, 1860–1914* (1971), is a study of the Indian community's struggle in South Africa; a study of Gandhi's role in Indian politics and the nationalist movement is presented in JUDITH M. BROWN, *Gandhi's Rise to Power: Indian Politics 1915–1922* (1972), and *Gandhi and Civil Disobedience: The Mahatma in Indian Politics, 1928–34* (1977). SUSANNE H. RUDOLPH and LLOYD I. RUDOLPH, *Gandhi: The Traditional Roots of Charisma* (1983), which discusses Gandhi's remaining influence, was originally published as the second part of the authors' *The Modernity of Tradition: Political Development in India* (1967). FRANCIS G. HUTCHINS, *India's Revolution: Gandhi and the Quit India Movement* (1973), is an interpretive study. GENE SHARP, *Gandhi as a Political Strategist* (1979), is a study of the relation of pacifist principles to political techniques; and JAI CHAND DEV SETHI, *Gandhi Today* (1978), includes an analysis of Gandhian economics.

Among the books containing reminiscences of Gandhi, the more important are: MILLIE G. POLAK, *Mr. Gandhi: The Man* (1931); JAWAHARLAL NEHRU, *An Autobiography* (1936, reissued 1980); SARVEPALLI RADHAKRISHNAN (ed.), *Mahatma Gandhi: Essays and Reflections of His Life and Work,* 2nd ed. (1949, reissued 1977); CHANDRASHANKER SHUKLA (ed.), *Incidents of Gandhiji's Life* (1949); NIRMAL KUMAR BOSE, *My Days with Gandhi* (1953, reissued 1974); ELI S. JONES, *Mahatma Gandhi: An Interpretation* (1948); and VINCENT SHEEAN, *Lead, Kindly Light* (1949). JAMES D. HUNT, *Gandhi in London* (1978), documents his five visits, with little-known details of those in 1906 and 1909. WILLIAM L. SHIRER, *Gandhi: A Memoir* (1979, reprinted 1982), is based on the author's work as a journalist in India in the 1930s.

Among the books highly critical of Gandhi are BHIMRAO R. AMBEDKAR, *What Congress and Gandhi Have Done to the Untouchables* (1945, reissued 1977); CHETTUR SANKARAN NAIR, *Gandhi and Anarchy* (1922); and INDULAL K. YAJNIK, *Gandhi As I Know Him,* rev. ed. (1943). MARTIN B. GREEN, *The Challenge of the Mahatmas* (1978), and *Tolstoy and Gandhi: Men of Peace* (1983), are the first and the last books of the author's trilogy on great leaders and their influence. RAGHAVAN N. IYER, *The Moral and Political Thought of Mahatma Gandhi* (1973, reprinted 1978), compares his concepts to those of Western thinkers. ARNE NAESS, *Gandhi and the Nuclear Age* (1965), and *Gandhi and Group Conflict* (1974), explore basic principles and assumptions of Gandhi's philosophical system. GLYN RICHARDS, *The Philosophy of Gandhi* (1982), explores the relation of his ideas to Hindu metaphysics and to contemporary philosophy. VED MEHTA, *Mahatma Gandhi and His Apostles* (1977), examines the spread of Gandhi's ideas.

There are numerous anthologies of Gandhi's writings. *Selected Writings of Mahatma Gandhi* (1951, reissued 1971), ed. by RONALD DUNCAN; and *All Men Are Brothers* (1959, reissued 1980), ed. by KRISHNA KRIPALANI, are judicious selections for the general reader. *The Words of Gandhi* (1982) is an illustrated selection of quotations, collected and edited by RICHARD ATTENBOROUGH.

Garden and Landscape Design

The vegetated landscape that covered most of the Earth's continents before men began to build still surrounds and penetrates even their largest metropolises. All human efforts to design gardens and to preserve and develop green open space in and around cities are efforts to maintain contact with the original pastoral, rural landscape. Gardens and designed landscapes, by filling the open areas in cities, create a kind of continuity in space between structural urban landscapes and the open rural landscapes beyond. Moreover, gardens and designed landscapes have a special kind of continuity in time. Buildings, paintings, and sculpture may survive longer than specific plants, but the constant cyclical growth and change in plants provide a continuous time dimension that static structures and sculpture can never achieve.

This article discusses the functional aspects of landscaping, the aesthetic and physical components of design, the various kinds of private and public design, and the role and development of gardening in human history.

The article is divided into the following sections:

Functions and concerns of garden and landscape design

ASPECTS OF LANDSCAPE ARCHITECTURE

Garden and landscape design is a substantial part but by no means all of the work of the profession of landscape architecture. Defined as "the art of arranging land and the objects upon it for human use and enjoyment," landscape architecture includes also site planning, land planning, master planning, urban design, and environmental planning. Site planning involves plans for specific developments in which precise arrangements of buildings, roadways, utilities, landscape elements, topography, water features, and vegetation are shown. Land planning is for larger scale developments involving subdivision into several or many parcels, including analyses of land and landscape, feasibility studies for economic, social, political, technical, and ecological constraints, and detailed site plans as needed. Master planning is for land use, conservation, and development at still larger scales, involving comprehensive areas or units of landscape topography or comprehensive systems such as open space, park-recreation, water and drainage, transportation, or utilities. Urban design is the planning and designing of the open-space components of urbanized areas; it involves working with architects on the building patterns, engineers on the traffic and utility patterns, graphic and industrial designers on street furniture, signs, and lighting, planners on overall land use and circulation, economists on economic feasibility, and sociologists on social feasibility, needs, and desires. Environmental planning is for natural or urbanized regions or substantial areas within them, in which the impact of development upon land and natural systems, their capacity to carry and sustain development, or their needs for preservation and conservation are analyzed exhaustively and developed as constraints upon urban design and master, land, and site planning. Within this framework of comprehensive survey, study, analysis, planning, and design of the continuous environment, garden and landscape design represents the final, detailed, precise, intensive refinement and implementation of all previous plans.

Various scales of design

Ideally all of these planning and design phases follow one another closely in a continuous sequential process, but this rarely happens. Various levels of planning and design are performed by different people at different times; often the more comprehensive phases are not performed at all or are performed in an oversimplified manner. The wise gardener or landscape architect, therefore, always begins with a careful analysis of conditions surrounding his project.

Function of garden and landscape design

Garden and landscape design deals with the treatment of land areas not covered by buildings, when those areas are considered important to visual experience, with or without utilitarian function. Typically, these land areas are of four types: those closely related to single buildings, such as front yards, side yards, and backyards, or more extensive grounds; those around and between groups of buildings such as campuses, civic and cultural centres, commercial and industrial complexes; those bordering and paralleling transportation and utility corridors such as parkways, freeways, waterways, power easements; and park-recreation open-space areas and systems. These areas may be of any size, from small urban courtyards and suburban gardens to many thousands of acres of regional, state, or national parks. Although usually conceived as vegetated green spaces on natural ground, they can include also playgrounds, urban plazas, covered malls, roof gardens, and decks, which may be almost entirely formed by construction and paving.

Garden and landscape design, therefore, works with a wide range of natural and processed materials capable of holding up well in the specific local climatic conditions of the site. These materials include earth, rock, water, and plants, either existing on the site or brought in; and construction materials such as concrete, stone, brick, wood, tile, metal, and glass.

ART, SCIENCE, AND NATURE

Garden and landscape design is uniquely concerned with direct relations among art, science, and nature. It operates exactly at the frontier between man and nature, developing transitional connecting zones between the outside limits of buildings and engineering structures and the natural forms and processes that surround them. This is true for large houses and gardens in the country, for regional parks at the edges of cities, for urban and suburban gardens, for urban plazas and roof decks; it is true wherever soil exists to be treated, wherever it may be brought in to fill containers, wherever open spaces are exposed to the weather.

If garden and landscape design is concerned with the relations between mankind and nature, it is largely determined by one or the other of the conflicting philosophies about how human beings do or should relate to nature. People know that they are biologically and physiologically the products of natural evolution; yet their great technological accomplishments lead them to feel that they are above, beyond, or outside nature, that they have conquered and dominated the wilderness and have it now within their power to remake the world. Every work of garden and landscape design reflects one or the other of these conflicting attitudes. The Japanese garden, for example, is inspired by the notion of mankind as a part of nature; the Renaissance garden, by the idea that humans are nature's masters. Garden and landscape design thus reveals much about a culture and a period. One result of the impact of the late 20th-century environmental movement on design in the West may be the emergence of design values that seek the integration of the human and the natural rather than their separation.

Garden and landscape design is an art insofar as it creates for people experiences that uplift their spirits, expand their vision, and invigorate their lives. It is a science insofar as it develops precise knowledge of its processes and materials. And it is directly related to and expressive of nature insofar as it incorporates natural materials and scenes. When the preservation of natural landscape is primary, as in a regional park, art and science manifest themselves in the skill and sensitivity with which necessary facilities and changes are related to the natural landscape. At the other extreme, in an urban plaza, trees in boxes or openings in the paving may be the only natural elements; art and science then are manifested in the design and construction of the total plaza, including its display of trees as symbols of nature, as pleasing forms, and as sources of shade.

Art, science, and nature become most intimately interlocked in certain aspects of horticulture expressed in designed gardens and landscapes: in improved varieties of herbaceous and woody plants; in the cultural practices that stimulate their maximum contributions to the scene; and in the techniques and skills for directing and reshaping the forms of plants—in a range from trimmed hedges and topiary (careful sculptural cutting), through espaliered (trained to grow flat against a wall or trellis) and pollarded (cut back to the trunk to promote a dense head of foliage) trees, to ultimate refinements such as the Japanese practice of removing individual needles from pine trees.

No doubt much art recognizes, expresses, or symbolizes nature in some way. Only the arts of garden and landscape, however, produce works in which nature participates directly with more processed forms and materials.

Functional and technical aspects

As in most other arts, garden and landscape design must solve not only aesthetic but also technical and functional problems. Gardens are for horticulture as well as for viewing, parks are for active recreation as well as for passive relaxation. The surface of the earth must be covered to prevent erosion, dust in summer, and mud in winter. Water persists in running downhill, and even light garden structures must have adequate footings.

This does not mean, however, that there is an inherent or inevitable conflict between utility and beauty. Such conflicts usually develop either because the designer tries to carry out an aesthetic concept that ignores the technical and functional requirements of the problem or because the program is so demanding technically, functionally, or economically that it eliminates aesthetic considerations from the design process. In most garden and landscape design situations it is necessary first to evaluate the technical conditions and functional demands and then to derive from them design concepts that resolve them.

Design

AESTHETIC COMPONENTS

Elements. The traditional elements of design are space; mass; line, or outline; colour; light and shade; texture; scent; and time, as related to climate, season, and growth factors.

Space. Space is air or atmospheric volume defined by physical elements and man's visual imagination. Space has floors: earth, rock, grass, low planting, concrete, asphalt, stone, brick, wood, carpet, tile, linoleum. It has sides or walls: topography, rock, vegetation, vertical structures. And it has ceilings: treetops, structural coverage, or the sky. The most easily understood spaces are the rooms, terraces, patios, and gardens of private residences. A room is defined precisely and unavoidably by floor, walls, and ceiling, particularly with doors closed and windows draped. Beyond these rooms there are the streets, squares, plazas, parks, and public buildings of the city. An urban plaza surrounded by major buildings likewise has positive floors and walls, with sky for ceiling. The fields, meadows, orchards, groves, forests, plains, lakes, river and stream valleys, hills, and mountains of the wider landscape have less precise and regular enclosures. Patios may have fences and walls, gardens hedges and trellises, but in parks there are loose spaces of many soft sizes and forms, defined by trees, ground forms, and shrubbery masses. And in the open landscape there are many different apparent space scales, from the intimate, small farming scenes of New England, Portugal, or Japan to the almost limitless panoramas of the Great Plains, Southwest deserts, or Rocky Mountains. In all of these, space is defined by ground or floor surfaces below, obstacles that block vision horizontally or terminate it at the horizon, and sky overhead. Man's sense of space in all of them results partly from what he actually sees and partly from his imaginative extension, interpretation, and structuring of what he actually sees. Thus, a sand dune, a rock, and a cactus may become a "room" in the desert, while the entire Yosemite Valley is a great room housing thousands of people.

Mass. Mass is the opposite of space. They define each other and depend upon each other for visual existence. Mass may be topographical earth forms, rock outcrops and boulders, trees and shrub groups, buildings, and water forms—streams, lakes, or waterfalls. These are masses in the larger landscape, even though they also incorporate spaces within themselves. Trees, shrubs, and buildings have multiple spaces within them, even though they read as masses from outside. Water forms contain spaces for divers and aquatic life, but of a different density.

Line. Line in the landscape may be the sharp edge of paving, structure, or rock; the boundary between two different surface materials, as grass and ivy; the edge of a shadow; or the silhouette outline of any three-dimensional form, such as a rock, plant, or building. Whatever its source, a line in the landscape plays an important role in the way man sees, interprets, and relates to the scene. A line may lead the eye into the distance, around a corner and out of the scene, or around the scene and back again, holding the viewer within it. It is similar to the role of lines in a painting, holding the viewer within or leading him out of the composition. In a landscape, however, the function of lines is vastly more complicated and difficult to predict. The pattern—that is, the form created by lines—is three-dimensional in any given scene that is viewed. It is four-dimensional in that a spectator continues to move through the landscape over periods of time. The pattern changes throughout each day because of the changing light and shade patterns produced by the movement of the earth around the sun. And the pattern is never exactly the same on one day as on any previous day, because of changes in the weather, the seasons, and the elements of the landscape. Buildings, topography, and rocks may be maintained almost the same for substantial periods of time; but vegetation changes constantly, with both seasonal adjustments and annual growth. That is one reason why landscapes without vegetation seem static, lifeless, and monotonous.

Line in painting and landscape compared

Colour. Colour gives physical landscapes that final dimension of real life, definition, and interest. Spring blossoms and fresh green leaves, after the cold barrenness of winter, herald a new season of vitality and fun. After the deep and stable green of summer, fall colours mark a last resurgence of liveliness before the winter barrenness sets in again. The apparent sizes and forms of landscape spaces change with each such seasonal change: bright colours advance, dull colours recede, changing apparent distances.

Structural colours, too, affect the apparent sizes and forms of landscape spaces. Most obvious is the negative effect of bright billboards upon quiet landscapes. To most people billboards seem destructive and arbitrary intrusions; they do not grow out of the scene but are forced onto it. Yet man-made forms—even billboards—can be made to appear to be a part of nature to the extent that they are designed to harmonize with the existing scene.

The aim of the garden and landscape designer is to combine the strong, artificial colours of paint and structure with the softer and more subdued grays, greens, browns, and blues of nature as well as with seasonal outbursts of the purest and truest colours in the world.

Colour variations

Colour varies by hue, the actual colour from the colour wheel; by value, the strength of the colours, bright or pale; the tone or grayness, how pure they are or how grayed by admixture with other colours; by the way that light and shade play on them; and by the texture, smooth or rough, of the surface they are on. All of these factors are taken into account by the garden and landscape designer.

Light and shade. Because the sun—and, to a lesser extent, the moon, stars, fire, and artificial lighting—has the property of casting shadows, landscape design, in placing trees, structures, and other elements on the land, must always take into consideration the light and shade resulting from such placement.

Light and shade are not the same in all parts of a country or the world. Light is welcome in cool, gray, northern climates, shade in hot, bright, desert or tropical regions. In the clear air of unspoiled deserts, man sees so far that he loses all sense of size, scale, and distance; in the foggy humidity of the western coasts of Europe and North America distances seen and objects perceived change from day to day, sometimes from hour to hour, so that one lives with a continuing sense of mystery and variety. Landscape design must, ideally, remain sensitive to and work carefully with the light and shade relations that are most desirable in each different region or subregion.

Texture. Texture—the smoothness or roughness of surfaces—is another element of landscape design. It is perceived primarily by touch, although through vision one approximates the textures of different surfaces and imagines how they would feel. The surface texture of the earth may vary from fine sand or silt to coarse clods, gravel, or boulders. The texture of plant coverage may vary from fine bent grasses through coarser meadow grasses to brush, ivy, or cactus. Wall surfaces range from the smoothness of glass and plaster to the roughness of brick, stone, or rough-sawn lumber.

Tactile textures must be experienced intimately. Visual textures may be experienced at any distance. Farther away, larger elements participate in texture effects; at medium distances the foliage of trees and the size of rocks create textural qualities; from an airplane or hilltop the size and arrangement of buildings, topographic forms, masses of vegetation, or water create textural effects.

Scent. Scent is a delicate and subtle element in landscape experience, often lost to 20th-century man because of widespread pollution of the air with foul-smelling exhaust and waste gases. The fragrance of flower and fruit is one of the traditional delights of garden and park, still attainable through sensitive selection and arrangement of plants.

Time, climate, and season. Unlike the static continuity of architectural and urban monuments, garden and landscape spaces are dependent on maintenance, which determines whether the form envisioned by the original designers will endure or change over decades or centuries. The Saihō-ji garden and many others in Japan continue today in much the same form as they began because of continuing maintenance. On the other hand, the inadequate maintenance of the Renaissance gardens—designed as geometric architectural abstractions, to which plant forms were made to conform by clipping and trimming—has allowed many of the larger plants to resume their natural forms. The results, however pleasant, are not what the designers envisioned. Instead of hundreds of years, the typical suburban garden in the United States has a predictable life of about five years. Ownership or tenancy tends to change in that cycle, with unpredictable results in the garden.

Maintenance of gardens

Time and climate are closely interrelated in their effects on garden and landscape spaces. Because relations between temperature and moisture, light and shade, change daily throughout the year, every region and locality on earth—in fact, every building site—has its own climate, unlike any other. Therefore, garden and landscape design for every region, locality, and site may be expected to be different. Nevertheless, climates can be generalized in certain broad categories that are similar, though not identical, over large areas of the earth.

Climatic factors having major impact on garden and landscape design are temperature range (hot to cold), precipitation range (high to low, rain to snow), their combinations (hot, wet summers; hot, dry summers; cold, wet winters; cold, dry winters; and so on), growing season (year around in the tropics, a few weeks in the Arctic), atmospheric humidity (clear air or clouds, fog, mist) and its effects on visibility and light-shade patterns, air movement (winds, breezes) and its effect on the other factors (cooling in hot weather, chilling in cold, moving clouds and fog).

The combination of all of these factors affects how one sees the landscape (bright, clear desert distances; soft, mysterious, changeable foggy landscapes), what one expects

from design (shade from the sun, protection from the wind, shelter from rain and snow), and how one designs gardens and landscapes. The patios, cloisters, and oases of Mediterranean and Middle East regions, the romantic naturalistic parks of Europe, China, and eastern North America, the esoteric garden abstractions of Japan—all of these different approaches to design were inspired partly by the particular qualities of the landscape climate in which they developed.

Time and natural light are, of course, intimately interlocked in the daily cycle of night and day, in the seasonal cycles (light is different in summer and winter because of differences in temperature and humidity), and in the annual cycles (long days in summer, short days in winter).

Time, climate, and season are all reflected in garden and landscape in the growth and change of plants. In the tropics, growth is constant and taken for granted, a problem of control. As growing seasons become shorter in the north and south or at higher elevations, they become more precious. In far northern and southern latitudes the short summer is a period of rejoicing and outdoor activity. A tree that will mature in five to ten years in Southern California or Florida will require 30 to 40 years in the North Central states. Spring blossoms, fall colour, the change from summer green to winter's exposed branch structures, all of these mark the seasonal changes clearly and strongly in the Eastern United States, in Europe, and in other temperate areas.

Principles. The basic principles of design deal with the arrangement or organization of the elements, as expressed in specific materials, on a specific site. The site—a piece of land, with surface form and internal content—may in itself require reshaping. On it will be placed—or may already exist—buildings, roads, minor structures, trees, shrubs, ground-cover planting, water elements, rocks.

The elements of design are contained in these individual components and in specific relations that may develop among them on a particular site. The principles of design—which deal with overall relations—are unity and variety, rhythm and balance, accent and contrast, scale and proportion, and composite three-dimensional spatial form.

Unity and variety. Unity and variety are derived from the number of elements, or kinds of material, within a given visual area and from the way they are combined. A brick building or a rose garden is unified by concentration on one material. The difficulty of achieving a sense of unity increases as the number of elements, or kinds of material, increase. A building of six materials or a garden of 30 kinds of plants, for example, will have more variety but unity can be achieved only by careful organization and arrangement. At a certain point, which varies with the situation and the skill of the designer, it becomes impossible to establish unity. Variety then dominates.

Rhythm and balance. Rhythm and balance result from the three-dimensional arrangement of elements and materials on the site. Rhythm is a sequence or repetition of similar elements—as a double row of trees. It tends to emphasize direction and movement, as along an allée toward a viewpoint or terminus. Balance is the sense one gets, looking in any direction, that the elements to one's left balance those to one's right and the feeling one has that the views one has just experienced are in equilibrium with what one sees now. The most obvious examples of balance are the symmetrical axial Renaissance gardens of Europe, but these are not the only or even the most interesting ways to achieve balance.

Difference between accent and contrast

Accent and contrast. Accent and contrast enliven arrangements that may be so balanced, orderly, and harmonious as to be dull. An accent is an element that differs from everything around it, as silver-gray foliage against dark-green conifers, but is limited in quantity in relation to surrounding elements. Contrast is stronger: two different elements may be juxtaposed in almost equal quantity to emphasize the special qualities of each. Well-known examples are the formal palace in the informal park, the green park in the densely built-up city. Accent and contrast are more difficult to handle successfully than straightforward, simple, harmonious design. An example of the failure to handle it successfully is the common practice of lining a street with alternate specimens of two quite different trees, as pines and cherries, which merely cancel each other out.

Scale and proportion. Scale refers to the apparent (not the actual) size of a landscape space or of the elements within it. Proportion is the determined relations among the sizes of all the parts within an element and of all the elements within a space. Thus, the proportionate sizes of the legs, arms, and back of a garden bench, for example, determine the scale of the seat. And the overall size of the seat, in proportionate relation to walk width, arbor height, lawn area, tree size, and so on, helps to determine the scale of the garden.

Composite three-dimensional spatial form. Composite three-dimensional spatial form results from the delineation of a block of air by physical elements, which enclose and frame the space and establish its relations with neighbouring spaces, distant views, and so on. A patio with paved floor and walled enclosure (with perhaps a grilled outlook) and sheltered by trees or pergola structures (arbor or trellis) is an obvious example of this form.

The design process. The design process has been called in the past modes of composition and style or period selection. In the first quarter of the 20th century, the arts, including architectural, garden, and landscape design, were dominated by traditional, eclectic, preconceived systems of form and approach called the Beaux Arts system, after the famous school in Paris. In essence, these systems told designers what to design and where. Their only choice and their only skill lay in how to adapt preconceived systems—such as formal and informal gardens—to the particular problem at hand. Innovation consisted of timid new relationships among traditional elements.

The modern revolt in design

In the first quarter of the century there also occurred what is called the modern revolt. Beginning in painting and sculpture, it soon swept through architecture and reached garden and landscape design toward the end of the quarter in Europe, reaching the United States in about 1935.

The essence of the modern revolt was the rejection of preconceived or traditional styles, periods, rules, regulations, or systems governing design. In place of these, systems and processes developed for analyzing problems and situations in their own terms and in terms of the modern resources available for solving them. Basic to the new theories was the idea that designed forms should arise from and express each specific situation and the contemporary, industrial culture around it. By the 1970s all fields of design seemed to be dominated by these theories; but, although submerged, traditional Beaux Arts design continues to surface regularly in strange new combinations with modern forms. A form of this eclecticism emerged in the early 1970s, when architects once again designed symmetrical monumental buildings with little functional or structural expression, and traditional formal–informal concepts in garden and landscape design began to reappear.

PHYSICAL COMPONENTS

Natural. Natural integrants of garden and landscape design include earth, rock, water, and plants.

Earth. As a base for design, earth is the floor of landscape spaces, the root medium in which half of every plant lives, the foundation for structures, the vehicle for surface and subsurface drainage of excess water, and a sculptural material in its own right.

As a floor, earth can be seen as an abstract surface. If apparently level, with just enough slope for drainage, it is ready to be covered with paving, grass, ground cover, or other planting, which is necessary to prevent dust in dry weather and mud in wet weather; if sloping or irregular, earthwork may be necessary to conform to new construction or to the design plan, to provide adequate drainage, or in order to relate properly to neighbouring topography and views.

Understanding earth as soil

As a root medium for plants, earth must be understood as soil. One must know the type and depth of soil before planning a garden or landscape. Soil occurs in layers: topsoil, in which there is a high percentage of organic humus and micro-organisms; subsoil, which is more sterile as it gets deeper; and bedrock, which is not yet broken up. There are many variations in these layers. In the mountains there may be only a few inches of soil over rock; in old valleys the soil may be hundreds of feet deep. Most plants require one to six feet of topsoil, with good drainage, but there are plants that will grow in rock, sand, sterile soil, boggy land, shallow water, or open water. If the soil is not adequate for the planting desired or if the form of the earth is to be changed, then new soil conditions must be created.

As a foundation for structures, earth must be dry and firm. Although structures can be built in almost any soil, they become more and more expensive as the earth becomes less dry and firm. Desirable foundation conditions, the exact opposite of the loose, moist soil that is best for most plants, create many technical problems in the relations between structures and plant areas.

As a drainage vehicle, earth absorbs a high percentage of the water that falls on its surface. This absorbed water may be stored below ground, or it may move horizontally through sloping soil patterns. Surface water that is not absorbed, either because the soil is saturated or because the slope of the ground makes it run off too fast, must drain away on the surface. This creates many technical problems, especially if the surface is not covered to prevent erosion or if a great deal of land is covered by roofed structures or paved surfaces, which increase the amount of water running off because none is absorbed.

As a sculptural material, earth can be contoured to conform with functional and maintenance demands. Rolling natural hills and golf-course earth forms demonstrate the potential. Slopes must not be too steep for planting to hold, unless they are structurally retained.

Rock. Rock is a major factor in some regions, minor in others, nonexistent in some. It varies in size from sand through pebbles, cobbles, boulders, and fixed outcrops to solid-rock mountains. It varies in form from square or jagged, newly cut or broken to rounded forms produced by the action of water. It varies also in colour and in texture. It can be used as a ground cover, dry or in cement; in vertical structures with various degrees of cutting and finishing; to simulate natural rock formations; and in sculptural groupings that emphasize the natural form of the rocks, as the Japanese do so well.

Water. Water is essential to all gardens and landscapes,

even in the desert, although amounts vary considerably. As a design element, water contributes coolness, moisture, sparkle, lightness, depth, serenity, the possibility of aquatic plants and animals, and recreation. It may run through natural stream and river channels and collect in natural ponds, lakes, and seas, or it may be kept in structural channels and pools, recirculated to avoid waste. In some soil conditions it may be necessary to seal thc bottoms of natural-appearing streams and ponds to hold the water. Under natural conditions water runs downhill through naturally formed channels and collects in low spots or bowls of firm form. Water also may be pumped uphill or thrown into the air in jets and fountains. Water is used increasingly throughout countries with technically complex artificial irrigation systems, which become distinctive landscape elements.

Aesthetic qualities of water

Plants. Plants are considered the primary material of gardens and landscapes, by contrast with the concentration of structures in cities. They may be grouped and organized for design purposes in several ways: by size (trees, shrubs, low plants, grass); by form (vertical, horizontal, round, irregular); by texture (size, shape, and arrangement of foliage and structure); by colour (flowers, fruit, foliage, structure); by rate of growth (fast, medium, slow); by seasonal effect (spring, summer, fall, winter); by fragrance (flowers, fruit, foliage); by environmental requirements (soil, drainage, sun–shade, temperature range, pests and diseases, pruning needs). All of these properties affect the selection, arrangement, and maintenance of plants in designed landscapes.

Structural. Structural integrants of garden and landscape include structures closely related to the earth, enclosure structures, shelter structures, engineering structures, and special buildings.

Earth-related structures. Earth-related structures include paving (walks, roads, terraces, patios) and change-of-level structures (retaining walls, steps, ramps, bridges), which must be made of materials that will resist decay, such as brick, stone, concrete, asphalt. These structures provide the connections for movement and circulation and the areas for intensive gathering, social use, or active recreation. They embody a complex technology.

Enclosure structures. Enclosure structures, such as walls and fences, are designed to control vision or movement or both. They may be of various heights, three to ten feet (one to three metres) or more, and of many materials: brick, stone, or concrete masonry; wood; metal; sheet materials such as glass, plastic, asbestos, pressed boards. Because they are at eye level and extend and connect buildings, they are very important in intimate visual design.

Shelter structures. Shelter structures, designed to protect from sun, rain, or wind, may incorporate enclosure elements at the sides with overhead elements, which may be open framework pergolas or arbors carrying vines or solid opaque or translucent roofs. Among such structures are gazebos, pavilions, garden temples, summer houses, hermit huts, follies, ruins, and grottoes.

Engineering structures. Engineering structures tend to appear unexpectedly, because incongruously, in gardens and landscapes. They are usually mechanical or electrical transformers, vents, valves, siphons, drains, culverts, headwalls, dams, and many other nameless and mysterious forms. In a good landscape design, these structures are integrated into the overall plan.

Special buildings. Special buildings include many that are nearly as complete as the fully enclosed buildings that are the province of the architect: greenhouses, conservatories, orangeries, tool sheds, dovecotes, icehouses, root houses, bathhouses, playhouses, and many more. These are usually auxiliary in relation to the main house or building but relate to them in character and detail.

Shelter structures, engineering structures, and special buildings are important in garden and landscape because they introduce precise geometric forms intermediate in scale between main buildings and landscape. If scattered or designed indiscriminately, they can destroy a pleasant landscape; carefully designed, they can be so grouped or arranged as to create rhythmic connections and patterns within the overall architectural-landscape design concept.

Importance of structures and buildings in design

Sculptural components and outdoor furnishings. Sculptural components of garden and landscape have traditionally been predictable forms and types: figurative sculpture, decorative urns and plaques, fountains, sundials, birdbaths, cisterns, and wells. All of these continue to appear as elements of the persistent underground Beaux Arts vocabulary. In contemporary design, however, they are eliminated or take on new forms derived from modern sculpture. The possibility now exists for the production of gardens and landscapes so completely sculptured that one cannot tell where design stops and sculpture begins.

Outdoor furnishings and equipment include all of those fixed and movable elements that tend to appear in garden or landscape after the plans are done and installed and therefore without benefit of design control. In the garden they are seats, tables, barbecues, umbrellas, plant containers, supports, and guards, as well as lights and light systems. In the public landscape they include these garden elements and many more: signs, trash containers, alarm boxes, mailboxes, newsstands, kiosks, service elements, telephone stands. If all of these elements are not predicted insofar as possible in the original design plans, incorporated in them, and carefully controlled thereafter, they can destroy carefully planned landscapes. One red oil drum for trash can dominate the visual experience of a large, pastoral picnic area.

Kinds of design

The landscape is everything an observer, whether still or in motion, can see. The landscape as a work of individual art is any garden or space designed, developed, and maintained for the private experience of an individual or family, a space not accessible to others either physically or visually. The landscape as a work of collective art is everything beyond this private range: everything seen beyond the confines of private gardens or estates, all borrowed landscapes, all streetscapes, all city, metropolitan, and regional landscapes, and their accumulation in national, continental, and world landscapes. This collective art may be good or bad depending on whether it results from the accidental accumulation of individual and conflicting efforts or from controlled and planned efforts.

PRIVATE OR RESIDENTIAL DESIGN

The history of landscape design is largely the history of landscape as a work of private, individual art. Plazas (structural public open spaces not dominated by foliage), throughout classical, medieval, and Renaissance history, were the concessions of the ruling class to the need for public meeting places; but it was not until Central Park was developed in New York City in the mid-19th century that this need reached the level of designed public green spaces. During most of its history, landscape design was of three kinds: private utilitarian farms and gardens; private gardens in which the enhancement of the quality of living was paramount; and private gardens designed to express the power and benevolence of the ruling or upper classes. The expansion in scale of private gardens beyond the needs of private living led inexorably, first, to the dedication of such spaces to public use and then to the development of public gardens and parks designed for public use.

Kinds of private gardens

The private garden, however, has remained the centre for private fantasy and a means of escape from the grinding and difficult world of reality. The most important aspect of the private garden is its seclusion: from the physical world, by means of distance and enclosure; from the social world, by separation and exclusion. Space and greenery are also important. The space may be very small, perhaps a tiny courtyard, and greenery limited to one or two plants, but these make possible that private world of fantasy that may make the difference between sanity and lunacy. The 20th-century mass migration to the suburbs is the latest expression of this need.

Generally, the private garden occupies a space somewhere between 20 feet (six metres) square and one quarter of an acre (100 feet square). The forms of private gardens range from the formalism of pure geometry or the artistic representation of natural processes through the variations of standard gardening techniques and the informalism of letting nature take its course to various manifestations of literary, poetic, historic, and subjective concepts.

When housing moves from single-family, detached buildings on private lots to higher density variations—duplexes, semidetached villas, town houses, clusters, condominiums, low- and high-rise apartments—new relationships develop. As population density increases, private design shrinks and public design increases. Somewhere between the extremes of the single-family dwelling with minimum public space and the high-rise apartment with minimum private space, there is an optimum relationship in which real needs can be expressed. Perhaps the best potential lies in town-house, cluster-house, and condominium developments, in which there is a flexible relationship between public and private elements.

PUBLIC DESIGN

Because of fixation on the notion that the original resource of land and landscape, continuous from sea to shining sea, is best organized for private or public use by gridiron subdivision into innumerable separate parcels, public landscape design begins at the level of single buildings on single lots, with front yards and backyards. The buildings may be government offices, quasi-public companies, or private corporations, but all tend to be designed in terms of public and private spaces, as though they were private residences for the groups involved.

Campus design

Campus design begins when publicly accessible buildings grow into complexes of two or more, for religious, commercial, industrial, governmental, or educational use. Instead of or in addition to simple front-yard and backyard design, there are more complex systems of spaces between buildings, which vary from courtyards and quadrangles of varying forms and dimensions to passageways connecting them in varying widths and degrees of overhead coverage. The open spaces range in character from paved architectural courtyards and cloisters to open playing fields and parklike spaces. Campus design makes possible the richest, most complex, and rewarding range of relationships between architectural and landscape design. Perhaps the best examples, in which the sequential experience of indoor and outdoor space approaches the maximum, are the religious, educational, and civic complexes of Europe, developed before the idea of gridiron subdivision fragmented environmental design. In China and Japan there are many highly refined and sophisticated temple, shrine, palace, and castle complexes. There are also many fine examples in the United States of similar institutions that have transcended or resisted subdivision.

Urban design

In the broader area of urban design, landscape architecture deals with such open-space components as public gardens, parks and playgrounds, plazas, squares, and malls. In these urban spaces, the designer attempts to meet the need for community, for play and recreation, for refreshment and relaxation, for individual withdrawal in a gregarious atmosphere.

Towns, cities, and metropolitan areas may be said to have three basic components: buildings, designed by architects or builders; open spaces, designed by landscape architects or technicians; and circulation-utility corridors—street, highway, railway, and rapid-transit systems—which are usually planned and designed by engineers.

The basic structure of urban areas consists of the open spaces together with corridors comprising a total open-space system, defined by and connecting the buildings. The corridors have usually been considered merely a utilitarian framework, connecting and servicing buildings and quality open spaces, channelling traffic and utilities throughout urban areas, and connecting them with the open country around. Modern urban thinking has begun to go beyond this concept, to see the total open-space-corridor system as the major qualitative structure of the city, which, when viewed in conjunction with overall building design, is seen to establish the city's basic character.

From this point of view the role of landscape architecture, once limited to tasteful planting of corridors designed by engineers, begins to expand. Some urban planners would expand it even further, believing that open-space corridors should be designed throughout primarily as social spaces for people and only secondarily as utilitarian passages for vehicles.

Commemorative sites—cemeteries, historic spots, battlefields—are important because they memorialize and symbolize important events in personal, local, national, or world history. Wherever they occur, these sites or areas are marked with stone or bronze memorials and often dramatized with more elaborate developments. The designs tend to follow traditional and conservative precedents, often impressive but seldom imaginative. It is still difficult to equal Asplund's Forest Crematorium (1940) in Stockholm or the Fosse Ardeatine memorial in Rome. (G.Ec.)

Historical development

The earliest surviving garden plan

entrance is aligned on a pergola (trellis-bordered) walk of vines leading directly to the dwelling. The rest of the garden is laid out with tree-lined avenues, four rectangular ponds containing waterfowl, and two garden pavilions. Although rigidly symmetrical, the garden is divided into self-contained, walled enclosures, so that the symmetry of the whole could not have been apparent to the viewer. Such a highly developed pattern argues a considerable incubation period, and it is likely that similar enclosed pleasure gardens had been designed as early as 2800 BC.

Assyrian, Babylonian, and Persian. The gardens of Assyria, Babylon, and Persia were of three kinds: large, enclosed game reserves such as the garden of Eden described by the Hebrews in the Old Testament; pleasure gardens, which were essentially places where shade and cool water could be privately enjoyed; and sacred enclosures rising in man-made terraces, planted with trees and shrubs, forming an artificial hill such as the Hanging Garden of Babylon.

Greek and Hellenistic. The urban life of ancient Greece led to houses built around central, private courtyards. Lined with colonnades that gave access to the rooms of the house, the courtyard, or peristyle, was open to the sky and insulated from the street. In the peristyle was a garden consisting of a water supply and potted plants. Much of life, however, was lived in public. The sports grounds, where exercise was taken, became popular gathering places and developed into the original academy and lyceum, which included the exercise ground, seats for spectators, porticoes for bad weather, statues of honored athletes, and groves of shade trees. These public recreation grounds set the type for the later classical Roman villa garden and the 19th-century European public park. A third type of Greek garden was the sacred landscape, such as the Vale of Tempe or the mountain sanctuary of Delphi.

The relatively austere Greek taste was transformed in the Hellenistic Age (*c.* 323 BC–30 BC) by the influence of the East. Luxurious pleasure grounds were made, especially at colonies such as Alexandria and Syracuse. These gardens were conspicuously luxurious in their display of precious materials, and artificial in their use of hydraulic automata.

Roman. Roman gardens derived from the Greek, those in the seaside resorts of Pompeii and Herculaneum (1st century BC) following the Hellenistic pattern. These small, enclosed town gardens were visually extended by landscapes painted on the walls. Throughout the imperial period, the more ambitious villa gardens flourished in many forms on sites carefully chosen for climate and aspect.

The most elaborate was that of Nero's Golden House, which covered over 300 acres (120 hectares) in the middle of Rome and included an artificial lake (where the Colosseum now stands) and a pastoral landscape of plowland, vineyard, pasture, and wood. More influential in later times was the vast garden complex of Hadrian's Villa, of which extensive ruins can still be found near Tivoli.

Middle Ages. The barbarian invasions of the 4th and 5th centuries AD destroyed Roman civilization and with it the gardens of western Europe. The Eastern Empire, centred on Constantinople, retained its hold on Greece and much of Asia Minor for another millennium; and Byzantine gardens persisted in the Hellenistic tradition, laying more emphasis on wonder-provoking apparatus than on aesthetic values. A recurrent feature of these gardens was a tree of gold or silver equipped with birds that flapped their wings and sang and branches that sprayed wine or perfume.

Byzantine gardens

Islāmic. Beginning in the 7th century, the Arabs progressively captured much of western Asia, Egypt, the whole of the North African coast, and Spain; in the process, they spread features of Persian and Byzantine gardens across the Mediterranean as far as the Iberian Peninsula. Most characteristic of these gardens was the use of water—the ultimate luxury to desert dwellers, who appreciated it not only because it allowed plants to grow but also because it cooled the air and gratified the ear with the sound of its movement. It was commonly used in regularly shaped, often rectangular, pools. The water was kept moving by simply designed fountains and fed by narrow canals resembling agricultural irrigation channels. Because water was rarely abundant, the pools were shallow but increased in apparent depth by a blue tile lining.

SCALA—Art Resource

These pools of water graced Islāmic gardens—such as those of the Alhambra in Granada—that resembled the Hellenistic colonnaded courtyard. The gardens provided shade, excluded hot winds, and created the sense of being in a jewelled private world. Water mirroring the sky gave an impression of spaciousness and introduced lightness, brightness, and an air of unreality.

In the Moorish Caliphate of Córdoba in Spain, in the valley of the Guadalquivir, there were said to have been 50,000 villas, all of which probably had such garden courts.

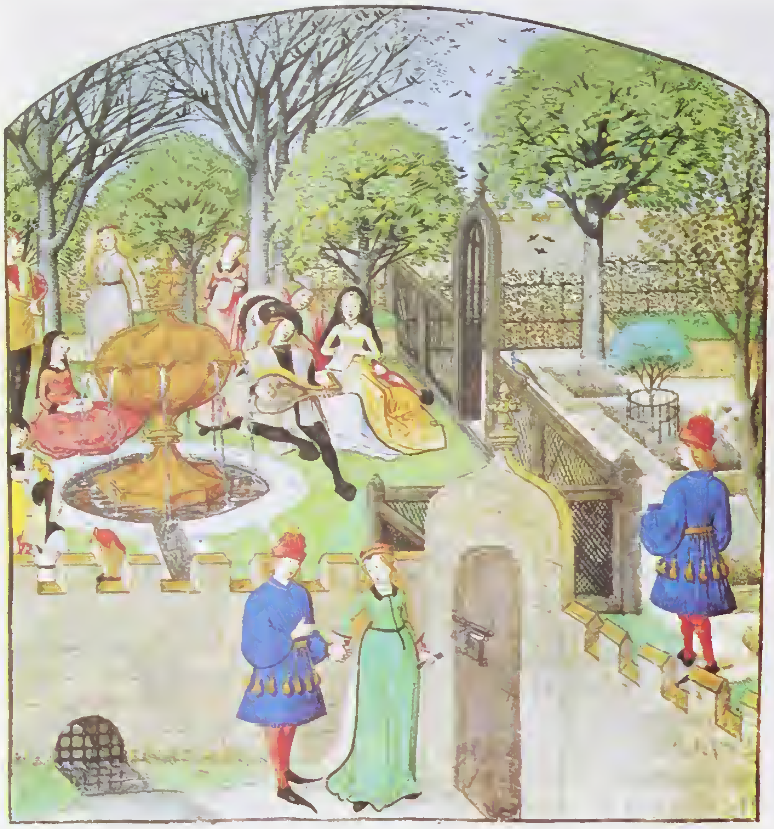
The greatest period of garden making in the Islāmic world was the 14th century. In the vicinity of the conqueror Timur Lenk's capital of Samarkand, the names of 11 royal gardens are recorded, and there were probably others belonging to his nobles. Whereas gardens of the Alhambra type were architecturally conceived within the total plan of a building, some of the more extensive Timurid gardens and their derivatives, the Mughal gardens of India, were pleasances of water, meadow, trees, and flowers, in which buildings took a subordinate place. Although these garden buildings were permanent, their subordinate role and the lightness and luxuriating frivolity of their design mark them as heirs of the casually positioned tents seasonally erected in hunting parks. There were also gardens of strictly architectural design—huge walled enclosures with corner towers, a central palace, regularly disposed avenues, and tanks of water. Deer and pheasants were kept in these gardens, which combined the quality of hunting park and of *hortus conclusus,* or closed garden. Trees were planted sometimes in regular quincuncial patterns (one in the middle and one at each corner of a square or rectangle) but more often freely. In all types of Islāmic gardens, flowers were lavishly used. Their presence was even simulated in garden carpets and in the woven hangings that were used as temporary screens.

Parks made by the Saracen emirs of Sicily

Influential on later Western practice were the parks made by the Saracen emirs of Sicily. The Normans who conquered the Saracens in the 11th century adopted the manner of life of those they had overthrown, and thus the emirs' gardens survived their makers. A large area of the Conca d'Oro, the great natural amphitheatre behind Palermo, was taken up with pleasure grounds—walled enclosures large enough to contain woods and hills, canals, artificial lakes, groves of oranges and lemons, fountains, water stairways, and wild creatures running free.

Western European. In Europe, beyond the limits of the Islāmic conquest, the destruction of civilized society by the barbarian tribes had been nearly complete; but the physical remains of the past shaped the reviving future: the peristyle gardens of Roman villas became the cloisters of Christian basilicas. Security and leisure existed only in the monastic system, which also preserved some of the traditional skills of cultivation. For some time the only type of garden was the cloister, with its well, herbs, pot plants, and shaded walk. Then secular gardens began to appear, but they were usually of limited extent, confined within the fortifications of a castle and often raised well above ground level on a battlemented turret. These Gothic gardens were rectangular, with the traditional division into four parts by paths, the quarters again subdivided according to the amount of ground available and the convenience of cultivation. At the point of principle intersection was a well, which, when elaborated, became the vertical feature of the garden. Seats—often of turf—were constructed in



Medieval walled garden combining a grassy and shaded pleasure area with an herb garden. *Roman de la Rose*, miniature from a 15th-century French manuscript. In the British Museum.

the walls. Many flowers were grown, but their season was short; after June and often earlier, the beds were flowerless. More extensive and elaborate gardens were rare.

Italian gardens of the Middle Ages

In 13th-century Italy, through the influence of the Holy Roman emperor Frederick II, who had spent much of his youth in Sicily, the example of the Saracen emirs was felt in Apulia and Naples. The *Triumph of Death*, painted by the Florentine artist Andrea Orcagna (Pisa, Campo Santo), shows a garden of considerably greater extent than the cloister or battlement type. Gardens like this existed also in Lombardy, where the court of Gian Galeazzo Visconti, the founder of the great walled park of Pavia, cultivated the arts of civilized life. In describing the Royal Gardens at Naples, the writer and poet Giovanni Boccaccio speaks of statues disposed regularly around a lawn, interspersed with marble seats. Such a garden suggests that Frederick II's classicizing influence extended into the mid-14th century. Also significant was the garden of Hesdin in Picardy, which became famous throughout France for its automata and water tricks. It was made by a crusader who, having returned to France by way of Palermo in 1270, no doubt incorporated in his garden what he had seen of Saracenic gardens there and in Syria. Hesdin was an exotic creation without parallel in its northerly location for several centuries.

Renaissance to modern: 15th to 20th centuries. *Italian.* The increasing prosperity of western Europe and man's increasing confidence in himself and in his capacity to impose order on the external world was reflected in the gardens of Italy by the mid-15th century. The change began near Florence, where the old medieval enclosures began to open up. The rectangles, which had been dissociated, were now sited one behind the other, thus prolonging the main axis, which was now aligned on the centre of the dwelling. This change inevitably introduced the idea that house and garden were a coherent, complementary whole. And, because villas were increasingly sited for amenity rather than defense, gardens became less enclosed, more susceptible first to visual, then to actual extension.

The unity of house and garden, together with the need for physical adjustment to the sloping sites favoured by classical precedent, threw the planning of the new Renaissance garden into the hands of architects. Most influential was the garden courtyard designed by Donato Bramante at the Vatican to link the Papal palace with the Villa Belvedere; the uneven site and the disparity in bulk of the two buildings was overcome with terraces and stairways. It remained an enclosed garden but one far removed from the earlier cloistral courtyards. The garden of the Belvedere combined the function of an open-air room with that of an outdoor sculpture gallery.

The typical Italian Renaissance garden

The ingredients of the Renaissance garden thus separately established were united in varying proportions. The typical evolved garden of the period was characterized by some openness of aspect, axial development, a tendency to prolongation, unity of concept between house and garden emphasized by a considerable "built" element of stone, lavish employment of statuary (often in the form of fountains), and the proliferation of such classical accents as grottoes, nymphaea (Roman buildings with a fountain, plants, and sculpture), urns, and inscriptions. There is no adequate evidence that this type of garden had an exact equivalent in the classical period, although there is evidence that each of its elements existed.

The variation in style among Italian gardens is considerable and is due not only to the date they were made, the exigencies of the site, and regional variation but also to their social function. The scale of the garden compartments at the back of the Villa Gamberaia at Settignano (1610), for example, is small in contrast with the extensive view over Florence from the front and thus suggests intimate use by members of a small household. The more extensive parterre garden (an ornamental garden with paths between the beds) of the Villa Lante at Bagnaia (begun 1564) is designed neither for solitary enjoyment nor for a crowd but for a select, discerning company—as is the garden of the far more splendid Villa Farnese at Caprarola (completed 1587). The most remarkable mid-16th-century garden, that of the Villa d'Este at Tivoli (1550), is situated on a steep slope of the Sabine hills. The river that plunges down this slope is harnessed to an astonishing variety of fountains, including a "water organ."

Although the garden is designed around a central axis, the stream is not used centrally but is led about the garden in order to take maximum advantage of its force. Unlike the less copious stream of the Villa Lante garden, which quietly emphasizes the central axis, the Tivoli stream is ostentatious. The Villa d'Este is, in fact, a spectacular permanent theatrical performance meant to astonish and impress the multitude. A different impression is given by the Boboli Gardens of the Pitti Palace at Florence (1550). Though, like the Villa d'Este gardens, they were designed for a crowd—specifically, for state functions—they are not dramatic in themselves. Unless used ceremonially, they are lifeless and arid. The ruined garden associated with, though detached from, the Orsini Castle at Bomarzo is a remarkable aberration probably influenced by accounts of visits to the Far East by a locally born traveller, Biagio Sinibaldi. Its original layout consisted of a grove in which were concealed the stone giants and strange monsters that now astonish visitors.

Flowers were extensively used in most Italian gardens, but because of the shortness of their season they could not be the principal feature. Beds were divided into decorative geometric compartments by trimmed herbs, rosemary, lavender, or box. In general, more emphasis was given to evergreens; ilex, cypress, laurel, and ivy gave shade and were an enduring contrast to stonework.

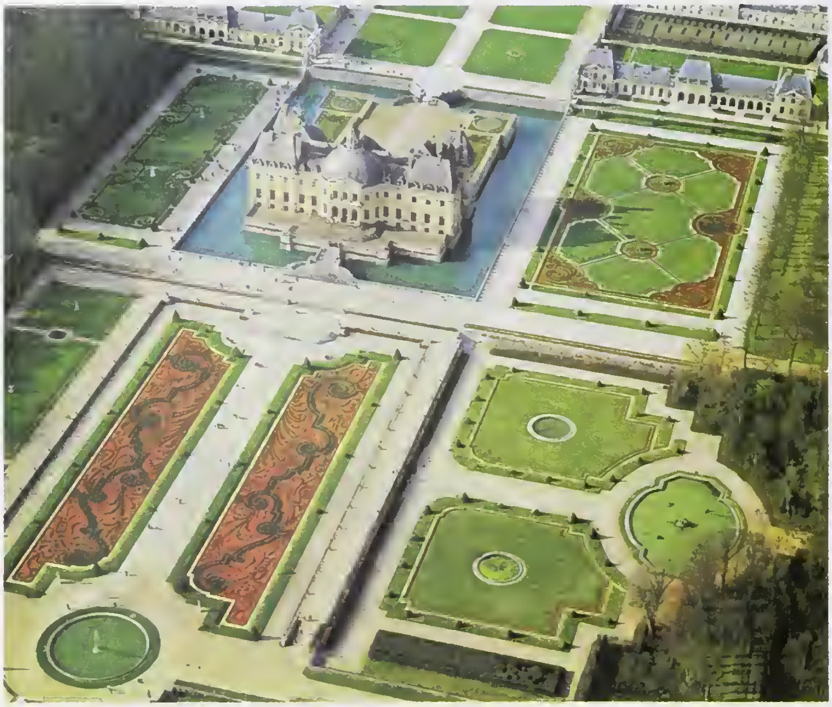
Influence of the Italian garden in France

17th- and 18th-century French. The French invasions of Italy in the last quarter of the 16th and first quarter of the 17th centuries introduced to France the idioms of the Italian garden. The first garden coordinated with dwelling appeared at the Château of Anet (1547–56) and was designed by the architect Philibert Delorme; but, despite its evident sophistication, it remained an inward-looking, essentially medieval garden. The first sign of prolongation and calculated extension of vision beyond the garden proper appeared in the grounds of Dampierre. Here the moat that formerly surrounded French castles became an ornamental body of water on one side and a decorative canal on the other. Both aspects of the new garden design—coordination with the dwelling and extension along a central axis—were united at the château of Richelieu (1631) and later at Vaux-le-Vicomte (completed 1661), the château of Nicolas Fouquet, the minister of finance. On Fouquet's fall in the mid-17th century, his team of artists—which included the landscape designer André Le Nôtre—was taken over by the young Louis XIV, and the gardens of Versailles were begun.

Typical French classical-baroque gardens

The French version of the Italian garden was created in the plain of north France, which largely conditioned the manner of its development. The array of steep terraces linked by stairways, which characterized the Villa d'Este and many others, was predominant in France only at St. Germain-en-Laye, where the steep site permitted it. Elsewhere, grandeur on the scale that competitive pride demanded was achieved by extraordinary extension: an axial development suggesting a domain coextensive with the world. The French 17th-century garden, a manifestation of Baroque taste, required variety as well as unlimited vista and achieved it with fountains, parterres, and lesser gardens disposed within the boscages (wooded enclosures) that flanked the central axis. These hidden gardens were the successors of the *giardini segreti* of the Italians but had a different function; they were not retreats for private contemplation or intimate conversation but the setting for ingenious theatrical entr'actes. Distinctively French was the unified and elaborate treatment of the compartmentalized garden beds, which the Italians had made in a variety of forms. These *compartiments de broderie* were arabesques, sometimes of box edging and flowers but more often of coloured stones and sand. The Persians had copied their flower gardens on carpets and taken them indoors; the French laid out their grounds in the form of carpets. The French garden was marked by a ruthlessly



Parterre de broderie composed of box, brick dust, earth, and sand, at the château of Vaux-le-Vicomte, France, a late 19th-century re-creation by Henri Duchêne based upon late 17th-century designs by André Le Nôtre.
Alain Perceval, Paris

logical extension of practices that had been empirically evolved in Italy.

French cultural dominance of Europe in the early 18th century led to an almost universal adoption of Versailles as the model for palatial gardens. Even at Naples, where the gardens of Poggio Reale had astonished the invading French in the late 15th century, a vast layout inspired by the axial extent of Versailles was developed at Caserta; and, as far away as Peter the Great's Peterhof in Russia, a pseudo-Versailles was laid out by the French gardener Alexandre-Jean-Baptiste Le Blond. Impressive exercises in the same manner were carried out in Germany and Austria. In Holland, also, the example of the French garden was irresistible, although local conditions and national temperament led to regional variation. Because Dutch canals were busy highways, they generally flanked gardens rather than constituted the main axis. No luxury in Holland, water was less extravagantly used than in drier, hotter climates. Moreover, fountains were less common because the absence of high ground required that they be power driven. Because stone was scarce, terraces were usually held by turf banks rather than by retaining walls, and sculpture was often of lead. Another sculpture typical of the Dutch garden was topiary: trees and shrubs were trained, cut, and trimmed into sculptural, ornamental shapes. Social conditions made the extension of a geometric garden easy, for a man-made landscape already existed in the intensively cultivated Netherlands. In Spain, aridity as well as Islāmic tradition perpetuated the patio garden, a room of air and shade in the Greek peristyle tradition. Although a famous layout in the French style was made on high ground at La Granja, where the cooler air and ample water made it acceptable, the classical extension garden remained basically alien to the Iberian Peninsula.

17th- and 18th-century English. The Italian pronouncement "things planted should reflect the shape of things built" had ensured that gardens were essentially open-air buildings and the making of them the province of architects. Before the 18th century, geometric regularity had been applied in great details of design and in small. England was committed to a version of the French geometric extension garden but with an emphasis on English grass lawns and gravel walks. Whereas the typical French vista was along the main axis, with subordinate vistas at right angles to it, in the two most influential gardens in England, St. James's and Hampton Court, the vistas sprang like the rays of the sun from a semi-circle. With the accession of William and Mary (1689–1702), Dutch influence led to widespread use of topiaried yew and box.

In 18th-century England, people became increasingly aware of the natural world. Rather than imposing their man-made geometric order on the natural world, they began to adjust to it. Literary men, notably Alexander Pope and Joseph Addison, began to question the propriety of trees being carved into artificial shapes as substitutes for masonry and to advocate the restoration of free forms.

Revolt against the "artificial" symmetrical garden

The man who led the revolt against the "artificial," symmetrical garden style was the painter and architect William Kent, the factotum of the Earl of Burlington. Together Burlington and Kent created at Chiswick House (1734) a garden with a meandering stream and an "irregular" path. As the writer Horatio Walpole put it, Kent's "principle was that nature abhors a straight line." The process of relaxing the garden's architectural discipline advanced with speed. At Stowe, Buckinghamshire, the original enclosed, geometrical garden was amended over the years until a totally different, "irregular" formality was achieved. Trees, for example, were allowed to assume their natural forms, and a large expanse of water was redesigned into two irregularly shaped lakes.

The use of the ha-ha, or sunken fence, to create and at the same time conceal the physical division between garden and contiguous park grounds (a division needed to keep grazing animals out of the garden) was a major step in the creation of the new, "natural" garden. Walpole explains the purpose of the visual unification:

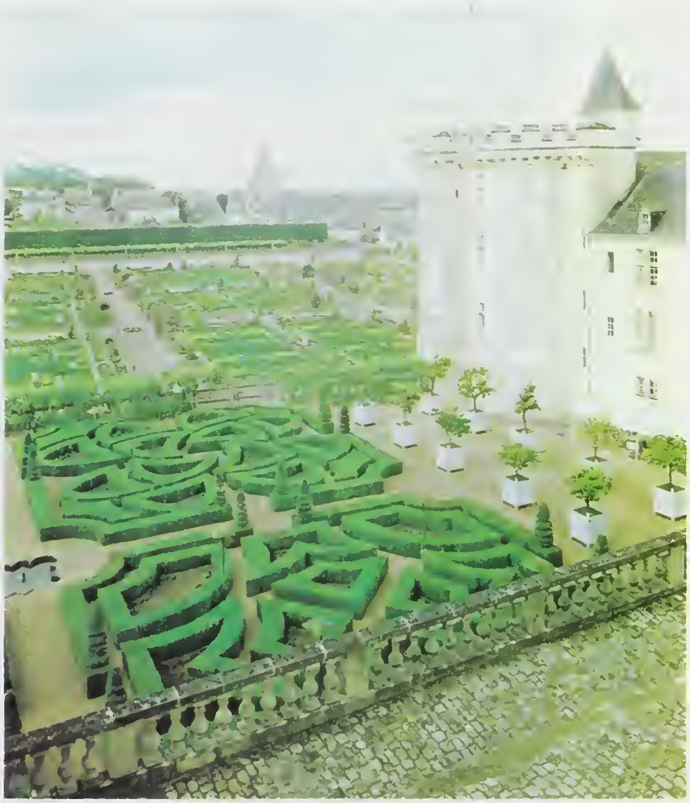
> The contiguous ground of the park without the sunk fence was to be harmonized with the lawn within; and the garden in its turn was to be set free from its prime regularity, that it might assort with the wilder country without.

The "natural" English gardens of the 18th century

The face of the "country without" was altered by the rage that afflicted the English nobility for planting vast areas of trees. Much of England was covered with new parks, traversed by rides and avenues that primarily were conceived as visual extensions of the garden paths. The unification of park and garden was virtually completed by Lancelot "Capability" Brown (1715–83) by the simple expedient of making the garden into a park. "Capability" (so-called because he always spoke of a place as having "capabilities of improvement") developed the current aesthetic that an undulating line was "natural" and that it was the "line of beauty" by using little statuary and few buildings and concentrating on designing landscapes according to nature's harmonies and gradients. His landscapes consist of expanses of grass, irregularly shaped bodies of water, and trees placed singly and in clumps.

Although the adherents of the new English school of garden design were in agreement in their abhorrence of the straight, classical line and the geometrically ordered garden, they did not agree on what the natural garden should be. Unlike Brown, for example, the taste for the romantic and the literary led many to seek inspiration in the dramatic and the bizarre, in the remote past, and in remote, exotic places. The Brownian style was strongly challenged, for example, by the "Picturesque" school, led by Sir Uvedale Price and the artist-parson William Gilpin, who argued, quite correctly, that the "naturalism" of the Brownians was no less unnatural than the geometric regularity of Le Nôtre's Versailles and that sudden declivities, rocky chasms, and rotting tree trunks (all deliberately designed) were more proper for the natural garden than were enormous, undulating meadows accented with tight clumps of thickly planted trees. Another school of opinion created what might be called the English garden of poetic bric-a-brac. The aim in this garden was to create an air of accident and surprise and to arouse varied sensations (solemnity, sublimity, terror) in the viewer—sensations evoked by associations with the remote in time and space. Wandering through the grounds one came upon classical statues, urns, and temples; Gothic ruins, ivy-covered and inhabited by owls; or Chinese pagodas and bridges. After Horatio Walpole recorded the first appearance of chinoiserie at Wroxton in 1753 (a garden no doubt laid out some years before), "Chinese" and Gothic details were featured, together with classic temples, in most fashionable grounds.

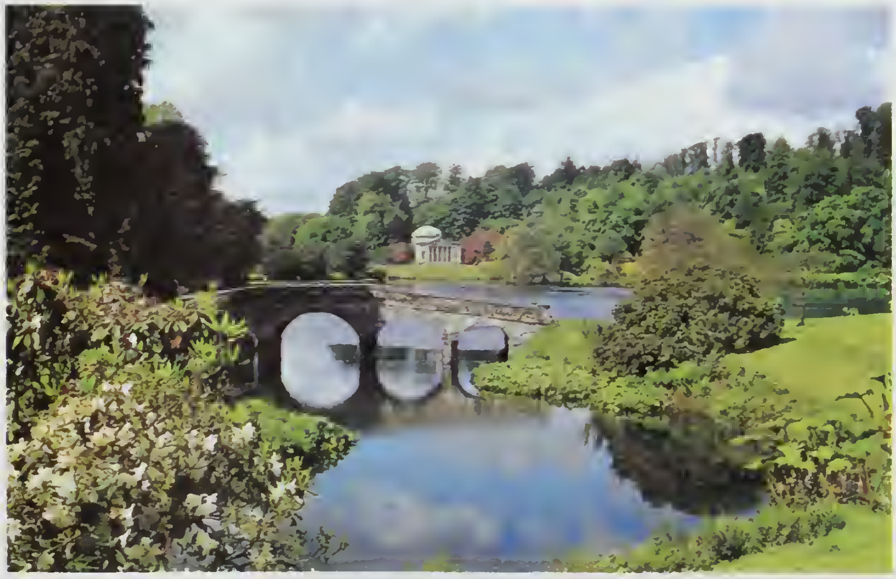
By 1760 the enthusiasm for this style had diminished in England; but in Europe the poetic bric-a-brac garden (*le jardin anglo-chinois*, or *le jardin anglais*, as the French



Reconstruction of the 16th-century gardens at Villandry, in the Loire Valley, France.

Edwin Smith

Noel Habgood Eastbourne



Idealized natural landscape, gardens at Stourhead, Wiltshire, designed by the owner, Henry Hoare, 18th century.

English influence on European gardens

called it) was almost as widely emulated as Versailles had been. In Italy, for example, Renaissance gardens were destroyed to make way for the new fashion, as at the Villa Mansi near Lucca. In France, the sculpted group of "Apollo Attended by the Nymphs" was removed from the classical "Grotto of Thetis" on the terrace of Versailles to a secluded boscage garden, where it was housed under ornamental "Turkish" tents; eventually it was moved from there to a simulated rocky cavern in the *jardin anglais* of the Petit Trianon. The *jardin anglais* was to be found even at Queluz in Portugal and in the Potsdam garden of Frederick the Great of Prussia.

19th century. Increasing world trade and travel brought to late 18th-century Europe a flood of exotic plants whose period of flowering greatly extended the potential season of the flower garden. Although the emphasis in Italian Renaissance gardens, in the classical Baroque gardens of France, in the lawns and gravelled walks of 17th-century England, and in the Brownian park garden was upon design, they had rarely been totally without flowers. In most gardens flowers were grown, sometimes in great numbers and variety; but flower gardens in the modern sense were limited to cottages, to small town gardens, and to relatively small enclosures within larger gardens. The accessibility of new plants, together with avidity for new experience and a high-minded concern with natural science, not only gave renewed life to the flower garden but was the first step toward the evolution of the garden from work of art to museum of plants. A compromise between the new flower garden and the Brownian park was effected by Humphry Repton. He was largely responsible for popularizing the open terrace overlooking the park, which frankly admitted the different functions of park and garden and also emphasized their stylistic disharmony. The plant collectors' garden, or "gardenesque" style, was most strongly advanced by J.C. Loudon in the mid-19th century. Loudon urged that garden making be taken out of the hands of the architect, the painter, and the cultivated dilettante and left to the professional plantsman.

The undiscerning use of the new palette that importation and plant breeding had made available was so patently an aesthetic disaster that by the end of the 19th century attempts were made to break its hold. The architect Sir Reginald Blomfield advocated a return to the formal garden, but to this, insofar as it required dressed stonework, there were economic objections. More successful and more in tune with the escapist needs of the increasing number of urban dwellers were the teaching and practice of William Robinson, who attacked both the old ceremonial garden and the collectors' garden with equal vigour and preached that botany was a science, but gardening was an art. Under his leadership a more critical awareness was brought to the planning and planting of gardens. His own garden at Gravetye Manor demonstrated that plants look best where they grow best and that they should be allowed to develop their natural forms. Adapting Robinson's principles, Gertrude Jekyll applied the cult of free forms over a substructure of concealed architectural regularity, bringing the art of the flower garden to its highest point.

Early gardens in the United States

In North America, where for a long time most men were preoccupied with making a world, not a garden, ornamental gardens were slow to take hold. In the gardens that did exist, the rectilinear style popular in late 17th- and early 18th-century Europe persisted well into the 18th century—perhaps because it met man's psychological need to feel he could master a world that was still largely untamed. The town gardens of Williamsburg (begun in 1698) were typical of the Anglo-Dutch urban gardens that were being attacked everywhere in 18th-century Europe except Holland. And Belmont, in Pennsylvania, was laid out as late as the 1870s with mazes, topiary, and statues, in a style that would have been popular in England about two centuries before.

Although garden improvers set up in business in the United States, there is no evidence that they prospered until the 19th century, when one hears of André Parmentier, a Belgian, who worked on Hosack's estate at Hyde Park and then of A.J. Downing, a successful protagonist of the gardenesque, who was succeeded by Calvert Vaux and Frederick Law Olmsted (the latter the originator of the title and profession of landscape architect), the planners of Central Park (begun 1857) in New York City and of public parks throughout the country.

The eclecticism of the 19th century was universal in the Western world. Besides the gardens that were fundamentally Reptonian—that is, an attempted compromise between the Brownian park garden and the Loudonian flower garden—gardens of almost every conceivable style were copied; designing teams such as Sir Charles Barry, the architect, and William Eden Nesfield, the painter, in England, for example, produced Italianate parterres as well as winding paths through thickets.

Modern. A sense of history still plays a part in 20th-century gardening. The desire to maintain and reproduce old gardens, such as the reconstruction of the 16th-century gardens of Villandry in France and the colonial gardens of Williamsburg in the United States, is not peculiarly modern (similar things were done in the 19th century); but, as man increasingly needs the reassurance of the past, it is likely to be, within limits, an accelerating process.

Parque del Este, Caracas, designed by Roberto Burle Marx, 1959.

Attempts to create a distinctive modern idiom are rare. Gardens large by modern standards are still made, in styles that vary from a version of the grand early 18th-century manner at Anglesey Abbey in Cambridgeshire to an inflated Jekyllism crossed with gardenesque at Bodnant near Conway. An air either of controlled wilderness or of slightly run-to-seed orderliness is preferred. Modern public gardens, which have evolved from the large private gardens of the past, seek instant popular applause for the quantity and brightness of their flowers. In Brazil Roberto Burle Marx uses tropical materials to give an air of contemporaneity to traditional modes of design. Gardens frequently reflect Japanese influence, particularly in America.

Functional planning

Most characteristic of the 20th century is functional planning, in which landscape architects concentrate upon the arrangement of open spaces surrounding factories, offices, communal dwellings, and arterial roads. The aim of such planning has been to provide, at best, a satisfactory setting for the practical aspects of living. It is gardening only in the negative, "tidying up" sense, with little concern for the traditional garden purpose of awakening delight. So starved has the spirit of those living in heavily populated regions become, however, that demands grow more and more insistent for gardening in the positive sense—for environmental planning with a chief goal not of facilitating man's economic activities but of refreshing his spirit.

NON-WESTERN

Chinese. Western gardens for many centuries were architectural, functioning as open-air rooms and demonstrating Western man's insistence on physical control of his environment. Because of a different philosophical approach, Oriental gardens are of a totally different type.

China—which is to Eastern civilization what Egypt, Greece, and Rome are to Western—practiced at the beginning of its history an animist form of religion. The sky, mountains, seas, rivers, and rocks were thought to be the materialization of spirits whom men regarded as their fellow inhabitants in a crowded world. Such a belief emphasized the importance of good manners toward the world of nature as well as toward the world of men. Against this background the Chinese philosopher Lao-tzu taught the quietist philosophy of Taoism, which held that one should integrate oneself with the rhythms of life; Confucius preached moderation as a means of attaining spiritual calm; and the teaching of Buddha elevated the attainment of calm to a mystical plane.

Such a history of thought led the Chinese to take keen pleasure in the calm landscape of the remote countryside. Because of the physical difficulty of frequent visits to the sources of such delight, the Chinese recorded them in landscape paintings and made three-dimensional imitations of them near at hand. Their gardens were therefore representational, sometimes direct but more often by substitution, making use of similar means to recreate the emotions that choice natural landscapes evoked. The kind of landscape that appealed was generally of a balanced sort; for the Chinese had discovered the principle of complementary forms, of male and female, of upright and recumbent, rough and smooth, mountain and plain, rocks and water, from which the classic harmonies were created. The principle of scroll painting, whereby the landscape is exposed not in one but in a continual succession of views, was applied also in gardens; and grounds were arranged so that one passed pleasantly from viewpoint to viewpoint, each calculated to give a different pleasure appropriate to its situation. A refined and expectant aestheticism, which their philosophy had inculcated, taught the Chinese to ignore nothing that would prepare the mind for the reception of such experiences, and every turn of path and slope of ground was carefully calculated to induce the suitable attitude. As the garden was in effect a complex of linked, related, but distinct sensations, seats and shelters were situated at chosen spots so that the pleasures that had been meticulously prepared for could be quietly savoured. Kiosks and pavilions were built at places where the dawn could best be watched or where the moonlight shone on the water or where autumn foliage was seen to advantage or where the wind made music in the bamboos. Such gardens were intended not for displays of wealth and magnificence to impress the multitude but for the delectation of the owner, who felt his own character enhanced by his capacity for refined sensation and sensitive perception and who chose friends to share these pleasures with the same discernment as he had exercised in planning his garden.

The typical Chinese garden

Based on natural scenery, Chinese gardens avoided symmetry. Rather than dominating the landscape, the many buildings in the garden "grew up" as the land dictated. A fanciful variety of design, curving roof lines, and absence of walls on one or on all sides brought these structures into harmony with the trees around them. Sometimes they were given the rustic representational character of a fisherman's hut or hermit's retreat. Bridges were often copied from the most primitive rough timber or stone-slab raised pathways. Rocks gathered from great distances became a universal decorative feature, and a high connois-

seurship developed in connection with their colour, shape, and placement.

Although the troubled 20th century has largely destroyed the old gardens, paintings and detailed descriptions of them dating from the Sung dynasty (AD 960–1279) reveal a remarkable historical consistency. Nearly all the characteristic features of the classic Chinese garden—man-made hills, carefully chosen and placed rocks, meanders and cascades of water, the island and the bridge—were present from the earliest times.

Influence of Chinese gardens on the West

Chinese gardens were made known to the West by Marco Polo, who described the palace grounds of the last Sung emperors, during whose reign the arts were at their most refined. Other accounts reached Europe from time to time but had little immediate effect except at Bomarzo, the Mannerist Italian garden that had no successors. In the 17th century, the English diplomat and essayist Sir William Temple, sufficiently familiar with travellers' tales to describe the Chinese principle of irregularity and hidden symmetry, helped prepare the English mind for the revolution in garden design of the second quarter of the 18th century. Chinese example was not the sole or the most important source of the new English garden; but the account of Father Attiret, a Jesuit at the Manchu court, published in France in 1747 and in England five years later, promoted the use of Chinese ornament in such gardens as Kew and Wroxton and hastened the "irregularizing" of grounds. The famous *Dissertation on Oriental Gardening* by the English architect Sir William Chambers (1772) was a fanciful account intended to further the current revolt in England against the almost universal Brownian park garden. Influence of the West on Chinese gardens was slight. Elaborate fountain works, Baroque garden pavilions, and mazes—all of which the Jesuits made for the imperial garden at Yüan Ming Yüan—took no root in Chinese culture. Not until the 20th century did European regularity occasionally become evident near the Chinese dwelling; at the same time, improved Western hybrids of plant species that had originated in the East appeared in China.

Japanese. Chinese culture permeated the Far East and, by way of Korea, infiltrated Japan. By the year AD 1000 Japan was already developing a distinctive national art best described as a stylized, ritualistic version of the Chinese. The typical early Japanese garden lay to the south of the dwelling and consisted of a narrow pond or lake orientated through its longer axis and containing an island. At the north end of the pond was an artificial hill from which a secondary stream descended in a cascade. These stereotyped gardens of the Heian period (AD 794–1185) show by their careful reproduction of magical detail that they derive from a single prototype—certainly Chinese. Variation entered only through the individual particularities of the site and the detailed handling of stones and trees.

William G. Froelich, Jr

Pond and moss-covered bridge, Katsura Imperial Gardens, Kyōto, Japan.

Creativity began to replace imitation in the Kamakura period (1192–1333). Although there were many subsidiary styles, gardens were broadly classified, according to terrain, as either hill or flat. The hill garden, consisting of hills and ponds, came to be associated with Mt. Fuji, the mountain of ideal form. The flat garden represented a surface of water—lake or sea—with its adjacent shores and islands. Since the scale was so small—a heap of earth 30 feet (nine metres) high representing a mountain and a half-acre (0.2-hectare) pond, an arm of the sea—the intention was to reproduce the spirit rather than the features of the chosen landscape. Association and symbolism thus played a major role in the creation and appreciation of these gardens.

Types of Japanese gardens

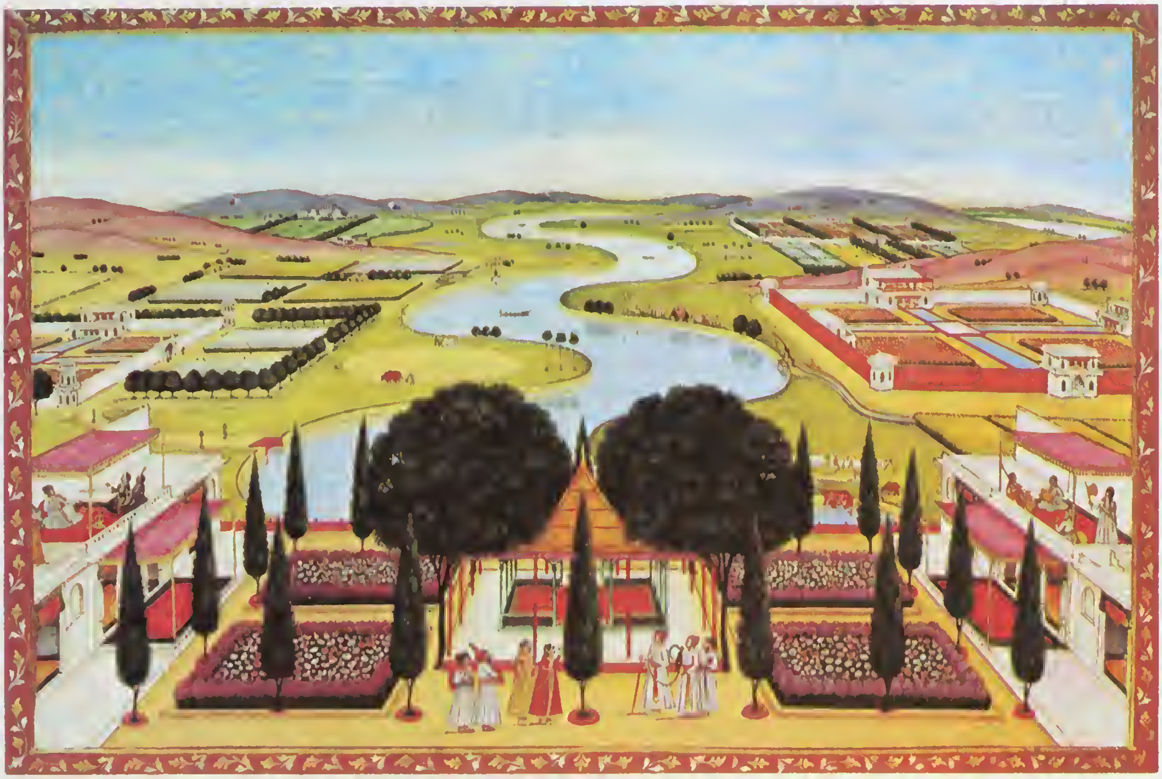
The scaling down of landscapes to garden size was logically continued to the point where miniature gardens were made in trays as small as a foot square containing lakes, streams, islands, hills, bridges, garden houses, and real trees painstakingly cultivated to an appropriate scale. These small, portable gardens reflected the extreme of the picturesque tradition of Oriental gardening.

Abstract and tea gardens

Two characteristic Japanese styles are the abstract garden and the tea garden. The most famous example of the former is the garden of the Ryōan-ji in Kyōto, where an area about the size of a tennis court is covered with raked sand and set with 15 stones divided into five groups. If anything is represented here, it is some rocky islets in a sea, but the appeal of the garden lies essentially in the charm of its relationships. The Japanese tea garden grew out of an esoteric ritual originated in China and connected with the taking of tea. The tea cult, which flourished from the 14th to the end of the 16th centuries, was calculated to instill humility, restraint, sensibility, and other cognate virtues. The gardens through which the guests approached the teahouse were governed by severe rules of design intended to create an appropriate spiritual atmosphere, such as the "lonely precincts of a secluded mountain shrine" or "a landscape in clouded moonlight, with a half-gloom between the trees" or any mood "in harmony with the spirit of tea." Even the precise number and arrangement of nails in the teahouse door were specified.

The use of stones

The Japanese fondness for systematization led them to classify garden treatment as well as subject. Three standard treatments were recognized: the elaborate, the moderate, and the modest. Once the degree of finish was determined, certain rules were followed to preserve consistency. The Taoist doctrine of complementary forms was at the root of much Japanese design, but the cult of stones is also central to Japanese gardening. The nine stones, five standing and four recumbent, used in Buddhist gardens were symbols of the nine spirits of the Buddhist pantheon; the shapes and postures chosen were presumed to have a relationship with the character and history of the persons represented. Sacred associations played a part in profane gardens as well. It was regarded as inauspicious, for example, if three stones, the "Guardian Stone," the "Stone of Adoration," and the "Stone of the Two Deities" (or the "Stone of Completeness"), were not present. In addition to the sacred symbols, a whole armoury of poetic associations and symbols grew up, and stones, according to their shape and use, acquired such names as "Torrent-breaking Stone," "Recumbent Ox Stone," "Propitious Cloud Stone," and "Seagull-resting Stone." Beyond what they represented, stones were part of an aesthetic design and had to be placed so that their positions appeared natural and their relationships harmonious. The concentration of the interest on such detail as the shape of a rock or the moss on a stone lantern led at times to an overemphatic picturesqueness and an accumulation of minor features that, to Occidental eyes accustomed to a more general survey,



Architecturally planned park landscape for an imperial residence, containing an artificially meandering river and pavilions. An example of the ideal landscapes of Mughal India. Miniature from a 17th- or 18th-century album. In the Staatliche Museen zu Berlin.

may seem cluttered and restless. Nevertheless, Japanese gardening has had and continues to have an influence on the gardens of the West, particularly in the United States. The influence appears not so much in direct imitation of Japanese themes as in the selection and presentation of detail.

Indian. The influence of Chinese culture throughout the East was such that other indigenous cultures usually succumbed to it; but India was an exception. Western garden styles were introduced into northern India first through contact with Iranian culture, then by the invasion of Alexander the Great and the subsequent Hellenistic influence, and, finally, by the invading Mughals, who introduced the Islāmic garden.

In southern India and in Ceylon elaborate gardens existed before the birth of the Buddha (563? BC). Beneath a tree in such a garden—containing baths, lotus-covered pools, trees, and beds of flowers—the Buddha himself was said to have been born. Anciently worshipped by the Hindus, trees thus acquired an additional sanctity. Buddhist temples were associated with gardens whose purpose was to promote contemplation and whose preferred sites were therefore away from cities.

African, Oceanic, and pre-Columbian. The African cultures beyond European and Asiatic influence did not evolve pleasure gardens, although in their more settled societies a beginning had perhaps been made. Nor is more than a love of flowers and a casual cultivation of decorative plants recorded of the Oceanic peoples; but of the Aztecs of Mexico and the Incas of Peru the conquistadores reported elaborate gardens with terraced hills, groves, fountains, and ornamental ponds that were essentially royal pleasure grounds, reflecting a need for private solace and public display not unlike contemporary gardens in the West. (D.P.Cl.)

BIBLIOGRAPHY. The 19th and 20th centuries have seen a spate of gardening literature, both of the how-to-do-it variety and of specialized studies of national types. General works include DEREK CLIFFORD, *A History of Garden Design*, 2nd ed. (1966), an attempt to relate garden design to cultural history; and MARIE LUISE GOTHEIN, *A History of Garden Art*, 2 vol. (1928; originally published in German, 1914), the most valuable detailed general history.

Gardening and Horticulture

Gardening belongs both to art and to science. It is an artistic activity in that it deals with the grouping of plants in harmonious or pleasing arrangements. It is scientific in its concern with the techniques of cultivating plants and producing satisfactory growth.

Horticulture is the more comprehensive term, embracing many forms of production from the soil. In common usage, and in the sense applied here, it refers to commercial gardening. It thus includes the growing of flowers, fruits, and vegetables as crops for profit, as in market gardening; the breeding of plants for sale, as in nursery gardening; and landscape architecture and design. The seed industry is also closely associated with horticulture.

Because plants are often grown in conditions markedly different from those of their natural environment, it is necessary to apply to their cultivation techniques derived from plant physiology, chemistry, and botany, modified by the experience of the planter. The basic principles involved in growing plants are the same in all parts of the world, but the practice naturally needs much adaptation to local conditions. The three main topics covered in this article, gardening, houseplants, and horticulture, thus have much in common, being closely linked in historical development and principles. The differences between them arise from size and scale.

For the main history of garden development, see the article GARDEN AND LANDSCAPE DESIGN.

This article is divided into the following sections:

Gardening

THE NATURE OF GARDENING

Gardening in its ornamental sense needs a certain level of civilization before it can flourish. Wherever that level has been attained, in all parts of the world and at all periods, people have made efforts to shape their environment into an attractive display. The instinct and even enthusiasm for gardening thus appear to arise from some primitive response to nature, engendering a wish to produce growth and harmony in a creative partnership with it.

It is possible to be merely an admiring spectator of gardens. However, most people who cultivate a domestic plot also derive satisfaction from involvement in the processes of tending plants. They find that the necessary attention to the seasonal changes, and to the myriad small "events" in any shrubbery or herbaceous border, improves their understanding and appreciation of gardens in general.

The upsurge of interest in gardening

A phenomenal upsurge of interest in gardening began in Western countries after World War II. A lawn with flower beds and perhaps a vegetable patch has become a sought-after advantage to home ownership. The increased interest produced an unprecedented expansion of business among horticultural suppliers, nurseries, garden centres, and seedsmen. Books, journals, and newspaper columns on garden practice have found an eager readership, while television and radio programs on the subject have achieved a dedicated following.

Several reasons for this expansion suggest themselves. Increased leisure in the industrial nations gives more people the opportunity to enjoy this relaxing pursuit. The increased public appetite for self-sufficiency in basic skills also encourages people to take up the spade. In the kitchen, the homegrown potato or ear of sweet corn rewards the gardener with a sense of achievement, as well as with flavour superior to that of store-bought produce. An increased awareness of threats to the natural environment and the drabness of many inner cities stir some people to cultivate the greenery and colour around their own doorsteps. The bustle of 20th-century life leads more individuals to rediscover the age-old tranquillity of gardens.

The varied appeal of gardening. The attractions of gardening are many and various and, to a degree perhaps unique among the arts and crafts, may be experienced by any age group and at all levels of ambition. At its most elemental, but not least valuable, the gardening experience begins with the child's wonder that a packet of seeds will produce a charming festival of colour. At the adult level it can be as simple as helping to raise a good and edible carrot, and it can give rise to almost parental pride. At higher levels of appreciation, it involves an understanding of the complexity of the gardening process, equivalent to a chess game with nature, because the variables are so many.

The gardening experience may involve visiting some of the world's great gardens at different seasons to see the relation of individual groups of plants, trees, and shrubs to the whole design; to study the positioning of plants in terms of their colour, texture, and weight of leaf or blossom; and to appreciate the use of special features such as ponds or watercourses, pavilions, or rockeries. Garden visiting on an international scale provides an opportunity to understand the broad cultural influences, as well as the variations in climate and soil, that have resulted in so many different approaches to garden making.

The appeal of gardening is thus multifaceted and wide in range. The garden is often the only place where someone without special training can exercise creative impulses as designer, artist, technician, and scientific observer. In addition, many find it a relaxing and therapeutic pursuit. It is not surprising that the garden, accorded respect as a part of nature and a place of contemplation, holds a special place in the spiritual life of many.

Practical and spiritual aspects of gardening are shown in an impressive body of literature. In Western countries manuals of instruction date to classical Greece and Rome. Images of plants and gardens are profuse in the works of the major poets, from Virgil to Shakespeare, and on to some of the moderns.

Another of gardening's attractions is that up to a certain level it is a simple craft to learn. The beginner can produce pleasing results without the exacting studies and practice required by, for example, painting or music. Gardens are also forgiving to the inexperienced to a certain degree. Nature's exuberance will cover up minor errors or short periods of neglect, so gardening is an art practiced in a relatively nonjudgmental atmosphere. While tolerant in many respects, nature does, however, present firm reminders that all gardening takes place within a framework of natural law; and one important aspect of the study of the craft is to learn which of these primal rules are imperatives and which may be stretched.

Control and cooperation. Large areas of gardening development and mastery have concentrated on persuading plants to achieve what they would not have done if left in the wild and therefore "natural" state. Gardens at all times have been created through a good deal of control and what might be called interference. The gardener attends to a number of basic processes: combating weeds and pests; using space to allay the competition between plants; attending to feeding, watering, and pruning; and conditioning the soil. Above this fundamental level, the gardener assesses and accommodates the unique complex of temperature, wind, rainfall, sunlight, and shade found within his own garden boundaries. A major part of the fascination of gardening is that in problems and potential no one garden is quite like another; and it is in finding the most imaginative solutions to challenges that the gardener demonstrates artistry and finds the subtler levels of satisfaction.

Basic processes of control

Different aesthetics require different balances between controlling nature and cooperating with its requirements. The degree of control depends on the gardener's objective, the theme and identity he is aiming to create. For example, the English wild woodland style of gardening in the mid-19th century dispensed with controls after planting, and any interference, such as pruning, would have been misplaced. At the other extreme is the Japanese dry-landscape garden, beautifully composed of rock and raked pebbles. The artistic control in this type of garden is so firm and refined that the intrusion of a single "natural" weed would spoil the effect.

Choice of plants. The need for cooperation with nature is probably most felt by the amateur gardener in choosing the plants he wants to grow. The range of plants available to the modern gardener is remarkably rich, and new varieties are constantly being offered by nurseries. Most of the shrubs and flowers used in the Western world are descendants of plants imported from other countries. Because they are nonnative, they present the gardener with some of his most interesting problems, but also with the possibility of an enhanced display. Plants that originated in subtropical regions, for example, are naturally more sensitive to frost. Some, like rhododendrons or azaleas, originated in an acid soil, mainly composed of leaf mold. Consequently they will not thrive in a chalky or alkaline soil. Plant breeding continues to improve the adaptability of such exotic plants, but the more closely the new habitat resembles the original, the better the plant will flourish. Manuals offer solutions to most such problems, and the true gardener will always enjoy finding his own. In such experiments, he may best experience his work as part of the historical tradition of gardening.

HISTORICAL BACKGROUND

Early history. Western gardening had its origins in Egypt some 4,000 years ago. As the style spread it was changed and adapted to different localities and climates, but its essentials remained those of disciplined lines and groupings of plants, usually in walled enclosures. Gardening was introduced into Europe through the expansion of Roman rule and, second, by way of the spread of Islām into Spain. Though clear evidence is lacking, it is presumed that Roman villas outside the confines of Italy contained native and imported plants, hedges, fruit trees, and vines, in addition to herbs for medicinal and culinary purposes.

The introduction of gardening to Europe

In medieval times the monasteries were the main repositories of gardening knowledge and the important herbal lore. Though little is certainly known about the design and content of the monastic garden, it probably consisted of a walled courtyard, built around a well or arbour, with colour provided by flowers (some of which, including roses and lilies, served as ecclesiastical symbols), all of which maintained the ancient idea of the garden as a place of contemplation.

The earliest account of gardening in English, *The Feate of Gardening,* dating from about 1400, mentions the use of more than 100 plants, with instructions on sowing, planting, and grafting of trees and advice on cultivation of herbs such as parsley, sage, fennel, thyme, camomile, and saffron. The vegetables mentioned include turnip, spinach, leek, lettuce, and garlic.

Early gardening was largely for utility. The emergence of the garden as a form of creative display properly began in the 16th century. The Renaissance, with its increased prosperity, brought an upsurge of curiosity about the natural world and, incidentally, stirred interest in composing harmonious forms in the garden.

This awakening took especially firm root in Elizabethan England, which notably developed the idea that gardens were for enjoyment and delight. Echoing the Renaissance outlook, the mood of the period was one of exuberance in gardening, seen in the somewhat playful arrangements of Tudor times, with mazes, painted statuary, and knot gardens (consisting of beds in which various types of plants were separated by dwarf hedges). Flowers began to appear profusely in paintings and, as mentioned above, were used by poets in their verbal images.

This enthusiasm was accompanied by an earnest search for knowledge, and the period saw the birth of botanical science. A leading figure in this work was Carolus Clusius (Charles de l'Écluse), whose botanical skills and introduction of the tulip and other bulbous plants to the botanical gardens at Leiden, Neth., laid the foundation for Dutch prominence in international horticulture. The earliest botanical garden was that of Pisa (1543), followed by that of Padua (1545). The first in England was founded at Oxford in 1621, followed by Scotland's first, at Edinburgh, in 1667. The gardens at Kew, near London, were founded almost a century later, in 1759. These centres of experiment and learning have contributed greatly to the art and science of horticulture.

Early botanical gardens

The advances from the simple medieval style were marked and rapid at this time. The English statesman and scholar Francis Bacon could already, by 1625, advance a sophisticated and almost modern conception of the garden in his essay "On Gardens." He saw it as a place that should be planted for year-round enjoyment, offering a wide range of experiences through colour, form and scent, exercise and repose. The flower garden, already well established by the early 17th century, was set against a background of tall, clipped hedges and neatly scythed lawns. The taste of the time, as contemporary lists show, was for perfumed varieties such as carnations, lavender, sweet marjoram, musk roses, and poppies.

The plant trade. As interest in gardening developed in Europe the new trade of nurseryman was established, and the trade became highly important to the spread of knowledge and materials. By the end of the 17th century, nurserymen were relatively numerous in England, France, and the Low Countries, with keen customers among the nobility and gentry for all the exotica they could provide. The catalog of the Tradescant family's private botanical garden in London listed 1,600 plants in 1656. A number of them had been brought back by the family from visits to Virginia. These early exotica from the New World included now familiar plants such as the Michaelmas daisy, the Virginia creeper, hamamelis, goldenrod, the first perennial lupine, and such fine autumn-colouring trees as liquidambar and the staghorn sumac. The work of the nurserymen thus spread new plants more widely and, as breeding skills developed, contributed to the acclimatizing of foreign imports.

Vegetables and fruits. The history of vegetables is imprecise. Though familiar types, including the radish, turnip, and onion, are known to have been in cultivation from early times, it is fairly supposed that they were meagre and would bear little clear resemblance to modern equivalents. The early range available to European gardens and, later, to those in America, included such native plants as kale, parsnips, and the Brussels sprout family, with peas and broad beans grown as field crops.

Introduced and imported plants

The Romans introduced the globe artichoke, leek, cucumber, cabbage, asparagus, and the Mediterranean strain of garlic to their imperial territory, wherever these plants would flourish. Among plants imported to Europe from the Americas were the scarlet runner bean and tomato (both originally grown for ornament), corn (maize), and the vastly important potato. The numerous herbs in use were mostly native to European locations. One curiosity to the modern mind is that certain flowers, such as marigolds, violets, and primroses, were used as flavourings in the kitchen.

The cultivation of fruit trees was one of the most advanced skills and interests from the 16th century onward. Pride was taken in variety while, judging by the opulent still-life paintings of the period, the quality was remarkably high. Among the challenges bravely taken up in the 17th century in northern Europe was the growing of orange and lemon trees, though this was done more for the pleasure of their evergreen qualities than for their fruit. The catalog of the British royal gardens in 1708 shows 14 varieties of cherry, 14 apricots, 58 kinds of peach and nectarine, 33 plums, eight figs, 23 vines, 29 pears, and numerous varieties of apple.

The French style. The most favoured style for great house gardens in Europe during much of this period derived from the influence of the French designer André Le Nôtre, creator of the gardens at Versailles. The French style represented an extreme of formality, with box-edged parterres (elaborate and geometrical beds) typically placed near the residence to provide an arranged view. Trees were grouped in neat plantations or in bold lines along avenues, with terraces and statuary carefully placed to emphasize the architectural symmetry of the grand manner. The widespread adoption of this style among the European nobility and gentry reflected the potency of French cultural influence at the time. It was also related, on a practical basis, to the limited availability of planting materials, especially those offering autumn and winter display.

The change to a more natural style of gardening came about when, in the latter part of the 18th century, the opinion arose among leading gardeners, particularly those of the English gentry, that the formal manner brought with it a certain monotony. The increasing importation of foreign plants also brought with it opportunities for a large-scale transformation.

The plant hunters. The early importation of plants to Europe was managed through informal channels, following the increase in exploration and the spread of empires. Seeds and tubers were sent home by diplomats and missionaries, sea captains and travelers. An example of this type of collecting is afforded by Henry Compton, bishop of London, whose diocese included the American colonies. He was an avid collector, and he corresponded with like-minded experts in Europe and America and thus brought numerous fine plants to his exceptional garden in Fulham, west London. He also encouraged his missionaries to send home seeds. From one such source in Virginia came the *Magnolia virginiana,* the first magnolia to be cultivated. This was the beginning of what became known as the American garden, based upon magnolias, azaleas, and other woodland species.

As the appetite for exotica developed, plant collecting around the world became more systematized. Expeditions to foreign parts were organized and financed by nurserymen, botanical gardens, or syndicates of private gardeners. The botanist plant hunters thus sent out were exceptional and patient. They were required to endure long voyages and residence for up to several years in an often hostile environment. Their goal was to find the plant in flower, return in due season to collect seed, then see their delicate specimens back to Europe through varying climatic zones.

Collecting in North America and South America

North America's potential to yield countless new specimens was recognized early: the first book on American plants, published in London in 1577, was entitled *Joyfull Newes out of the New Founde Worlde* and was in itself a hint of the excited spirit of contemporary gardening. The jacaranda, flowering catalpa, and wisteria were among the finds made by Compton's missionaries in the Carolinas. An early resident collector in North America was John Bartram, regarded as the founder of American botany. He settled on a farm near Philadelphia in 1728 and, in 30 years of collecting in the Alleghenies, Carolinas, and other areas of North America, sent some 200 important plants to British gardens in sufficient quantity that they became widespread there.

The extremely rich west coast of North America was not exploited by plant collectors until the early 19th century. The contemporary importance of such discoveries is suggested by the fact that, in their celebrated crossing of the American continent in 1804–06, Lewis and Clark found time to collect the seeds of *Mahonia aquifolium* and *Symphoricarpos racemosus.* Perhaps the most distinguished collector among an exceptional fraternity was David Douglas, one of the numerous Scotsmen who contributed to international botany. His expeditions to the North American Far West brought to Europe such important timber trees as the Douglas fir, the Sitka spruce, the Monterey pine, and a number of now familiar shrubs such as *Garrya elliptica* and *Ribes sanguineum.* The California annuals he discovered made a lasting impact on the colour of Western gardens. In the 19th century plant collectors began to explore South America, where two Cornish brothers, William and Thomas Lobb, gained prominence. They are credited with carrying back to Europe the monkey puzzle tree (*Araucaria araucana*), native to the Andes mountains; the *Berberis darwinii;* and the *Escallonia macrantha.*

Collecting in China

Collectors went to a number of countries in the 19th century, but the most important area was China. Its flora was more intact than that in the West, because the erosions of the Ice Age had been less severe for climatic reasons, and it had a long history of skilled gardening. Plant collection was difficult, however, because for many years the only foreigners allowed to travel within its borders were Jesuit priests. They aided botanists by sending many specimens to Paris and London. The first professional collector to live in China was William Kerr, who sent out 238 new plants. Real exploration of the interior did not begin until the 1840s. China, Japan, and the Himalayas produced unparalleled riches in rhododendrons, azaleas, flowering cherries, ornamental maples, roses, lilies, primulas, poppies, kerrias, and quinces.

The conditions for transporting plants from such distances had been much improved by Nathaniel B. Ward's invention of the wardian case, an airtight glass box that protected the plants from sea air and harsh climate. Gradually almost all regions and countries were visited, and new plants and their progeny were dispersed around the Western world. And still the search for new specimens continues.

From the 19th century. By the early 19th century, with the expansion of the horticultural trade, gardening had become international in scope. Numerous handbooks spread knowledge. The founding of new garden and botanical societies, such as the London (later Royal) Horticultural Society, helped to increase interest, encourage science, and raise standards. Such moves signaled the rise of the small leisure gardener; a floral retreat was no longer the sole property of the rich. It now extended from the manor to the small suburban garden.

Gardens in North America had generally been smaller and trimmer than their European counterparts, with box edgings and pleached trees (that is, lines of trees allowed to grow with branches interlaced to form a screen) as seen in the reconstructed gardens of Williamsburg, Va. The "natural" gardening style (known on the European continent as the English style), which had overtaken earlier formality, allowed wider use of plant varieties. This approach became the pervasive trend in the west, notably through the views of John Claudius Loudon, whose *Encyclopaedia of Gardening* (1822) set the pattern of domestic cultivation over a long period with a style known as Gardenesque. His style encouraged the individual qualities of garden elements while ensuring that together they made a harmonious blend.

The "natural" style

The natural style was further enhanced by an English artist and landscape architect, Gertrude Jekyll. In her opinion, the first purpose of a garden is to give happiness and repose of mind. With experience derived from the richly floral cottage gardens of Surrey, she developed the idea of supporting plants with an architectural base and allowing them to grow in a free form, encouraging natural shape and creating harmonious relationships of colour.

The period saw much progress in garden equipment and supplies. Heated greenhouses had been in use since the late 17th century, and mass production led to great strides in nursery gardening. The modern, bladed lawn mower was first seen in a design of 1832; in more recent times the application of the jet-engine principle led to the hover mower. Fertilizer development was also important, from the discovery of superphosphate to the devising of modern kinds of foliar feeding.

In the second half of the 20th century interest in gardening brought in new adherents in unprecedented numbers; they were advised and encouraged by numerous publications and by television and radio programs. Though the process was very gradual, domestic gardening became somewhat more adventurous. Among the more ambitious, designs took a multiplicity of forms, from the Japanese garden, producing an austere magic out of rock and pebble, to the other extreme of the wild country garden, virtually left to seed itself. Increasing numbers of professional designers at their best set high standards to emulate. But the art of gardening still depends on a simple empathy with the needs and nature of living things. Symbolic of this essential, the spade has remained much the same implement that it had been in medieval times.

TYPES OF GARDENS

The domestic garden can assume almost any identity the owner wishes within the limits of climate, materials, and means. The size of the plot is one of the main factors, deciding not only the scope but also the kind of display and usage. Limits on space near urban centres, as well as the wish to spend less time on upkeep, have tended to make modern gardens ever smaller. Paradoxically, this happens at a time when the variety of plants and hybrids has never been wider. The wise small gardener avoids the temptations of this banquet. Some of the most attractive miniature schemes, such as those seen in Japan or in some Western patio gardens, are effectively based on an austere simplicity of design and content, with a handful of plants given room to find their proper identities.

In the medium- to large-sized garden the tradition generally continues of dividing the area to serve various purposes: a main ornamental section to enhance the residence and provide vistas; walkways and seating areas for recreation; a vegetable plot; a children's play area; and features to catch the eye here and there. Because most gardens are mixed, the resulting style is a matter of emphasis rather than exclusive concentration on one aspect. It may be useful to review briefly the main garden types.

Flower gardens. Though flower gardens in different countries may vary in the types of plants that are grown, the basic planning and principles are nearly the same, whether the gardens are formal or informal. Trees and shrubs are the mainstay of a well-designed flower garden. These permanent features are usually planned first, and the spaces for herbaceous plants, annuals, and bulbs are arranged around them. The range of flowering trees and shrubs is enormous. It is important, however, that such plants be appropriate to the areas they will occupy when mature. Thus it is of little use to plant a forest tree that will grow 100 feet (30 metres) high and 50 feet across in a small suburban front garden 30 feet square, but a narrow flowering cherry or redbud tree would be quite suitable.

Blending and contrast of colour as well as of forms are important aspects to consider in planning a garden. The older type of herbaceous border was designed to give a maximum display of colour in summer, but many gardeners now prefer to have flowers during the early spring as well, at the expense of some bare patches later. This is often done by planting early-flowering bulbs in groups toward the front. Mixed borders of flowering shrubs combined with herbaceous plants are also popular and do not require quite so much maintenance as the completely herbaceous border.

The old-fashioned garden

Groups of half-hardy annuals, which can withstand low night temperatures, may be planted at the end of spring to fill gaps left by the spring-flowering bulbs. The perpetual-flowering roses and some of the larger shrub roses look good toward the back of such a border, but the hybrid tea roses and the floribunda and polyantha roses are usually grown in separate rose beds or in a rose garden by themselves.

Woodland gardens. The informal woodland garden is the natural descendant of the shrubby "wilderness" of earlier times. The essence of the woodland garden is informality and naturalness. Paths curve rather than run straight and are of mulch or grass rather than pavement. Trees are thinned to allow enough light, particularly in the glades, but irregular groups may be left, and any mature tree of character can be a focal point. Plants are chosen largely from those that are woodlanders in their native countries: rhododendron, magnolia, pieris, and maple among the trees and shrubs; lily, daffodil, and snowdrop among the bulbs; primrose, hellebore, St.-John's-wort, epimedium, and many others among the herbs.

Rock gardens. Rock gardens are designed to look as if they are a natural part of a rocky hillside or slope. If rocks are added, they are generally laid on their larger edges, as in natural strata. A few large boulders usually look better than a number of small rocks. In a well-designed rock garden, rocks are arranged so that there are various exposures for sun-tolerant plants such as rockroses and for shade-tolerant plants such as primulas, which often do better in a cool, north-facing aspect. Many smaller perennial plants are available for filling spaces in vertical cracks among the rock faces.

The main rocks from which rock gardens are constructed are sandstone and limestone. Sandstone, less irregular and pitted generally, looks more restful and natural, but certain plants, notably most of the dianthuses, do best in limestone. Granite is generally regarded as too hard and unsuitable for the rock garden because it weathers very slowly.

Water gardens. The water garden represents one of the oldest forms of gardening. Egyptian records and pictures of cultivated water lilies date as far back as 2000 BC. The Japanese have also made water gardens to their own particular and beautiful patterns for many centuries. Many have an ornamental lantern of stone in the centre or perhaps a flat trellis roof of wisteria extending over the water. In Europe and North America, water gardens range from formal pools with rectangular or circular outline, sometimes with fountains in the centre and often without plants or with just one or two water lilies (*Nymphaea*), to informal pools of irregular outline planted with water lilies and other water plants and surrounded by boggy or damp soil where moisture-tolerant plants can be grown. The pool must contain suitable oxygenating plants to keep the water clear and support any introduced fish. Most water plants, including even the large water lilies, do well in still water two to five feet deep. Temperate water lilies flower all day, but many of the tropical and subtropical ones open their flowers only in the evening.

In temperate countries water gardens also can be made under glass, and the pools can be kept heated. In such cases, more tropical plants, such as the great *Victoria amazonica* (*V. regia*) or the lotus (*Nelumbo nucifera*), can be grown together with papyrus reeds at the edge. The range of moisture-loving plants for damp places at the edge of the pool is great and includes many beautiful plants such as the candelabra primulas, calthas, irises, and osmunda ferns.

Herb and vegetable gardens. Most of the medieval gardens and the first botanical gardens were largely herb gardens containing plants used for medicinal purposes or herbs such as thyme, parsley, rosemary, fennel, marjoram, and dill for savouring foods. The term herb garden is usually used now to denote a garden of herbs used for cooking, and the medicinal aspect is rarely considered. Herb gardens need a sunny position because the majority of the plants grown are native to warm, dry regions.

The vegetable garden also requires an open and sunny location. Good cultivation and preparation of the ground are important for successful vegetable growing, and it is also desirable to practice a rotation of crops as in farming. The usual period of rotation for vegetables is three years; this also helps to prevent the carryover from season to season of certain pests and diseases.

The French *potager*

The old French *potager*, the prized vegetable garden, was grown to be decorative as well as useful; the short rows with little hedges around and the high standard of cultivation represent a model of the art of vegetable growing. The elaborate parterre vegetable garden at the Château de Villandry is perhaps the finest example in Europe of a decorative vegetable garden.

Specialty gardens. *Roof gardens.* The modern tendency in architecture for flat roofs has made possible the development of attractive roof gardens in urban areas above private houses and commercial buildings. These gardens follow the same principles as others except that the depth of soil is less, to keep the weight on the rooftop low, and therefore the size of plants is limited. The plants are generally set in tubs or other containers, but elaborate roof gardens have been made with small pools and beds. Beds of flowering plants are suitable, among which may be stood tubs of specimen plants to produce a desired effect.

Scented gardens. Scent is one of the qualities that many people appreciate highly in gardens. Scented gardens, in which scent from leaves or flowers is the main criterion for inclusion of a plant, have been established, especially for the benefit of blind people. Some plants release a strong scent in full sunlight, and many must be bruised or

rubbed to yield their fragrance. These are usually grown in raised beds within easy reach of visitors.

CONTENTS OF GARDENS

Permanent elements. The more or less permanent plants available for any garden plan are various grasses for lawns, other ground-cover plants, shrubs, climbers, and trees. More transitory and therefore in need of continued attention are the herbaceous plants, such as the short-lived annuals and biennials, and the perennials and bulbous plants, which resume growth each year.

Lawns and ground covers. Areas of lawn, or turf, provide the green expanse that links all other garden plantings together. The main grasses used in cool areas for fine-textured lawns are fescues (*Festuca* species), bluegrasses (*Poa* species), and bent grasses (*Agrostis* species), often in mixtures. A rougher lawn mixture may contain ryegrass (*Lolium* species). In drier and subtropical regions, Bermuda grass (*Cynodon dactylon*) is frequently used, but it does not make nearly as fine a lawn as those seen in temperate regions of higher rainfall.

Ground covers are perennial plants used as grass substitutes in regions where grasses do poorly, or they are sometimes combined with grassy areas to produce a desired design. The deep greens, bronzes, and other colours that ground-cover plants can provide offer pleasing contrasts to the green of a turf. Ground covers, however, are not so durable as lawns and do not sustain themselves as well under foot traffic and other activities. Among the better known plants used as ground covers are Japanese spurge (*Pachysandra terminalis*), common periwinkle (*Vinca minor*), lily of the valley (*Convallaria majalis*), ajuga, or bugleweed (*Ajuga reptans*), many stonecrops (*Sedum* species), dichondra (*Dichondra repens*), and many ivies (*Hedera* species).

Shrubs and vines (climbers). Smaller woody plants, such as shrubs and bushes, have several stems arising from the base. These plants attain heights up to about 20 feet. They often form the largest part of modern gardens because their cultivation requires less labour than that of herbaceous plants, and some flowering shrubs have extended blooming periods. Among the popular garden shrubs are lilac (*Syringa vulgaris*), privet (*Ligustrum* species), spirea (*Spiraea* species), honeysuckle (*Lonicera* species), forsythia (*Forsythia* species), mock orange (*Philadelphus* species), and hydrangea (*Hydrangea* species).

Bushlike azaleas and rhododendrons (both of which are species of *Rhododendron*) provide colourful blossoms in spots where there is semishade.

Climbers are often useful in softening the sharp lines of buildings, fences, and other structures. They can provide shade as an awning or cover on an arbour or garden house. Some species are also useful as ground covers on steep slopes and terraces. Among the many woody perennial climbers for the garden are the ivies, trumpet creeper (*Bignonia*, or *Campsis, radicans*), clematis (*Clematis* species), wisteria (*Wisteria sinensis*), climbing roses, annual herbaceous vines such as morning glory (*Ipomoea* species), and ornamental gourds, the last of which can provide rapid but temporary coverage of unsightly objects.

Trees. Trees are the most permanent features of a garden plan. The range of tree sizes, shapes, and colours is vast enough to suit almost any gardening scheme, from shrubby dwarf trees to giant shade trees, from slow to rapid growers, from all tones of green to bronzes, reds, yellows, and purples. A balance between evergreen trees, such as pines and spruces, and deciduous trees, such as oaks, maples, and beeches, can provide protection and visual interest throughout the year.

Transitory elements. *Herbaceous plants.* Herbaceous plants, which die down annually and have no woody stem above ground, are readily divided into three categories, as mentioned earlier: (1) Annuals, plants that complete their life cycle in one year, are usually grown from seed sown in the spring either in the place they are to flower or in separate containers, from which they are subsequently moved into their final position. Annuals flower in summer and die down in winter after setting seed. Many brilliantly coloured ornamental plants as well as many weeds belong in this category. Examples of annuals are petunia and lobelia. (2) Biennials are plants sown from seed one year, generally during the summer. They flower the second season and then die. Examples are wallflower and sweet william. (3) Herbaceous perennials are those that die down to the ground each year but whose roots remain alive and send up new top growth each year. They are an important group in horticulture, whether grown as individual plants or in the assembly of the herbaceous border. Because they flower each year, they help to create the structure of the garden's appearance, so their placement must be considered carefully. Examples are delphinium and lupine.

Annuals, biennials, and herbaceous perennials

Bulbous plants. For horticultural purposes, bulbous plants are defined to include those plants that have true bulbs (such as the daffodil), those with corms (such as the crocus), and a few that have tubers or rhizomes (such as the dahlia or iris). A bulb is defined as a modified shoot with a disklike basal plate and above it a number of fleshy scales that take the place of leaves and contain foods such as starch, sugar, and some proteins. Each year a new stem arises from the centre. A corm consists of the swollen base of a stem, generally rounded or flattened at the top and covered with a membranous tunic in which reserve food materials are stored. A tuber or rhizome is not the base of the stem but rather a swollen part of an underground stem; it is often knobbly. All such plants have evolved in places where they can survive in a semidormant state over long unfavourable seasons, either cold, mountain winters or long, droughty summers.

THE PRINCIPLES OF GARDENING

Soil: its nature and needs. Soil is the basic element in the cultivation of all plants, although soilless growth in water with or without gravel or sand, enriched with suitable chemicals (hydroponics) can be very successful.

Soil consists of particles, mainly mineral, derived from the breakdown of rocks and other substances together with organic matter. In the pore spaces between the particles both water (containing dissolved salts) and air circulate. The air contains more carbon dioxide and less oxygen than does the atmosphere. Minute living organisms are also present in soil in immense quantities and are what make it "alive." Plants must penetrate this pore space to reach much of their nourishment.

Soil fertility

The soil must be managed for fertility (the ability to supply plant nutrients) and physical condition. Nutrients must be supplied and released in forms available to the plant. Sixteen elements are necessary for plant growth. Three of these, carbon, oxygen, and hydrogen, are provided through water and air; the other 13 are provided through the soil. The elements required in relatively large amounts are called major elements: nitrogen, phosphorus, potassium, calcium, magnesium, and sulfur. The minerals required in small quantities are called trace elements: iron, boron, manganese, zinc, molybdenum, copper, and chlorine.

Soils can be roughly divided into three main types on the basis of their usefulness horticulturally, but many areas contain a mixture.

Clays. Clays, in which the particles are very fine, are called in horticulture heavy soils, because it is difficult to turn them over with a spade. They can be very fertile but tend to be lacking in good drainage, holding their water closely adhered to the soil particles; therefore, they cannot be worked when wet, and under pressure they tend to compact tightly, driving out the air. During drought they tend to become hard and even to develop large cracks so that they cannot be worked satisfactorily. Clay soils can be lightened with as much humus as can be dug into them. Humus may be any decayed organic matter, such as farmyard manure, leaf mold, or compost made from kitchen scraps and grass clippings.

Sands and gravels. Sands and gravels are opposite in properties to clay. The soil particles are large, and the soils are called light because they are easy to work and turn in nearly all weather. Since their water-holding capacity is very low, however, they tend to dry out quickly. They are "hungry" soils requiring great quantities of manures, humus, and fertilizers to keep them prolific.

Peats and heaths. Peats and heaths are usually very acid and ill-drained. They result where conditions have prevented the complete breakdown of old vegetable matter into humus, generally because of poor aeration and surplus acid bog water. Much peat is derived from the decaying roots of sphagnum moss, useful for mulching in the garden. A heath soil is generally less fertile, consisting of a large mixture of sand with the peat and tending to be very low in mineral content and in water-retaining capacity.

The ideal garden soil is a medium loam consisting of a mixture of clay and sand, fairly rich in humus and easily worked, and not forming large clods when dry. The consistency of the soil is important, for a porous, properly tilled soil provides a medium through which roots can penetrate readily and rapidly. Another factor of importance in soils is the degree of acidity or alkalinity. Soil alkalinity is usually derived from free calcium carbonate or a similar alkaline salt. Soil reaction can be modified. It may be made more alkaline by adding one of the organic salts, of which calcium is best, in the form of lime. Acidity may be increased by adding hydrogen, in the form of sulfur compounds such as ammonia sulfate or superphosphate.

Feeding: fertilizing and watering. Maximum return can be obtained only from soil with an ample supply of elements necessary for plant growth, combined with sufficient moisture to enable them to be dissolved and absorbed through the plant hairs.

Treatment with farmyard manure or garden compost can supply the majority of these requirements. Because manure and compost are scarce in urban areas it is often necessary to use mineral fertilizers as well as organics. The soil is such a complex substance that all fertilizers must be applied in moderation and in balance with each other according to the deficiencies of the soil and the requirements of the particular crop. Different crops have different fertilizer needs. Manures are generally best dug into the ground in autumn in a temperate climate but also may be used as mulches in spring to control weeds. A mulch is a surface layer of organic matter that helps the several needs of feeding, conserving moisture, and controlling weeds. Black polyethylene sheeting is now widely used for all the mulching functions except feeding.

Watering

Watering of newly placed plants and of all plants during periods of drought is an essential gardening chore. Deep and thorough watering—not simply sprinkling the soil surface—can result in greatly improved growth. Water is essential in itself, but it also makes minerals available to plants in solution, the only form usable by plants. About one inch of water applied each week to the soil surface will percolate down about six inches; this is a minimal subsistence amount for many herbaceous garden plants, and small trees and shrubs require more. Proper watering once a week encourages deep penetration of roots, which in turn enables plants to survive dry surface conditions.

Drainage. Drainage is the other important side of water management. All plants need water but the amount needed varies, and if plants are forced to absorb more than they need, a form of drowning occurs. The symptoms are most easily seen in overwatered pot plants but are also visible to an experienced eye in badly drained corners of a garden. Roots require air as well as water and depend on subsurface water to bring the necessary oxygen. In large private gardens and in commercial gardens, buried earthenware piping is commonly used. In smaller gardens drainage can be readily achieved by the use of sumps, that is, holes dug to a depth of about four feet in affected places. The bottom half of the sump is filled with stones, through which excess water drains. Such measures may greatly improve the potential of a garden and the workability of its soil.

Protecting plants. Most plants have a precise level of tolerance to cold, below which they are killed. Many plants from tropical or subtropical regions cannot survive frost and are killed by temperatures below 32° F (0° C). These are called frost-tender. Others, called half-hardy, can withstand a few degrees of frost. Fortunately many of the best garden plants are completely hardy, a quality often encouraged by careful breeding, and will withstand any low temperatures likely to be reached in temperate regions.

Various measures can be taken to give frost protection, from the simple ones appropriate for smaller gardens to the elaborate coverings used to protect valuable horticultural crops. Removing weeds that shade the soil increases the amount of heat stored during the day. Well-drained soil is less susceptible. Any shield against wind in frosty weather enhances survival capability. The simplest form of protection is a wrapping to keep warmer air around the plant. This can be a mulch (leaves, soil, ashes) placed over the crown of a slightly tender plant in winter or a shield of sacking for leaf-shedding plants (not as desirable for evergreens, which utilize their leaves all the year).

Forcing flowers

Glass structures such as greenhouses or outdoor frames can provide additional protection for tender plants. Such structures can be heated and the temperature regulated by a thermostat to any required degree. Thus in temperate regions, orchids and other tropical plants can be grown so that they flower throughout the winter, many being forced to flower earlier than their normal season by the higher temperature. Greenhouses are divided by gardeners into four rough categories: (1) The cold house, in which there is no supplementary heating and which is suitable only for plants that will not be killed by a few degrees of frost (such as alpines or potted bulbous plants). The combination of heat from the sun and protection from wind will keep such a house appreciably warmer than the temperature outside. (2) The coolhouse, in which the minimum temperature is kept to 45° F (7° C). Most amateurs' greenhouses fall into this class, and a very large range of plants can be grown in them. (3) The intermediate house, in which the minimum temperature is kept at 55° or 60° F (13° or 16° C), and which is suitable for a wide range of orchids. (4) The hothouse, or stove house, in which the minimum temperature is kept above 60° F (16° C) and in which tropical plants such as anthuriums and cattleyas (a genus of the orchid family) can be grown.

Training and pruning. Training, the orienting of the plant in space, is achieved by techniques that direct the shape, size, and direction of plant growth. It may be accomplished by use of supports to which plants can be bent, twisted, or fastened. Pruning, the judicious cutting away of plant parts, is performed for other purposes: to contain size, to encourage fruiting in orchard trees, or to improve the appearance of ornamental trees and shrubs. It is one of the most important horticultural arts.

Where trees and shrubs are left to grow naturally, they often become much too large for their space in the garden. Also they may grow lanky and misshapen and have much dead growth. Where a branch or shoot is cut, it will often be induced to make a number of young shoots from below the cut, and these are likely to flower more freely than the older branches. Fruit trees in particular when pruned annually often give fruit of finer quality, larger in size, freer of disease, and of better colour. The two basic pruning cuts are known as heading back and thinning out. Heading back consists of cutting back the terminal portion of a branch to a bud; thinning out is the complete removal of a branch to a lateral or main trunk. Heading back, usually followed by the stimulation of lateral budbreak below the cut, produces a bushy, compact plant, suitable for a hedgerow, and it is often used to rejuvenate shrubs that have become too large or that flower poorly. Thinning out, which encourages longer growth of the remaining terminals by reducing lateral branches, tends to open up the plant, producing a longer plant. In general, pruning, started when the plant is young, obviates the need for drastic and risky remedial pruning later of a large, old, or misshapen bush or tree.

Pruning systems

Particular spatial arrangements may increase light utilization, facilitate harvesting or disease control, or improve productivity and quality. Thus, training and pruning form an essential part of fruit growing throughout the life of the plant. Special attention is given in the formative years to obtain desired shape and structure. The key to training is the point on the main stem from which branches form. In the central-leader system of training, the trunk forms a central axis with branches distributed laterally up and down and around the stem. In the open-centre or vase system the main stem is terminated and growth forced through a number of branches originating close to the upper end of the trunk. An intermediate system is called the modified-leader system. In espalier systems, plants are trained to grow flat along a wire or trellis (see Figure 1). Properly executed espaliers are extremely attractive as ornamentals. Espaliers in combination with dwarfing rootstocks allow high density orchards that are very productive on a per-unit-area basis with the fruit close to the ground for easy harvest. Extensive pruning is required annually to maintain the system.

There are a number of physiological responses to training and pruning. Orientation of the plant may have a marked effect on growth and fruiting. Thus fruit trees planted on an inclined angle become dwarfed and flower earlier; training branches in a horizontal position produces the same effect. This effect is achieved naturally when a heavy fruit load bends a limb down. The main effects of pruning are achieved by altering the root–shoot balance. Thus an explosion of vegetative growth normally occurs after extensive shoot pruning. Severely pruned plants, especially if they are in the juvenile stage of growth, tend to remain vegetative. Similarly the slowdown of vegetative growth by root pruning encourages flowering.

The training of plants to grow in unnatural shapes for ornamental purposes is called topiary. In Roman and Renaissance times, when ingenious topiary was in high fashion, plants were trained to unusual and fantastic shapes such as beasts, ships, and building facades. Though more modestly, hedges and shrubs are still trained to geometric shapes in formal gardens.

Another extreme form of training is the Japanese art of bonsai, the creation of dwarfed potted trees by a combination of pruning (both roots and tops) and restricted nutrition. Living trees more than 100 years old and only a few feet high are grown in special containers arranged to resemble the natural landscape.

Propagation. New plants are produced either from seed or by the techniques of division, taking cuttings, grafting, budding, or layering. (A fuller description of propagation and breeding processes is found below in the section *Horticulture.*) For the ordinary gardener propagation is a relatively simple but interesting process normally used for economic provision of more versions of favourite plants; as part of exchanges with other gardeners; or as a wise precaution against winter losses.

Propagation by cuttings is the most common practice. Young shoots of the current season are usually the most successful at rooting. Roses are usually propagated by budding, in which a bud from the rose desired is inserted in rootstock (that part of the plant tissue from which a root can form) just above ground level. Fruit trees are usually propagated by layering, in which a young shoot is pegged down in the ground with the end twisted upward almost at right angles; the lower side of the wood just before the twist is wounded so as to induce rooting. When this has taken place, the layer is severed from the parent.

Control of weeds. Controlling weeds is a basic, and probably the most arduous, factor of cultivation and has been carried on from the time the earliest nomads settled down to an agricultural life. It has always been necessary to free the chosen crops of competition from other plants. For smaller weeds hoeing is practicable. The weeds are cut off by the action of the hoe and left to wither on the surface. Hand weeding, by pulling out individual weeds, is often necessary in gardens, particularly the rock garden, in seed boxes, and in the herbaceous border or among annuals. Chemical and biological control of weeds developed greatly after World War II and has made much mechanical cultivation unnecessary.

Control of pests and diseases. Damage to plants is most often caused by pests such as insects, mites, eelworms, and other small creatures but may also be caused by mammals such as deer, rabbits, and mice. Damage by disease is that caused by fungi, bacteria, and viruses.

Pest control through vigilance

Prevention is generally better than cure, and constant vigilance is necessary to prevent a pest infestation or a disease outbreak. Control can be obtained by the use of chemical sprays, dusts, and fumigants, but some of these are so potent that they should be used only by the experienced operator. Considerable evidence is available regarding the possible harmful long-term effects on the biological chain of excessive use of some of these noxious chemicals, particularly the hydrocarbons. Some control can be obtained through good garden practices: clearing up all dead and diseased material and burning it; pruning and thinning so that a reasonable circulation of air is obtained through the plants; and crop rotation. Some control may also be obtained through the natural biological predators. The breeding of plants immune to certain pests and diseases is also a valuable means of control.

Mechanical aids. Mechanical devices to aid the gardener include tillers, lawn mowers, hedge cutters, sprinklers, and a variety of more esoteric equipment that has made gardening an easier pursuit. Such machines are not a substitute for good judgment and technique in the garden, however, nor will they give anyone a completely labour-free garden. They do enable a considerably larger area to be cultivated and maintained than if all labour is performed by hand. (G.A.C.H./P.M.Sy./Ro.P.)

Raising houseplants

The range of houseplants

Many exotic plants native to warm, frost-free parts of the world can be grown indoors in colder climates, in portable containers or miniature gardens. Most houseplants are derived from plants native to the tropics and near tropics. Those that make the best indoor subjects are the species that adjust comfortably to the rather warm, dry conditions that generally prevail in indoor living spaces.

Although many plants can be grown successfully indoors, there are certain groups that, because of their attractiveness and relative ease of maintenance, are generally considered the best houseplants. These include the aroids, bromeliads, succulents (including cacti), ferns, begonias, and palms, all of which have long been favourites. Somewhat more

Selection of houseplants that, with care, grow well indoors.
Pamela J Harper

demanding are those that are grown primarily for their flowers—African violets, camellias, gardenias, geraniums (*Pelargonium* species), and orchids.

HISTORICAL BACKGROUND

Paintings and sculptures make clear that the practice of indoor gardening can be traced at least to the early Greeks and Romans, who grew plants in pots and perhaps brought them into their homes. The older civilizations of Egypt, India, and China also made use of pot plants but usually in outdoor situations, often in courtyards that were extensions of the house; and for centuries the Japanese have carried on the dwarfing of trees and other plants for room ornaments. But the popular art of growing houseplants did not receive much comment until the 17th century, when, in *The Garden of Eden* (1652), Sir Hugh Platt, an English agricultural authority, wrote of the possibility of cultivating plants indoors. Shortly thereafter, glasshouses (greenhouses) and conservatories, which had been used during Roman times to force plants to flower, were built in England and elsewhere to house exotic plants. In mid-19th-century England and France, books began to appear on the growing of plants in private residences, and the use of enclosed glass cases of plants (the wardian cases, or terraria) became popular.

TYPES OF HOUSEPLANTS

There are thousands of tropical and subtropical plants that can adapt to growing indoors. Although some fancy exotic species do well only in a humid conservatory or a glass-enclosed terrarium, a great many species have been introduced that endure the adverse conditions of dry heat and low light intensity that prevail in many houses. A selection of the more widely favoured houseplants follows, under two sections: foliage plants, some of which also bear interesting flowers; and flowering plants, species kept primarily for their flowers.

Foliage plants. In the aroid family, which has provided a range of long-lived houseplants, most prominent are the philodendrons. These are handsome tropical American plants, generally climbers, with attractive leathery leaves, heart-shaped, and often cut into lobes. *Monstera deliciosa,* or *Philodendron pertusum,* the Swiss cheese plant, has showy, glossy, perforated leaves slashed to the margins.

The dumb canes, of the genus *Dieffenbachia,* appear in a number of attractive species. They are handsome tropical foliage plants usually with variegated leaves; they tolerate neglect and thrive even in dry rooms. The Chinese evergreens, of the genus *Aglaonema,* are fleshy tropical Asian herbs of slow growth, with leathery leaves often bearing silvery or colourful patterns; they are durable and are tolerant of indoor conditions. Members of *Scindapsus,* popularly known as pothos, or ivy-arums, are tropical climbers from the Malaysian monsoon area; their variegated leaves are usually small in the juvenile stage. They do well in warm and even overheated rooms. The peace lilies (not a true lily), of the genus *Spathiphylla,* are easy-growing, vigorous tropical herbs forming clumps; they have green foliage and a succession of flowerlike leaves (spathes), usually white. Species of *Anthurium,* many of which, such as the flamingo flower, have colourful spathes, do best in humid conditions. *Caladium*'s tropical American tuberous herbs produce fragile-looking but colourful foliage; they keep surprisingly well if protected from chills and wintry drafts.

Begonias, with their often very decorative leaves, have long been favourites among houseplants, but, with few exceptions, they require more humidity and fresh air than the modern home provides. *Begonia metallica,* with its olive-green, silver-haired foliage; *B. masoniana,* with beautiful green, puckered leaves splotched brown; and *B. serratipetala,* with small leaves spotted pink, are examples of types more resistant to dry rooms.

Small foliage plants

There are many small foliage plants, often with strikingly patterned foliage, native to the tropical forest floor, some of which have become remarkably good houseplants. Among them are several prayer plants (*Maranta* species), which fold their attractive leaves at night; and the exquisite *Calathea makoyana,* or peacock plant, with translucent foliage marked with a feathery peacock design. *Pilea cadierei,* or aluminum plant, is easy to grow; it has fleshy leaves splashed with silver. *Codiaeum* species, or crotons, are multicoloured foliage plants that need maximum light and warmth to hold their leaves and coloration well. Although primarily thought of as bedding plants, the varicoloured coleuses, or painted nettles, can decorate a sunny window with a brilliant array of leaf patterns. *Peperomia* species form miniature rosettes or vines with waxy foliage, corrugated and decorated either with silver or creamy white.

Bromeliads constitute a plant family peculiar to the Western Hemisphere; they dwell on trees and rocks (as epiphytic plants) or on the forest floor (as terrestrial plants) and usually form rosettes of leathery, concave leaves, many with bizarre designs or striking variegations. Their flowers may be hidden deep in the centre of the rosette, surrounded by a cup of brilliant crimson inner leaves, as in *Neoregelia* and *Nidularium.* Species of *Aechmea* and *Guzmania* form colourful spikes or heads of long-lasting leathery bracts or bright berries. *Billbergia* species are tubular in shape; their showy flower stalk, with blue flowers, is often pendant. Most forms of *Tillandsia* and *Vriesea* have spear-shaped, flattened, colourful flower spikes. The earth stars of the terrestrial genus *Cryptanthus* are more or less flattened rosettes with striking leaf design, mottled, striped, or tiger-banded in silver over greens and bronzes.

Succulents. Cacti, most members of which are native to the Western Hemisphere, have developed a special capacity to store water in thick, fleshy bodies. They thrive in much sunlight and need very little water. There are many often curious forms: the tiny button cactus, *Epithelantha;* the myriad pincushion species of *Mammillaria; Parodia,* or Tom Thumb cactus; and *Rebutia,* the pygmy cactus. The last two bloom when young and tiny. Other forms include *Gymnocalycium,* or chin cactus; *Notocactus,* or ball cactus; *Echinocactus,* known as barrel cactus; various *Opuntia* species, including bunny ears and chollas; and *Cephalocereus,* or old-man cactus, with its glistening white hair. Larger cacti include *Cereus* and its relatives, often night-blooming, and the giants of the desert, such as the saguaro (classified as *Cereus giganteus* or as *Carnegiea gigantea*), with branching columns up to 50 feet (15 metres) in height. Cacti of tropical forests include the epiphytic *Rhipsalis,* found also in Africa, Madagascar, and Sri Lanka, and the near-epiphytic leaf, or orchid, cacti, *Epiphyllum,* which bloom in many colours.

Succulents other than cacti have also contributed favourite subjects for indoor growing. A typical stem succulent is *Euphorbia,* with its often angled candelabra-like columns resembling those of cacti. Leaf succulents are represented by *Aloe,* famous since ancient times as a medicinal plant; *Echeveria,* or hen and chickens; *Kalanchoe tomentosa,* the panda plant; *Crassula,* the jade plant; and *Haworthia,* which has rosettes with pearly dotted leaves. Durable pot plants include the strap-leaf snake plants, or *Sansevieria* species; they are remarkable for tolerating much neglect and growing in less than ideal locations.

Trees. *Dracaena,* the dragon trees, includes such houseplants as *D. marginata,* from Madagascar, which forms clusters of twisted stems topped by rosettes of narrow, leathery leaves. Other examples are *D. deremensis* 'Warneckei,' with its handsome, symmetrical rosette of sword-shaped, milky-green leaves with white stripes; and *D. sanderiana,* the ribbon plant, a diminutive and slender, highly variegated species that can be grown in water. Similar in appearance is *Pandanus veitchii,* which has a rosette of leathery, sword-shaped leaves—glossy green and banded white—arranged in spirals.

Sub-tropical evergreens

Several subtropical evergreens can be grown in cooler locations indoors. Preeminent among them is the Norfolk Island pine (*Araucaria heterophylla,* or *A. excelsa*)—not a true pine—an undemanding graceful conifer with tiered branches of fresh green needles; it is long-lived even in dim corners in any temperature above freezing. *Podocarpus,* the somber Buddhist pine, forms dense pyramids of dark-green needlelike leaves; it also prefers cooler locations.

Common houseplants.
(Top left) African violets (*Saintpaulia*); (top right) spider plant (*Chlorophytum comosum*); (centre right) rabbit's foot fern (*Davallia fejeensis*); (bottom left) weeping fig (*Ficus benjamina*); (bottom centre) peperomia (*Peperomia obtusifolia*); (bottom right) jade plant (*Crassula argentea*).

Among the many broad-leaved woody evergreens used as houseplants is *Brassaia actinophylla,* the umbrella tree, better known as *Schefflera.* Its spreading crowns of palmately divided, glossy green leaves do best in a light and warm location. Another picturesque plant is *Polyscias fruticosa,* the Ming aralia, with willowy, twisting stems densely clothed toward their tops with fernlike, lacy foliage.

The so-called rubber trees of the genus *Ficus* are widely used in homes and offices. All require good light to hold their foliage well. Best known is the large-leaved *F. elastica* 'Decora,' but perhaps even more attractive, because of their very graceful habit, are several small-leaved kinds, such as *F. benjamina, F. retusa,* and *F. nitida.* The giant violin-like, leathery leaves of *F. lyrata,* better known as *F. pandurata,* make the plant an attractive indoor "tree." *Coccoloba,* the sea grape, is another sturdy woody plant, somewhat resembling *Ficus,* with leathery, rounded leaves and crimson veining.

Because of their majestic beauty and distinctive decorative appeal many palms are grown indoors. Best known of the feather palms is the paradise palm (*Howea,* or *Kentia*), which combines grace with sturdiness; its thick, leathery leaves can stand much abuse. The parlour palms and bamboo palms of the genus *Chamaedorea* have dainty fronds on slender stalks; they keep well even in fairly dark places. Similar in appearance is the areca palm (*Chrysalidocarpus*) with slender yellowish stems carrying feathery fronds in clusters. The pygmy date (*Phoenix roebelenii*), a compact palm with gracefully arching, dark-green leaves, is an excellent houseplant if kept warm and moist.

Ferns. Ferns, which come in a wide variety of forms, provide many popular houseplants. Among the best smaller parlour ferns is the sword fern, *Nephrolepis,* with bushy rosettes of leafy fronds; the holly fern (*Cyrtomium*), which has glossy dark leathery leaves; and the leather-leaf fern (*Rumohra*), with its leathery but lacy fronds. The bird's-nest fern (*Asplenium nidus*) forms a rosette of parchment-textured, fanlike, light-green fronds. Long-lasting *Polypodium,* often known as hare's-foot fern because of its pawlike, woolly rhizomes (rootlike structures), has feathery leaves on slender stalks. Among the attractive damp-loving ferns are the several species of dainty maidenhairs (*Adiantum*). The so-called table ferns are a varied group of mainly *Pteris* and *Pellaea* species; some are frilly, others variegated; and in their younger stages they are ideal subjects for terraria. The *Platycerium,* or staghorn fern, has always aroused great curiosity because of its unusual shape. Growing as epiphytes on trees, these ferns have sterile fronds that cling snugly to the bark or, in cultivation, to a wire basket or wooden block; their much divided fertile fronds resemble the antlers of deer. One of the best of the palmlike tree ferns is the Hawaiian *Cibotium,* with a stout, fibrous trunk that bears a crown of light-green fronds.

Popular fernlike plants include *Asparagus* species that have plumy fronds. Species of *Selaginella,* called sweat plants or club moss, are strictly warm terrarium subjects; their delicate fronds greedily soak up moisture from the atmosphere to keep from shriveling.

Climbers and trailers. Climbers and trailers, weeping plants with stems too weak to support themselves, occur in most plant families. Best known are many varieties of ivy (*Hedera*). Generally, they prefer a cool location, but some small-leaved or variegated varieties do well on the windowsill. Several *Cissus* species, such as *C. rhombifolia,* the grape ivy, with metallic foliage, and the leathery *C. antarctica,* or kangaroo vine, are excellent plants for boxes or room dividers. Intriguing is the slow-growing *Hoya,* or wax plant, with leathery foliage and waxy, wheel-shaped blooms. By contrast, the inch plants and wandering jew, species of *Tradescantia* and *Zebrina,* are rapid growers with watery stems and varicoloured leaves; these long-beloved houseplants are used widely in window shelves or hanging baskets. The spider plants (*Chlorophytum,* or *Anthericum*) are houseplant favourites, forming clusters of fresh green ribbonlike leaves banded white; young plantlets develop from the tips of arching stalks.

Flowering plants. Most of the flowering potted plants seen at holiday times are not easy subjects for long-term indoor cultivation. They require high light intensity, careful watering, and day–night differences in temperature that are not usually available in the home; greenhouses offer better chances for successful cultivation. There are exceptions, however; one of the most successfully adapted houseplants is the African violet (*Saintpaulia*), with countless named varieties, with blossoms from violet blue through rose to white and single- and double-flowered forms. Window bloomers, such as *Abutilon,* the parlour maples, have bell-like flowers resembling Chinese lanterns. *Impatiens,* or busy Lizzie, is a genus of succulent herbs producing a succession of spurred flowers in gay colours. *Hibiscus,* the rose mallows, has short-lived giant blossoms in brilliant colours. Geraniums (botanically *Pelargonium*) have long been popular flowering plants in the sunny window; the foliage is often variegated or scented, and flower clusters may be in reds, pinks, and white.

A number of bulbous plants do well in lighted windows: *Hippeastrum,* better known as amaryllis; *Clivia,* the Kaffir lily; *Haemanthus,* the blood lily; *Neomarica,* the apostle plant; and *Veltheimia,* the forest lily.

Orchids present a more difficult and specialized subject for successful home cultivation, usually because of their requirements for light, controlled temperature, and sufficient humidity and ventilation. There are some kinds, however, that give good results with ordinary care: epiphytic *Epidendrum* species, with waxy, usually fragrant, often greenish blossoms; and *Oncidium* species, or butterfly orchids, with brightly coloured, long-lasting yellow flowers marked with brown and often produced in large sprays.

Small fruit plants

Small flowering plants that produce edible fruit can be grown on a windowsill. With sufficient light and ventilation, success may be had with the Calamondin orange (×*Citrofortunella mitis*), the dwarf Chinese lemon (*Citrus limon* 'Meyeri'), and the American-wonder lemon (*C. limon* 'Ponderosa'). The fig tree (*Ficus carica*) can be grown to yield edible fruit, as can the dwarf Cavendish banana (*Musa acuminata,* formerly *M. nana*) and the dwarf pomegranate (*Punica granatum nana*), the pineapple (*Ananas comosus*), and the coffee tree (*Coffea arabica*).

(A.B.Gr./Ro.P.)

Horticulture

Horticulture is the branch of plant agriculture dealing with garden crops, generally fruits, vegetables, and ornamental plants. The word is derived from the Latin *hortus,* "garden," and *colere,* "to cultivate." As a general term, it covers all forms of garden management; but in ordinary use it refers to intensive commercial production. In terms of scale, horticulture falls between domestic gardening and field agriculture, though all forms of cultivation naturally have close links.

Horticulture is divided into the cultivation of plants for food (pomology and olericulture) and plants for ornament (floriculture and landscape horticulture). Pomology deals with fruit and nut crops. Olericulture deals with herbaceous plants for the kitchen, including, for example, carrots (edible root), asparagus (edible stem), lettuce (edible leaf), cauliflower (edible flower), tomatoes (edible fruit), and peas (edible seed). Floriculture deals with the production of flowers and ornamental plants; generally, cut flowers, pot plants, and greenery. Landscape horticulture is a broad category that includes plants for the landscape, including lawn turf, but particularly nursery crops such as shrubs, trees, and climbers.

The specialization of the horticulturist and the success of the crop are influenced by many factors. Among these are climate, terrain, and other regional variations. (Ro.P.)

HORTICULTURAL REGIONS

Temperate zones. Temperate zones for horticulture cannot be defined exactly by lines of latitude or longitude but are usually regarded as including those areas where frost in winter occurs, even though rarely. Thus most parts of Europe, North America, and northern Asia are included, though some parts of the United States, such as southern California and Florida, are considered subtropical. A few parts of the north coast of the Mediterranean and the Mediterranean islands are also subtropical. In the Southern Hemisphere, practically all of New Zealand, a few parts of Australia, and the southern part of South America have temperate climates. For horticultural purposes altitude is also a factor; the lower slopes of great mountain ranges, such as the Himalayas and the Andes, are included. Thus the temperate zones are very wide and the range of plants that can be grown in them is enormous, probably greater than in either the subtropical or tropical zones. In the temperate zones are the great coniferous and deciduous forests: pine, spruce, fir, most of the cypresses, the deciduous oaks (but excluding many of the evergreen ones), ash, birch, and linden (lime).

The temperate zones are also the areas of the grasses—the finest lawns particularly are in the regions of moderate or high rainfall—and of the great cereal crops. Rice is excluded as being tropical, but wheat, barley, corn (maize), and rye grow well in the temperate zones.

The winter rest

Plants in the temperate zones benefit from a winter resting season, which clearly differentiates them from tropical plants, which tend to grow continuously. Bulbs, annuals, herbaceous perennials, and deciduous trees become more frost-resistant with the fall of sap and therefore have a better chance of passing the resting season undamaged. Another influence is the varying length of darkness and light throughout the year, so that many plants, such as chrysanthemums, have a strong photoperiodism. The chrysanthemum flowers only in short daylight periods, although artificial lighting in nurseries can produce flowers the year round.

Most of the great gardens of the world have been developed in temperate zones. Particular features such as rose gardens, herbaceous borders, annual borders, woodland gardens, and rock gardens are also those of temperate-zone gardens. Nearly all depend for their success on the winter resting period.

Tropical zones. There is no sharp line of demarcation between the tropics and the subtropics. Just as many tropical plants can be cultivated in the subtropics, so also many subtropical and even temperate plants can be grown satisfactorily in the tropics. Elevation is a determining factor. For example, the scarlet runner bean, a common plant in temperate regions, grows, flowers, and develops pods normally on the high slopes of Mt. Meru in Africa near the Equator; it will not, however, set pods in Hong Kong, a subtropical situation a little south of the Tropic of Cancer but at a low elevation.

Effect of rainfall and length of daylight

In addition to elevation, another determinant is the annual distribution of rainfall. Plants that grow and flower in the monsoon areas, as in India, will not succeed where the climate is uniformly wet, as in Bougainville in the Solomon Islands. Another factor is the length of day, the number of hours the Sun is above the horizon; some plants flower only if the day is long, but others make their growth during the long days and flower when the day is short. Certain strains of the cosmos plant are so sensitive to light that, where the day is always about 12 hours, as near the Equator, they flower when only a few inches high; if grown near the Tropics of Cancer or Capricorn, they attain a height of several feet, if the seeds are sown in the spring, before flowering in the short days of autumn and winter. Poinsettia is a short-day plant that may be seen in flower in Singapore on any day of the year, while in Trinidad it is a blaze of glory only in late December.

In the tropics of Asia and parts of Central and South America the dominant features of the gardens are flowering trees, shrubs, and climbers. Herbaceous plants are relatively few, but many kinds of orchids can be grown.

Vegetable crops vary in kind and quality with the presence or absence of periodic dry seasons. In the uniformly wet tropics, the choice is limited to a few root crops and still fewer greens. Sweet potatoes grow and bear good crops where the average monthly rainfall, throughout the year, exceeds 10 inches (25 centimetres); they grow even better where there is a dry season. The same can be said of taro, yams, and cassava. Tropical greens from the Malay Peninsula are not as good as those grown in South China, the Hawaiian Islands, and Puerto Rico. They include several spinaches, of which Chinese spinach or amaranth is the best; several cabbages; Chinese onions and chives; and several gourds, cucumbers, and, where there is a dry season, watermelons. Brinjals, or eggplants, peppers, and okra are widely cultivated. Many kinds of beans can be grown successfully, including the French bean from the American subtropics, the many varieties of the African cowpea, and yard-long bean. The yam bean, a native of tropical America, is grown for its edible tuber. In the drier areas the pigeon pea, the soybean, the peanut (groundnut), and the Tientsin green bean are important crops. Miscellaneous crops include watercress, ginger, lotus, and bamboo. (G.A.C.H./P.M.Sy./Ed.)

PROPAGATION

Propagation, the controlled perpetuation of plants, is the most basic of horticultural practices. Its two objectives are to achieve an increase in numbers and to preserve the essential characteristics of the plant. Propagation can be achieved sexually by seed or asexually by utilizing specialized vegetative structures of the plant (tubers and corms) or by employing such techniques as cutting, layering, grafting, and tissue culture. (A detailed discussion of the methods of controlling sexual propagation can be found in the article FARMING AND AGRICULTURAL TECHNOLOGY.)

Seed propagation. The most common method of propagation for self-pollinated plants is by seed. In self-pollinated plants, the sperm nuclei in pollen produced by a flower fertilize egg cells of a flower on the same plant. Propagation by seed is also used widely for many cross-pollinated plants (those whose pollen is carried from one plant to another). Seed is usually the least expensive and often the only means of propagation and offers a convenient way to store plants over long periods of time. Seed kept dry and cool normally maintains its viability from harvest to the next planting season. Some can be stored for years under suitable conditions. Seed propagation also makes it possible to start plants free of most diseases. This is especially true with respect to virus diseases, because it is almost impossible to free plants of virus infections and because most virus diseases are not transmitted by seed. There are two disadvantages to seed propagation. First, genetic variation occurs in seed from cross-pollinated plants because they are heterozygous. This means that the plant grown from seed may not exactly duplicate the characteristics of its parents and may possess undesirable characteristics. Second, some plants take a long time to grow from seed to maturity. Potatoes, for example, do not breed true from seed and do not produce large tubers the first year. These disadvantages are overcome by vegetative propagation.

The practice of saving seed to plant the following year has developed into a specialized part of horticulture. Seed technology involves all of the steps necessary to ensure production of seed with high viability, freedom from disease, purity, and trueness to type. These processes may include specialized growing and harvesting techniques, cleaning, and distribution.

Relatively little tree and shrub seed is grown commercially; it is generally harvested from natural stands. Rootstock seed for fruit trees is often obtained as a by-product in fruit-processing industries. Seed growing and plant improvement are related activities. Thus many seed-producing firms actively engage in plant-breeding programs to accomplish genetic improvement of their material.

Harvesting of dry seed is accomplished by threshing. Seed from fleshy fruits is recovered through fermentation of the macerated (softened by soaking) pulp or directly from screening. Machines have been developed to separate and clean seed, based on size, specific gravity, and surface characteristics. Extended storage of seed requires low humidity and cool temperature.

Trade in seed requires quality control. For example, U.S. government seed laws require detailed labeling showing germination percentage, mechanical purity, amount of seed, origin, and moisture content. Seed testing is thus an important part of the seed industry.

While most vegetable seed germinates readily upon exposure to normally favourable environmental conditions, many seed plants that are vegetatively (asexually) propagated fail to germinate readily because of physical or physiologically imposed dormancy. Physical dormancy is due to structural limitations to germination such as hard impervious seed coats. Under natural conditions weathering for a number of years weakens the seed coat. Certain seeds, such as the sweet pea, have a tough husk that can be artificially worn or weakened to render the seed coat permeable to gases and water by a process known as scarification. This is accomplished by a number of methods including abrasive action, soaking in hot water, or acid treatment. Physiologically imposed dormancy involves the presence of germination inhibitors. Germination in such seed may be accomplished by treatment to remove these inhibitors. This may involve cold stratification, storing seed at high relative humidity and low temperatures, usually slightly above freezing. Cold stratification is a prerequisite to the uniform germination of many temperate-zone species such as apple, pear, and redbud.

Scarification

Vegetative propagation. Asexual or vegetative reproduction is based on the ability of plants to regenerate tissues and parts. In many plants vegetative propagation is a completely natural process; in others it is an artificial one. Vegetative propagation has many advantages. These include the unchanged perpetuation of naturally cross-pollinated or heterozygous plants and the possibility of propagating seedless progeny. This means that a superior plant may be reproduced endlessly without variation. In addition, vegetative propagation may be easier and faster than seed propagation, because seed dormancy problems are eliminated and the juvenile nonflowering stage of some seed-propagated plants is eliminated or reduced.

Vegetative propagation is accomplished by use of (1) apomictic seed; (2) specialized vegetative structures such as runners, bulbs, corms, rhizomes, offshoots, tubers, stems, and roots; (3) layers and cuttings; (4) grafting and budding; and (5) tissue culture.

Apomixis. Apomixis, the development of asexual seed (seed not formed via the normal sexual process), is a form of vegetative propagation for some horticultural plants including Kentucky bluegrass, mango, and citrus. Virus-free progeny can be produced in oranges from a seed that is formed from the nucellus, a maternal tissue.

Vegetative structures. Many plants produce specialized vegetative structures that can be used in propagation. These may be storage organs such as tubers that enable the plant to survive adverse conditions or organs adapted for natural propagation—runners or rhizomes—so that the plant may rapidly spread.

Bulbs and corms

Bulbs consist of a short stem base with one or more buds protected by fleshy leaves. They are found in such plants as the onion, daffodil, and hyacinth. Bulbs commonly grow at ground level, though bulblike structures (bulbils) may form on aerial stems in some lilies or in association with flower parts, as in the onion. Buds in the axils (angle between leaf and stem) of the fleshy leaves may form miniature bulbs (bulblets) that when grown to full size are known as offsets. Corms are short, fleshy, underground stems without fleshy leaves. The gladiolus and crocus are propagated by corms. They may produce new cormels from fleshy buds. Rhizomes are horizontal, underground stems that are compressed, as in the iris, or slender, as in turf grasses. Runners are specialized aerial stems, a natural agent of increase and spread for such plants as the strawberry, strawberry geranium, and bugleweed (*Ajuga*). Tubers are fleshy enlarged portions of underground stem. The edible portion of the potato, the tuber, is also used as a means of propagation.

A number of plants form lateral shoots from the stem, which when rooted serve to propagate the plant. These are known collectively as offshoots but are often called offsets, crown divisions, ratoons, or slips.

Roots may also be structurally modified as propagative and food-storage organs. These tuberous roots, fleshy swollen structures, readily form shoots (called adventitious, because they do not form from nodes). The sweet potato and dahlia are propagated by tuberous roots. Shoots that rise adventitiously from roots are called suckers. The red raspberry is propagated by suckers.

Layering and cutting. Propagation can be accomplished by methods in which plants are induced to regenerate missing parts, usually adventitious roots or shoots. When the regenerated part is still attached to the plant the process is called layerage, or layering; when the regenerating portion is detached from the plant the process is called cuttage, or cutting.

Layering often occurs naturally. Drooping black raspberry stems tend to root in contact with the soil. The croton, a tropical plant, is commonly propagated by wrapping moist sphagnum enclosed in plastic around a stem cut to induce rooting. After rooting, the stem is detached and planted. Though simple and effective, layering is not normally adapted to large-scale nursery practices.

Cutting is one of the most important methods of propagation. Many plant parts can be used; thus cuttings are classified as root, stem, or leaf. Stem cuttings are the most common.

The ability of stems to regenerate missing parts is variable; consequently plants may be easy or difficult to root. The physiological ability of cuttings to form roots is due to an interaction of many factors. These include transportable substances in the plant itself: plant hormones (such as auxin), carbohydrates, nitrogenous substances, vitamins, and substances not yet identified. Environmental factors such as light, temperature, humidity, and oxygen are important, as are age, position, and type of stem.

Although easy-to-root plants such as willow or coleus can be propagated merely by plunging a stem in water or moist sand, the propagation of difficult-to-root species is a highly technical process. To achieve success with difficult-to-root plants special care is taken to control the environment and encourage rooting. A number of growth regulators stimulate rooting. A high degree of success has been achieved with indolebutyric acid, a synthetic auxin that is applied to the cut surface. A number of materials known as rooting cofactors have been found that interact with auxin to further stimulate rooting, and these are sold as a hormone rooting compound.

Humidity control is particularly important to prevent death of the stem from desiccation before rooting is complete. The use of an intermittent-mist system in propagation beds has proved to be an important means of improving success in propagation by cuttings. These operate by applying water to the plant for a few seconds each minute.

Grafting. Grafting involves the joining together of plant parts by means of tissue regeneration. The part of the combination that provides the root is called the stock; the added piece is called the scion. When more than two parts are involved, the middle piece is called the interstock. When the scion consists of a single bud, the process is called budding. Grafting and budding are the most widely used of the vegetative propagation methods.

How grafting works

Stock cambium and scion cambium respond to being cut by forming masses of cells (callus tissues) that grow over the injured surfaces of the wounds. The union resulting from interlocking of the callus tissues is the basis of graftage. In dicots (*e.g.,* most trees) cambium—a layer of actively dividing cells between xylem (wood) and phloem (bast) tissues—is usually arranged in a continuous ring; in woody members, new layers of tissue are produced annually. Monocot stems (*e.g.,* lilacs, orchids) do not possess a continuous cambium layer or increase in thickness; grafting is seldom possible.

The basic technique in grafting consists of placing cambial tissues of stock and scion in intimate association, so that the resulting callus tissue produced from stock and scion interlocks to form a living continuous connection. A snug fit can be obtained through the tension of the split stock and scion or both. Tape, rubber, and nails can be used to achieve close contact. In general, grafts are only compatible between the same or closely related species. Success in grafting depends on skill in achieving a snug fit. Warm temperatures (80°–85° F [27°–30° C]) increase callus formation and improve "take" in grafting. Thus grafts using dormant material are often stored in a warm, moist place to stimulate callus formation.

In grafting and budding, the rootstock can be grown

from seed or propagated asexually. Within a year a small amount of scion material from one plant can produce hundreds of plants. Some methods of grafting and budding are illustrated in Figure 2.

Grafting has uses in addition to propagation. The interaction of rootstocks may affect the performance of the stock through dwarfing or invigoration and in some cases may affect quality. Further, the use of more than one component can affect the disease resistance and hardiness of the combination.

Healed cleft graft on cherry (*Prunus*) stock. The scions (top) are double flowering cherry.

Grafting as a means of growth control is used extensively with fruit trees and ornamentals such as roses and junipers. Fruit trees are normally composed of a scion grafted onto a rootstock. Sometimes an interstock is included between the scion and stock. The rootstock may be grown from seed (seedling rootstock) or asexually propagated (clonal rootstock). In the apple, a great many clonal rootstocks are available to give a complete range of dwarfing; rootstocks are also available to invigorate growth of the scion cultivar.

Tissue-culture techniques utilizing embryos, shoot tips, and callus can be used as a method of propagation. The procedure requires aseptic techniques and special media to supply inorganic elements; sugar; vitamins; and, depending on the tissue, growth regulators and organic complexes such as coconut milk, yeast, and amino-acid extract.

Embryo culture has been used to produce plants from embryos that would not normally develop within the fruit. This occurs in early-ripening peaches and in some hybridization between species. Embryo culture can also be used to circumvent seed dormancy.

A shoot tip, when excised and cultured, may produce roots at the base. This technique is employed for the purpose of producing plants free of disease. Certain orchids are rapidly multiplied by this method. Cultured shoot tips form an embryo-like stage that can be sectioned indefinitely to build up large stocks rapidly. These bulblike bodies left unsectioned develop into small plantlets. A similar procedure is used with the carnation, in which the shoot tip forms a cell mass that can be subdivided.

Callus-tissue culture—a very specialized technique that involves growth of the callus, followed by procedures to induce organ differentiation—has been successful with a number of plants including carrot, asparagus, and tobacco. Used extensively in research, callus culture has not been considered a practical method of propagation. Callus culture produces genetic variability because in some cases cells double their chromosome number. In rice and tobacco, mature plants have been obtained from callus formed from pollen. These plants have half the normal number of chromosomes.

BREEDING

The isolation and production of superior types known as cultivars are the very keystones of horticulture. Plant breeding, the systematic improvement of plants through the application of genetic principles, has placed improvement of horticultural plants on a scientific basis. The raw material of improvement is found in the great variation that exists between cultivated plants and related wild species. The incorporation of these changes into cultivars adapted to specific geographical areas requires a knowledge of the theoretical basis of heredity and art and the skill to discover, perpetuate, and combine these small but fundamental differences in plant material.

The goal of the plant breeder is to create superior crop varieties. The cultivated variety, or cultivar, can be defined as a group of crop plants having similar but distinguishable characteristics. The term cultivar has various meanings, however, depending on the mode of reproduction of the crop. With reference to asexually propagated crops, the term cultivar means any particular clone considered of sufficient value to be graced with a name. With reference to sexually propagated crops, the concept of cultivar depends on the method of pollination. The cultivar in self-pollinated crops is basically a particular homozygous genotype, a pure line. In cross-pollinated crops the cultivar is not necessarily typified by any one plant but sometimes by a particular plant population, which at any one time is composed of genetically distinguishable individuals.

ENVIRONMENTAL CONTROL

Control of the natural environment is a major part of all forms of cultivation, whatever its scale. The basic processes involved in this task have already been described in a preceding section on the principles of gardening, and these also apply to horticulture. The scale, intensiveness, and economic risk in commercial gardening and nurs-

Poinsettias (*Euphorbia pulcherrima*) being cultivated in the controlled environment of a modern greenhouse.

John H Gerard

eries, however, often require approaches markedly different from those of the small home garden; and some of these are described here.

The intensive cultivation practiced in horticulture relies on extensive control of the environment for all phases of plant life. The most basic environmental control is achieved by location and site: sunny or shady sites, proximity to bodies of water, altitude, and latitude.

Structures. Various structures are used for temperature control. Cold frames, used to start plants before the normal growing season, are low enclosed beds covered with a removable sash of glass or plastic. Radiant energy passes through the transparent top and warms the soil directly. Heat, however, as long-wave radiation, is prevented from leaving the glass or plastic cover at night. Thus heat that builds up in the cold frame during the day aids in warming the soil, which releases its heat gradually at night to warm the plants. When supplemental heat is provided, the structures are called hotbeds. At first, supplemental heat was supplied by respiration through the decomposition of manure or other organic matter. Today, heat is provided by electric cables, steam, or hot-water pipes buried in the soil.

Greenhouses

Greenhouses are large hotbeds, and in most cases the source of heat is steam. While they were formerly made of glass, plastic films are now extensively used. Modern greenhouse ranges usually have automatic temperature control. Summer temperatures can be regulated by shading or evaporative "fan-and-pad" cooling devices. Air-conditioning units are usually too expensive except for scientific work. Greenhouses with precise environmental controls are known as phytotrons. Other environmental factors are controlled through automatic watering, regulation of light and shade, addition of carbon dioxide, and the regulation of fertility.

Shade houses are usually walk-in structures with shading provided by lath or screening. Summer propagation is often located in shade houses to reduce excessive water loss by transpiration.

Temperature control. A number of temperature-control techniques are used in the field, including application of hot caps, cloches, plastic tunnels, and mulches of various types. Hot caps are cones of translucent paper or plastic that are placed over the tops of plants in the spring. These act as miniature greenhouses. In the past small glass sash called cloches were placed over rows to help keep them warm. Polyethylene tunnels supported by wire hoops that span the plants are now used for the same purpose. As spring advances the tunnels are slashed to prevent excessive heat buildup. In some cases the plastic tunnels are constructed so that they can be opened and closed when necessary. This technique is widely used in Israel for early production of vegetables.

Mulching (already described in its application to domestic gardens) is important in horticulture. Whether in the form of a topdressing of manure or compost or plastic sheeting, mulches offer the grower the various benefits of economical plant feeding, conservation of moisture, and control of weeds and erosion. Winter mulches are commonly used to protect such sensitive and valuable plants as strawberries and roses.

The storage of perishable plant products is accomplished largely through the regulation of their temperature to retard respiration and microbial activity. Excess water loss can be prevented by controlling humidity. Facilities that utilize the temperature of the atmosphere are called common storage. The most primitive types take advantage of the reduced temperature fluctuations of the soil by using caves or unheated cellars. Aboveground structures must be insulated and ventilated. Complete temperature-regulated storages utilizing refrigeration and heating are now common for storage of horticultural products. The regulation of oxygen and carbon dioxide levels along with the regulation of temperature is known as controlled-atmosphere storage. Rooms are sealed so that gaseous exchange can be effectively controlled. Many horticultural products, such as fruit, can be kept fresh for as long as a year under these controlled conditions.

Frost control. Frost is one of the high-risk elements for commercial growers, and the problem is accentuated by the fact that growers are striving to produce early-season crops. The precautions are consequently far more elaborate and costly than those of the domestic garden. Frost is especially damaging to perennial fruit crops in the spring—because flower parts are sensitive to freezing injury—and to tender transplants. The two weather conditions that produce freezing temperatures are rapid radiational cooling at night and introduction of a cold air mass with temperatures below freezing. Radiation frost occurs when the weather is clear and calm; air-mass freezes occur when it is overcast and windy.

Frost-control methods involve either reduction of radiational heat loss or conservation or addition of heat. Radiational heat loss may be reduced by hot caps, cold frames, or mulches. Heat may also be added from the air. Wind machines that stir up the air, for example, provide heat when temperature inversions trap cold air under a layer of warm air. These have been used extensively in citrus groves. Heat may be added directly by using heaters, usually fueled with oil. Sprinkler irrigation can also be used for frost control. The formation of ice is accompanied by the release of large amounts of heat, which maintains plants at the freezing temperature as long as the water is being frozen. Thus continuous sprinkling during frosty nights has been used to protect strawberries from frost injury.

Frost injury to transplants can be prevented through processes that increase the plant's ability to survive the impact of unfavourable environmental stress. This is known as hardening off. Hardening off of plants prior to transplanting can be accomplished by withholding water and fertilizer, especially nitrogen. This prevents formation of succulent tissue that is very frost-tender. Gradual exposure to cold is also effective for hardening. Induced cold resistance in crops such as cabbage, for example, can have a considerable effect; unhardened cabbages begin to show injury at 28° F (−2.2° C), while hardened plants withstand temperatures as low as 22° F (−5.6° C).

Light control. Light has a tremendous effect on plant growth. It provides energy for photosynthesis, the process by which plants, with the aid of the pigment chlorophyll, synthesize carbon compounds from water and carbon dioxide. Light also influences a great number of physiological reactions in plants. At energy values lower than those required for photosynthesis, light affects such processes as dormancy, flowering, tuberization, and seed-stalk development. In many cases these processes are affected by the length of day; the recurrent cycle of light is known as the photoperiod.

The control of light in horticultural practices involves increasing energy values for photosynthesis and controlling day length. Light is controlled in part by site and location. In the tropics day length approaches 12 hours throughout the year, whereas in polar regions it varies from zero to 24 hours. Light is also partly controlled by plant distribution and density.

Supplemental illumination in greenhouses increases photosynthesis. The cost of power to supply the artificial light, however, makes this impractical for all but crops of the highest value. Fluorescent lights are the most efficient for photosynthesis; special lights, rich in the wavelengths required, are now available.

Extension of day length through supplemental illumination and shading is common practice in the production of greenhouse flower crops, which are often induced to flower out of season. Artificial lengthening of short days, or interruption of the dark period, promotes flowering in long-day plants such as lettuce and spinach and prevents flowering of short-day plants such as chrysanthemums. Similarly, during naturally long days, shading to reduce day length prevents flowering of long-day plants and promotes flowering of short-day plants. The manipulation of day length is standard practice to control flowering of greenhouse chrysanthemums throughout the year. Tungsten lights have proved very effective for extending day length because they are rich in the red end of the spectrum that affects the photoperiodic reaction. Extending the day length is a relatively affordable practice because only a low light intensity is required. The same effects can be obtained through interruption of the dark period, even with light flashes. Decreasing day length is usually accomplished by simply covering the plants with black shade cloth.

Soil management. The principles involved here are again similar to those of home gardening. But the financial considerations of horticulture naturally require a more scientific approach to soil care. To be successful, the grower must ensure the economic use of every square yard of ground, especially because the cost of sound horticultural land is among the highest of any in agriculture. Crop rotation is planned to ensure that the soil is not depleted of essential chemicals by repeated use of one type of plant in the same plot. Soil analysis is employed so that any such depletion can be rectified promptly. Fertilizers are applied in a precise routine and, of course, in a variety beyond the reach or needs of the ordinary gardener. They are frequently applied through leaves or stems in the form of chemical sprays.

Water management. Depending on the terrain, water management may involve extensive works for irrigation and drainage. While the home gardener may well be content with a rough-and-ready appraisal of the wetness or dryness of the soil, horticulture is more exacting. Production of the high-quality fruits and vegetables demanded by the modern market requires a precise all-year balance of soil moisture, adjusted to the needs of the particular crop. These considerations apply whether the grower is situated in a high-rainfall area of Europe or in the parched land of the southwestern United States or Israel.

There are a number of general methods of land irrigation. In surface irrigation water is distributed over the surface of soil. Sprinkler irrigation is application of water under pressure as simulated rain. Subirrigation is the distribution of water to soil below the surface; it provides moisture to crops by upward capillary action. Trickle irrigation involves the slow release of water to each plant through small plastic tubes. This technique is adapted both to field and to greenhouse conditions.

Removal of excess water from soils can be achieved by surface or subsurface drainage. Surface drainage refers to the removal of surface water by development of the slope of the land utilizing systems of drains to carry away the surplus water. In subsurface drainage open ditches and tile fields intercept groundwater and carry it off. The water enters the tiling through the joints, and drainage is achieved by gravity feed through the tiles.

Pest control. Horticultural plants are subject to a wide variety of injuries caused by other organisms. Plant pests include viruses, bacteria, fungi, higher plants, nematodes, insects, mites, birds, and rodents. Various methods are used to control them. The most successful treatments are preventive rather than curative.

Control of pests is achieved through practices that prevent harm to the plant and methods that affect the plant's ability to resist or tolerate intrusion by the pathogen. These can be classified as cultural, physical, chemical, or biological.

Traditional practices that reduce effective pest population include the elimination of diseased or infected plants or seeds (roguing), cutting out of infected plant parts (surgery), removal of plant debris that may harbour pests (sanitation), and alternating crops unacceptable to pests (rotation). Any of a number of techniques can be employed to render the environment unfavourable to the pest, such as draining or flooding and changing the soil's level of acidity or alkalinity.

Physical methods can be used to protect the plant against intrusion or to eliminate the pest entirely. Physical barriers range from the traditional garden fence to bags that protect each fruit, a common practice in Japan. Heat treatment is used to destroy some seed-borne pathogens and is a standard soil treatment in greenhouses to eliminate soil pests such as fungi, nematodes, and weed seed. Cultivation and tillage are standard practices for weed control.

The horticultural industry is now dependent upon chemical control of pests through pesticides, materials toxic to the pest in some stage of its life cycle. Commercial growers of practically all horticultural crops rely on complete schedules utilizing many different compounds. Pesticides are usually classed according to the organism they control: for example, bactericide, fungicide, nematicide, miticide, insecticide, rodenticide, and herbicide.

Pesticide selectivity

Selectivity of pesticides, the ability to discriminate between pests, is a relative concept. Some nonselective pesticides kill indiscriminately; most are selective to some degree. Most fungicides, for example, are not bactericidal. The development of highly selective herbicides makes it possible to destroy weeds from crops selectively. Selectivity can be achieved through control of dosage, timing, and method of application.

Plant pests can also be controlled through the manipulation of biological factors. This may be achieved through directing the natural competition between organisms or by incorporating natural resistance to the whole plant. The introduction of natural parasites or predators has been a successful method for the control of certain insects and weeds. Incorporation of genetic resistance is an ideal method of control. Thus breeding for disease and insect resistance is one of the chief goals of plant breeding programs. A major obstacle to this method of control is the ability of pathogens (disease-producing organisms) to mutate easily and attack previously resistant plants.

GROWTH REGULATION BY CHEMICALS

Control of plant growth through growth-regulating materials is a modern development in horticulture. These materials have resulted from basic investigations into growth and development, as well as systematic screening of materials to find those that affect differentiation and growth. This field was given great impetus by the discovery of a class of plant hormones known as auxins, which affect cell elongation.

Auxins have been correlated with inhibition and stimulation of growth as well as differentiation of organs and tissues. Such processes as cell enlargement, leaf and organ separation, budding, flowering, and fruit set (the formation of the fruit after pollination) and growth are influenced by auxins. In addition, auxins have been associated with the movement of plants in response to light and gravity. Auxin materials are used in horticulture for the promotion of rooting, fruit setting, fruit thinning, and fruit-drop control.

Gibberellins are a group of related, naturally occurring compounds of which only one, gibberellic acid, is commercially available. Gibberellins have many effects on plant development. The most startling is the stimulation of growth in many compact or dwarf plants. Minute applications transform bush to pole beans or dwarf to normal corn. Perhaps the most widespread horticultural use has been in grape production. The application of gibberellin is now a regular practice for the culture of the 'Thompson seedless' cultivar ("Sultanina") of grapes to increase berry size. In Japan applications of gibberellic acid are used to induce seedlessness in certain grapes.

Cytokinins are a group of chemical substances that have a decisive influence on the stimulation of cell division. In tissue culture high auxin and low cytokinin give rise to root development; low auxin and high cytokinin encourage shoot development.

Ethylene, a hydrocarbon compound, acts as a plant hormone to stimulate fruit ripening as well as rooting and flowering of some plants. An ethylene-releasing compound, 2-chloroethylphosphonic acid, has many horticultural applications, of which the most promising may be uniform ripening of tomatoes and the stimulation of latex flow in rubber.

Many compounds that inhibit growth hormones have application in horticulture. For example, a number of materials that inhibit formation of gibberellins by the plant cause dwarfing. These include chlorinated derivatives of quaternary ammonium and phosphonium compounds. Many of these have applications in floriculture. Growth retardants such as succinic acid–2,2-dimethylhydrazide, a gibberellin suppressor, have applications in horticulture from a wide array of effects that include dwarfing and fruit maturity. The growth inhibitor maleic hydrazide has been effective in preventing the sprouting of onions and potatoes.

ORNAMENTAL HORTICULTURE

Ornamental horticulture consists of floriculture and landscape horticulture. Each is concerned with growing and marketing plants and with the associated activities of flower arrangement and landscape design. The turf industry is also considered a part of ornamental horticulture. Although flowering bulbs and flower seed represent an important component of agricultural production for the Low Countries of Europe, ornamentals are relatively insignificant in world trade.

Floriculture has long been an important part of horticulture, especially in Europe and Japan, and accounts for about half of the nonfood horticultural industry in the United States. Because flowers and pot plants are largely produced in plant-growing structures in temperate climates, floriculture is largely thought of as a greenhouse industry; there is, however, considerable outdoor culture of many flowers.

The industry is usually very specialized with respect to its crop; the grower must provide precise environmental control. Exact scheduling is imperative since most floral crops are seasonal in demand. Because the product is perishable, transportation to market must function smoothly to avoid losses.

The floriculture industry involves the grower, who mass-produces flowers for the wholesale market, and the retail florist, who markets to the public. The grower is often a family farm, but, as in all modern agriculture, the size of the growing unit is increasing. There is a movement away from urban areas, with their high taxes and labour costs, to locations with lower tax rates and a rural labour pool and also toward more favourable climatic regions (milder temperature and more sunlight). The development of airfreight has emphasized interregional and international competition. Flowers can be shipped long distances by air and arrive in fresh condition to compete with locally grown products.

The industry of landscape horticulture is divided into growing, maintenance, and design. Growing of plants for landscape is called the nursery business, although a nursery refers broadly to the growing and establishment of any young plant before permanent planting. The nursery industry involves production and distribution of woody and herbaceous plants and is often expanded to include ornamental bulb crops—corms, tubers, rhizomes, and swollen roots as well as true bulbs. Production of cuttings to be grown in greenhouses or for indoor use (foliage plants), as well as the production of bedding plants, is usually considered part of floriculture, but this distinction is fading. While most nursery crops are ornamental, the nursery business also includes fruit plants and certain perennial vegetables used in home gardens, for example, asparagus and rhubarb.

Next to ornamental trees and shrubs, the most important nursery crops are fruit plants, followed by bulb crops. The most important single plant grown for outdoor cultivation is the rose. The type of nursery plants grown depends on location; in general (in the Northern Hemisphere) the northern areas provide deciduous and coniferous evergreens, whereas the southern nurseries provide tender broad-leaved evergreens.

The nursery industry includes wholesale, retail, and mail-order operations. The typical wholesale nursery specializes in relatively few crops and supplies only retail nurseries or florists. The wholesale nursery deals largely in plant propagation, selling young seedlings and rooted cuttings, known as "lining out" stock, of woody material to the retail nursery. The retail nursery then cares for the plants until growth is complete. Many nurseries also execute the design of the planting in addition to furnishing the plants.

Bulb crops. The bulb crops include plants such as the tulip, hyacinth, narcissus, iris, daylily, and dahlia. Included also are nonhardy bulbs used as potted plants indoors and summer outdoor plantings such as amaryllises, anemones, various tuberous begonias, caladiums, cannas, dahlias, freesias, gladioli, tigerflowers, and others. Hardy bulbs, those that will survive when left in the soil over winter, include various crocuses, snowdrops, lilies, daffodils, and tulips.

Tulips

Many bulb crops are of ancient Old World origin, introduced into horticulture long ago and subjected to selection and crossing through the years to yield many modern cultivars. One of the most popular is the tulip. Tulips are widely grown in gardens as botanical species but are especially prized in select forms of the garden tulip (which arose from crosses between thousands of cultivars representing several species). Garden tulips are roughly grouped as early tulips, breeder's tulips, cottage tulips, Darwin tulips, lily-flowered tulips, triumph tulips, Mendel tulips, parrot tulips, and others. The garden tulips seem to have been developed first in Turkey but were spread throughout Europe and were adopted enthusiastically by the Dutch. The Netherlands has been the centre of tulip breeding ever since the 18th century, when interest in the tulip was so intense that single bulbs of a select type were sometimes valued at thousands of dollars. The collapse of the "tulipmania" left economic scars for decades. The Netherlands remains today the chief source of tulip bulbs planted in Europe and in North America. The Netherlands has also specialized in the production of related bulbs in the lily family and provides hyacinth, narcissus, crocus, and others. The Dutch finance extensive promotion of their bulbs to support their market. Years of meticulous growing are required to yield a commercial tulip bulb from seed. Thorough soil preparation, high fertility, constant weeding, and careful record keeping are part of the intensive production, which requires much hand labour. Bulbs sent to market meet specifications as to size and quality, which assure at least one year's bloom even if the bulb is supplied nothing more than warmth and moisture. The inflorescence (flowering) is already initiated and the necessary food stored in the bulb. Under less favourable maintenance than prevails in The Netherlands, a subsequent year's bloom may be smaller and less reliable; it is not surprising therefore that tulip-bulb merchants suggest discarding bulbs after one year and replanting with new bulbs to achieve maximum yield.

Herbaceous perennials. Garden perennials include a number of herbaceous species grown for their flowers or occasionally used as vegetative ground covers. Under favourable growing conditions the plants persist and increase year after year. The biggest drawback to perennials as compared with annuals is that they must be maintained throughout the growing season but have only a limited flowering period. Typical perennials are hollyhocks, columbines, bellflowers, chrysanthemums, delphiniums, pinks, coralbells, phlox, poppies, primroses, and speedwells.

Perennials are often produced and sold as a sideline to other nursery activities; some are sold through seed houses. Perennial production could be undertaken on a massive scale, with attendant economies, but the market is neither large enough nor predictable enough (except for the greenhouse growing of such cut flowers as chrysanthemums and carnations) to interest most growers.

Shrubs. Production of ornamental shrubs is the backbone of the nursery trade in Europe and the United States. The nursery business is about equally divided between the production of (1) coniferous evergreens such as yew, juniper, spruce, and pine; (2) broad-leaved evergreens such as rhododendron, camellia, holly, and boxwood; (3) deciduous plants such as forsythia, viburnum, berberis, privet, lilac, and clematis; and (4) roses.

Fields of specialization have evolved within the ornamental shrub industry. Some firms confine activity mostly to production of "lining out" stock, which must be tended several years before reaching salable size.

The field grower may, in turn, specialize in mass growing for the wholesale trade only. The field plantings are tended until they attain marketable size. Because of the time required to produce a marketable crop and because of rising labour costs, this phase of the nursery industry involves economic hazards. But wholesale growing escapes the high overhead of retail marketing in urban areas, and, although many growers do sell stock at the nursery, they generally avoid the expensive merchandising required of the typical urban-area garden centre. Growers are especially interested in laboursaving technology and are turning to herbicidal control of weeds and shortcut methods for transplanting.

There is a well-established trade in container-grown stock—that is, nursery stock grown in the container in which it is sold. This practice avoids transplanting and allows year-round sales of plant material.

Roses. The production of roses is probably the most specialized of all shrub growing; the grower often deals solely in rose plants. Most are bud-grafted onto rootstocks (typically *Rosa multiflora*). This is the only way to achieve rapid and economical increase of a new selection to meet market demands. Large-scale production of roses has tended to centre in areas where long growing seasons make rapid production possible.

Because the budding operation calls for skilled hand labour and because field maintenance is expensive, few economies can be practiced in the production of roses. But distribution techniques that do offer certain economies have been developed. These include covering the roses with coated paper or plastic bags instead of damp moss to retain humidity and applying a wax coating to stems of dormant stock to inhibit desiccation.

Trees. Ornamental shade trees are usually grown and marketed in conjunction with shrubs. The 20th-century migration of people in many countries to suburban areas, coupled with the construction of houses on cleared land, has made shade trees an increasingly important part of the nursery trade. As interest in shade and ornamental trees increased, creation of improved cultivars followed. There is still some activity in transplanting native trees from the woodlot, and some are still grown from genetically unselected seed or cuttings; but more and more, like roses and shrubs before them, trees are vegetatively propagated as named cultivars, and many are patented.

The design and planning of landscapes has become a distinct profession that in many cases is only incidentally horticultural. Landscape architecture in its broadest sense is concerned with all aspects of land use. As a horticulturist, the landscape architect uses plants along with other landscape materials—stone, mortar, wood—as elements of landscape design. Unlike the materials of the painter or sculptor, plants are not static but change seasonally and with time. The colour, form, texture, and line of plants are used as design elements in the landscape. Plant materials are also manipulated as functional materials to control erosion, as surface materials, and for enclosures to provide protection from sunlight and wind.

Landscape architecture originated in the design of great estates, and home landscape is still an integral part of landscape architecture. More recently, however, landscape architecture has begun to include larger developments such as urban and town planning, parks both formal and "wild," public buildings, industrial landscaping, and highway and roadside development. (See GARDEN AND LANDSCAPE DESIGN.)

Horticultural education and research

Scholarly works in horticulture appear continuously in scientific literature. Specific institutions devoted to horticultural research, however, go back to the beginning of the experiment-station system, the first being a private laboratory of John Bennet Lawes, with the later collaboration of Joseph Henry Gilbert, in Rothamsted, Eng. (1843). Horticultural education and research in the United States was given great impetus by Justin S. Morrill, a supporter of the Morrill Act (1862), which provided educational institutions in agricultural and mechanical arts for each state. State experimental stations and the federal experimental stations of the U.S. Department of Agriculture, with its centre at Beltsville, Md., carry out systematic research efforts in horticulture. Although much research is carried out on horticultural food crops, there has been an increasing emphasis on ornamentals. Horticultural research is also conducted by private companies among the seed industry, canning and processing firms, and private foundations and botanical gardens.

Horticultural education is an established part of professional agricultural education worldwide. Training in horticulture up to the Ph.D. degree is offered in universities. There are relatively few schools devoted to the training of gardeners and horticultural technicians in the United States, although a number of state universities have two-year programs in horticulture. Vocational horticultural training is more highly developed in Europe.

There are a great number of national and international societies devoted to horticulture. These include community organizations such as garden clubs, specialty organizations devoted to a particular plant or group of plants (*e.g.*, rose and orchid societies), scientific societies, and trade organizations. The first society devoted to horticulture originated in 1804 with the establishment in England of the Royal Horticultural Society. There are similar organizations in other European countries. The American Pomological Society, dedicated to the science and practice of fruit growing, was formed in 1848. The American Horticultural Society, established in 1945, is devoted largely to ornamentals. The American Society for Horticultural Science was established in 1903 and became perhaps the most widely known scientific society devoted to horticulture. The International Society for Horticultural Science, formed in 1959 with permanent headquarters in The Hague, sponsors international congresses every four years. Most societies and horticultural organizations publish periodicals.

There are thousands of publications in the world devoted to some aspect of horticulture. The scientific and technical horticultural literature since 1930 is abstracted in *Horticultural Abstracts*, prepared by the Commonwealth Bureau of Horticulture and Plantation Crops, East Malling, Kent, Eng. (J.J./Ro.P.)

BIBLIOGRAPHY

Gardening. *History:* Short histories may be found in many of the larger gardening encyclopaedias. Fuller accounts include CHRISTOPHER THACKER, *The History of Gardens* (1979, reprinted 1985); ANTHONY HUXLEY, *An Illustrated History of Gardening* (1978, reprinted 1983); MILES HADFIELD, *A History of British Gardening*, 3rd ed. (1979); and JOSEPHINE VON MIKLOS and EVELYN FIORE, *The History, the Beauty, the Riches of the Gardener's World* (1969).

Classics and good reading: WILLIAM ROBINSON, *Wild Garden*, 4th ed. (1894, reprinted 1977); GERTRUDE JEKYLL, *Wood and Garden* (1899, reprinted 1983), *Home and Garden* (1900, reprinted 1982), and *Colour Schemes for the Flower Garden* (1908, reprinted 1983); GERTRUDE JEKYLL and LAWRENCE WEAVER, *Gardens for Small Country Houses* (1912, reprinted 1981); HENRY N. Gastronomy

Gastronomy is the art of selecting, preparing, serving, and enjoying fine food. Anthelme Brillat-Savarin, the celebrated French aphorist and gastronomic authority of the late 18th and early 19th centuries, called gastronomy "the intelligent knowledge of whatever concerns man's nourishment."

Through the ages gastronomy has proved to be a stronger cultural force among the peoples of the world than linguistic or other influences. Today, the world may be divided into definite gastronomic regions, areas where distinctive cuisines prevail and common culinary methods are practiced.

Rice is the staple in most of Southeast Asia. The distinctive feature of the cooking of India and Indonesia is the generous and imaginative use of spices to lend an added zest to foods. Olive oil is the common denominator of the Mediterranean cuisines. Northern Europe and North America use a variety of cooking fats, among them butter, cream, lard, and goose and chicken fats, but the common gastronomic denominator throughout most of these lands is wheat, the basic crop. In Latin America corn (maize) is the staple and is used in a wide variety of forms.

This article covers the history of gastronomy from ancient civilizations through Greece and Rome, the Middle Ages, and the Italian Renaissance; the development of the great cuisines of France and of China; and the leading regional and national cuisines of the world.

The article is divided into the following sections:

HISTORY OF GASTRONOMY IN THE WEST

The first significant step toward the development of gastronomy was the use of fire by primitive man to cook his food, which gave rise to the first meals as families gathered around the fire to share the foods they had cooked. Prehistoric cave paintings such as those in Les Trois Frères in Ariège, in southern France, depict these early gastronomic events.

In the ancient civilizations of Assyria, Babylonia, Persia, and Egypt, the selection, preparation, service, and enjoyment of food were practiced on an elaborate scale. In the Book of Daniel the Bible relates the story of how Belshazzar, the king of the Chaldeans, "made a great feast to a thousand of his lords, and drank wine before the thousand." He then commanded gold and silver vessels to be brought, and he and his wives, princes, and concubines drank wine and praised gods of gold, silver, brass, iron, wood, and stone.

Greece and Rome. In ancient Greece, the Athenians believed that mealtime afforded an opportunity to nourish the spirit as well as the body. They reclined on couches while eating and accompanied their repasts with music, poetry, and dancing. The Greeks provided a philosophical basis for good living, Epicureanism. It held that pleasure was the main purpose of life; but pleasure was not intended to imply the self-indulgence that it connotes today. The Epicureans believed that pleasure could best be achieved by practicing self-restraint and indulging as few desires as possible. Today the epicure is defined as one who is "endowed with sensitive and discriminating tastes in food and wine."

Epicurean restraint and Roman excesses

The ancient Greeks practiced moderation in all things, but the Romans were known for their excesses. Ordinary citizens subsisted on barley or wheat porridge, fish, and ground pine nuts (edible pine seeds), but the Roman emperors and wealthy aristocrats gorged themselves on a staggering variety of foods. They staged lavish banquets where as many as 100 different kinds of fish were served, as well as mountainous quantities of beef, pork, veal, lamb, wild boar, venison, ostrich, duck, and peacock. They ordered ice and snow hauled down from the Alps to refrigerate their perishable foods, and they dispatched emissaries to outposts of the Roman Empire in search of exotic delicacies. Mushrooms were gathered in France, and the Roman author Juvenal, writing in the late first and early 2nd century AD, describes a dinner at his patron's house where mullet from Corsica and lampreys from Sicily were served.

Yet, whereas the Romans placed great value on exotic delicacies, they were not gastronomes in the true sense of the word. The term implies a sensitivity and discrimination that they lacked. The unbridled appetites of the Roman emperors and nobles often carried them to wild extremes. The emperor Caligula drank pearls that had been dissolved in vinegar. Maximus reportedly consumed 60 pounds of meat in a day, and Albinus was alleged to have eaten 300 figs, 100 peaches, 10 melons, and vast quantities of other foods all at a single sitting. Lucullus was an immensely wealthy man who entertained so lavishly that his name became a symbol both for extravagance and for culinary excellence.

The vulgarity and ostentation of Roman banquets were satirized by Petronius in the *Satyricon*, written in the 1st century AD. A former slave named Trimalchio entertains at a gargantuan feast at which the guests are treated to one outlandish spectacle after the other. A donkey is brought in on a tray, encircled with silver dishes bearing dormice that have been dipped in honey. A huge sow is carved and live thrushes fly up from the platter. A chef cuts open the belly of a roast pig, and out pour blood sausages and blood puddings.

The European Middle Ages. Through most of the Middle Ages banquets and feasts were characterized by their crudity and extravagance. In more affluent households in Gaul, for example, huge quarters of beef, mutton, and pork were served up whole before the guests. Wild game was frequently served, including wild boar, hedgehog, roebuck, crane, heron, and peacock. Meats and other foods were cooked over fires on spits and in caldrons positioned close by the tables. Diners seated themselves on bundles of straw and gobbled huge quantities of food, sometimes drawing knives from sheaths in their sword scabbards to saw off huge chunks of meat.

The first French cookbook of importance

The Frankish emperor Charlemagne introduced a touch of refinement. He decorated the walls of his banquet halls with ivy. Floors were strewn with flowers. Tables were laid with silver and gold utensils, but food was coarse, and menus offered little variety. The subtle seasonings and sauces that later were to characterize French cooking were still unknown. An insight into the relative crudeness of the French culinary art during the Middle Ages is provided by *Le Viander* (*c.* 1375), the first French cookbook of importance. It was written by Guillaume Tirel, more familiarly known as Taillevent, who served as chef to King Charles VI. Like the Romans, he used bread as the thickener for his sauces, instead of flour (which has been used for the past two centuries). He relied heavily on spices—such as ginger, cinnamon, cloves, and nutmeg (a Moorish influence via Spain and Italy). His menus consisted mostly of soups, meats, and poultry, which were so heavily seasoned that the taste of the food was largely obscured. French cooking ultimately would be distinguished by the subtlety of its seasonings and sauces and by the imaginative blend of textures and flavours. But in Taillevent's day the principal object of cooking was to disguise the flavour of the food (which, because of the lack of refrigeration, frequently was tainted) rather than to complement it.

The Italian Renaissance. The turning point in the development of gastronomic excellence was the Italian Renaissance. By the beginning of the 15th century wealthy merchants in Italy were dining in elegant style. In place of the crude slabs of meat served elsewhere, they savoured delicacies such as mushrooms, garlic, truffles, and tournedos (thick slices of beef fillets) and pasta dishes such as lasagne or ravioli. In wealthier households such delicacies were served in sumptuous style. When Vincenzo I, the duke of Mantua, celebrated his wedding feast in 1581, a guest reported that there were

> 100 ladies beautiful beyond measure and most richly garbed . . . [and there,] on a handsome sideboard, was visible a perspective of divers cups, carafes and goblets, and such beautiful vessels of Venetian glass as I think would defy description . . .

The duke's wedding feast lasted three hours. Tables were laid with delicately embroidered cloths. The guest reported that

> the first service from the sideboard was large salads decked out with various fantasies such as animals made of citron, castles of turnips, high walls of lemons; and variegated with slices of ham, mullet roes, herrings, tunny, anchovies, capers, olives, caviar, together with candied flowers and other preserves.

The duke's guest also reported that the tables were tastefully and imaginatively decorated.

> There were three large statues in marzipan. One was the horse of Campidoglio come to life, the second Hercules with the lion, and the third a unicorn with its horn in the dragon's mouth.

The bounty of these tables was almost beyond belief.

> The table was filled with many other things—jellies, blancmanges in half relief, spiced hard-bake, royal wafers, Milanese biscuits, pine kernels, minced meat, salami, cakes of pistachio nuts, sweet almond twists, flaky pastries . . . Indian turkey hens stuffed and roasted on the spit, marinated pullets, fresh grapes, strawberries strewn with sugar, wild cherries, and asparagus cooked in butter in various ways.

DEVELOPMENT OF FRENCH GRANDE CUISINE

Catherine de Médicis' Florentine cooks

The Italian influence on France. Italy has been called the mother of the Western cuisines, and perhaps its greatest contribution was its influence on France. The crucial event was the arrival of Catherine de Médicis in France in the 16th century. The great-granddaughter of Lorenzo the Magnificent, Catherine married the young man who later was to become Henry II of France. She brought with her a retinue of Florentine cooks who were schooled in the subtleties of Renaissance cooking—in preparing such elegant dishes as aspics, sweetbreads, artichoke hearts, truffles, liver crépinettes, quenelles of poultry, macaroons, ice cream, and zabagliones. Catherine also introduced a new elegance and refinement to the French table. Although, during Charlemagne's reign, ladies had been admitted to the royal table on special occasions, it was during Catherine's regime that this became the rule and not the exception. Tables were decorated with silver objects fashioned by Benvenuto Cellini. Guests sipped wine from fine Venetian crystal and ate off beautiful glazed dishes. An observer reported that

> the Court of Catherine de' Médici was a veritable earthly paradise and a school for all the chivalry and flower of France. Ladies shone there like stars in the sky on a fine night.

The French view of cooking

Catherine's cousin, Marie de Médicis, who married Henry IV of France, also advanced the culinary arts. An important new cookbook appeared in her time. It was called *Le Cuisinier françois* (1652) and was written by La Varenne, an outstanding chef, who is believed to have learned to cook in Marie de Médicis' kitchens. La Varenne's cookbook was the first to present recipes in alphabetical order, and the book included the first instructions for vegetable cooking. By now spices were no longer used to disguise the taste of food. Truffles and mushrooms provided subtle accents for meats, and roasts were served in their own juices to retain their flavours. A basic point of French gastronomy was established; the purpose of cooking and of using seasoning and spices was to bring out the natural flavours of foods—to enhance rather than disguise their flavour. In keeping with this important principle, La Varenne cooked fish in a fumet, or stock made with the cooked fish trimmings (head, tail, and bones). The heavy sauces using bread as a thickener were discarded in favour of the roux, which is made of flour and butter or another animal fat.

Contributions of the Sun King. La Varenne's cookbook was a gastronomic landmark, but a long time was to pass before the French cuisine would achieve its modern forms. In pre-Revolutionary France extravagance and ostentation were the hallmarks of gastronomy. Perhaps the most extravagant Frenchman of the time was the Sun King, Louis XIV, who, with members and guests of his court, wined and dined in unparalleled splendour at his palace at Versailles. There the kitchens were some distance from the King's quarters; the food was prepared by a staff of more than 300 people and was carried to the royal quarters by a procession headed by two archers, the lord steward, and other notables. As the cry "the King's meat" proclaimed their progress, an assemblage laden with baskets of knives, forks, spoons, toothpicks, seasonings, and spices solemnly made their way to the King's quarters. Before the King dined, tasters sampled the food to make certain it had not been poisoned. The King himself was such a prodigious eater that members of the court and other dignitaries considered it a privilege merely to stand by and watch him devour his food. His sister-in-law reported that at one meal he ate

> four plates of different soups, an entire pheasant, a partridge, a large plateful of salad, mutton cut up in its juice with garlic, two good pieces of ham, a plateful of cakes, and fruits and jams.

Table protocol and use of the fork

Louis XIV is remembered principally for his extravagance, but he was genuinely interested in the culinary arts. He established a new protocol for the table; dishes were served in a definite order instead of being placed on the table all at once without any thought to complementary dishes. The fork came to be widely used in France during his reign, and the manufacture of fine French porcelain was begun. The King himself hired a lawyer-agronomist, La Quintinie, to supervise the gardens at Versailles and was intensely interested in the fruits and vegetables—strawberries, asparagus, peas, and melons—that were grown there. He paid special honour to members of his kitchen staff, conferring the title of officer on his cooks.

Triumph of French grande cuisine. During the reigns of Louis XV and Louis XVI, culinary methods were refined and a new order and logic were introduced into the French cuisine. Brillat-Savarin noted that in the reign of Louis XV

> there was generally established more orderliness of meals, more cleanliness and elegance, and those refinements of service, which having increased steadily to our own time....

By the time of the Revolution the interest in the culinary arts had intensified to the point where Brillat-Savarin could report:

> The ranks of every profession concerned with the sale or preparation of food, including cooks, caterers, confectioners, pastry cooks, provision merchants and the like, have multiplied in ever-increasing proportions... New Professions have arisen; that, for example, of the pastry cook—in his domain are biscuits, macaroons, fancy cakes, meringues... The art of preserving has also become a profession in itself, whereby we are enabled to enjoy, at all times of the year, things naturally peculiar to one or other season... French cookery has annexed dishes of foreign extraction... A wide variety of vessels, utensils and accessories of every sort has been invented, so that foreigners coming to Paris find many objects on the table the very names of which they know not, nor dare to ask their use.

The Revolution and the rise of the restaurant

The Revolution changed almost every aspect of French life: political, economic, social, and gastronomic as well. In pre-Revolutionary days the country's leading chefs performed their art in wealthy aristocratic households. When the Revolution was over those who had survived the guillotine and remained in the country found employment in restaurants. The restaurant became the principal arena for the development of the French cuisine, and henceforth French gastronomy was to be carried forward by a succession of talented chefs, men whose culinary genius has not been matched in any other land. From the long roll of great French chefs, a select company have made a lasting contribution to gastronomy.

The great French chefs. The first, and in many ways the most important of all French chefs, was Marie-Antoine Carême, who has been called the Architect of the French Cuisine. As the French novelist and gastronome Alexandre Dumas *père* related the story, Carême was born shortly before the Revolution, the 16th child of an impoverished stonemason; when he was only 11, his father took him to the gates of Paris one evening, fed him supper at a tavern, and abandoned him in the street. Fortunately for gastronomy, Carême found his way to an eating house, where he was put to work in the kitchen. Later he moved to a fine pastry shop where he learned not only to cook but also to read and draw.

Carême, the "Architect of the French Cuisine"

Carême was an architect at heart. He liked to spend time in strolling about Paris, admiring the great classic buildings, and he fell into the habit of visiting the Bibliothèque Royale, where he spent long hours studying prints and engravings of the great architectural masterpieces of Greece, Rome, and Egypt. He designed massive, elaborate table decorations called *pièces montées* ("mounted pieces") as an outlet for his passionate interest in architecture. In an age of Neoclassicism his tables were embellished with replicas of classic temples, rotundas, and bridges constructed with spun sugar, glue, wax, and pastry dough. Each of these objects was fashioned with an architect's precision, for Carême considered confectionery to be "architecture's main branch," and he spent many months executing these designs, rendering every detail with great exactness.

Carême was employed by the French foreign minister, Charles-Maurice de Talleyrand, who was not only a clever diplomat but a gastronome of distinction. Talleyrand believed that a fine table was the best setting for diplomatic manoeuvring. Following his service with Talleyrand, Carême practiced his art for a succession of kings and nobles. He catered a series of feasts for Tsar Alexander of Russia, was *chef de cuisine* to England's Prince Regent (who later became George IV), and finally was employed by Baroness Rothschild in Paris.

Today Carême's monumental table displays seem ostentatious almost beyond belief, but he lived in an opulent age that was obsessed with classical architecture and literature. To appreciate him fully, one must put him in the context of his time. Before Carême, the French cuisine was largely a jumble of dishes; little concern was given to textures and flavours and compatibility of dishes. Carême brought a new logic to the cuisine. "I want order and taste," he said. "A well displayed meal is enhanced one hundred per cent in my eyes." Every detail of his meals was planned and executed with the greatest of care. Colours were carefully matched, and textures and flavours carefully balanced. Even the table displays, mammoth as they were, were designed and carried out with an architect's precision.

Carême's voluminous cookbooks, *L'Art de la cuisine au dix-neuvième siècle* (1833) and *Le Pâtissier royal parisien* (1815), included hundreds of recipes, menus for every day in the year, a history of French cooking, sketches for Carême's monumental *pièces montées*, instructions for garnishes, decorations, and tips on marketing and organizing the kitchen.

Montagné and Escoffier

After Carême, the two men who probably had the greatest impact on French gastronomy and that of the world at large were Prosper Montagné and Georges-Auguste Escoffier. Montagné was one of the great French chefs of all time, and he achieved a secure place in gastronomic history by creating *Larousse Gastronomique* (1938), the basic encyclopaedia of French gastronomy. As a young man, while serving as an assistant chef at the Grand Hotel in Monte-Carlo, he came to the conclusion that all *pièces montées*, as well as superfluous garnitures and decorations, should be discarded. This was a drastic step, and Montagné's call might have gone unheeded had it not been brought to the attention of Escoffier. Escoffier was unimpressed at first. But his friend and literary collaborator Philéas Gilbert (also an outstanding chef) persuaded him that Montagné was right. Escoffier became a zealot for culinary reform, insisting on refining and modifying nearly every aspect of the cuisine. He simplified food decorations, greatly shortened the menus, accelerated the service, and organized teams of cooks to divide and share tasks in order to prepare the food more expertly and efficiently.

All of this progress was greatly facilitated by the introduction of the Russian table service around 1860. Before then, the service *à la française* was used. Under that method the meal was divided into three sections or services. All of the dishes of each service were brought in from the kitchen and arrayed on the table at once. Then, when this service was finished, all of the dishes of the next service were brought in. The first service consisted of everything from soups to roasts, and hot dishes often cooled before they could be eaten. The second service comprised cold roasts and vegetables, and the third was the desserts. Under the Russian table service, which was popularized by the great chef Félix Urbain-Dubois, each guest was served each course individually, while the food was at its best.

Escoffier invented scores of new dishes. One was *poularde Derby*, roast chicken with rice, truffles, and foie gras stuffing, garnished with truffles and foie gras. Other better known Escoffier inventions were *pêche Melba*, a dessert made with peaches, and Melba toast, tributes to the Australian soprano Nellie Melba.

In naming some of his culinary creations after friends and celebrities Escoffier was following a well-established tradition. *Tournedos Rossini*, the tender slices of the heart of the fillet of beef, topped by foie gras and truffles, was named after the celebrated Italian composer. The composer Giuseppe Verdi and the actress Sarah Bernhardt were among those who were similarly honoured. Many famous dishes have taken their names from the chefs who invented them—*Sole Dugléré*, for example, was named after the chef Adolphe Dugléré, who presided at the Café Anglais in Paris in the middle of the 19th century. French dishes have also been named after their dominant colours, such as *carmen* or *cardinale*, which refers to a pinkish-reddish hue. Great events have also given dishes their names: chicken Marengo, for example, was named after the battle in 1800 in which Napoleon defeated the Austrians.

Escoffier created a cold dish called chicken Jeannette. It was named after a ship that was crushed by icebergs. Escoffier's creation was stuffed breast of chicken, and, in honour of the ill-fated ship, he served it on top of a ship carved out of ice.

The *grande cuisine* of France is the only structured and organized system of gastronomy in the world. Many dishes are interrelated, and their names contain clues as to their ingredients. For example, soups are broken down into consommés (clear soups), potages (thick soups), crèmes (cream soups), and veloutés (made with a white sauce). Within each of these categories there are sub-categories, depending upon the base used, the thickening agent, the garniture, the flavouring spice, herb, or alcohol, and other considerations.

Escoffier's fame today rests mostly on the cookbooks he wrote—*Le Livre des menus* (1924), *Ma Cuisine* (1934), and *Le Guide culinaire* (1921), written in collaboration with Gilbert—in which he codified the French cuisine in its modern form, setting down thousands of menus and clarifying the principles of French gastronomy. With the great hotel entrepreneur César Ritz, he established a string of the world's most luxurious hostelries in Paris, Rome, Madrid, New York, Budapest, Montreal, Philadelphia, and Pittsburgh.

In the late 1950s a group of young French chefs led by Paul Bocuse, Michel Guérard, the Troisgros brothers Jean and Pierre, and Alain Chapel invented a free-form style of cooking (named *nouvelle cuisine* by the French restaurant critics Henri Gault and Christian Millau). Their style disregarded the codification of Escoffier and replaced it with a philosophy rather than a structured system of rules, creating not a school but an anti-school, in reaction to the French *grande cuisine*. The basic characteristics of *nouvelle cuisine* included the replacement of the thickening of sauces with reductions of stocks and cooking liquids; the serving of novel combinations in very small quantities artistically arranged on large plates; a return to the importance of purchasing of food; and infinite attention to texture and detail.

At its best, *nouvelle cuisine* produced dishes that avoided rich sauces and lengthy cooking times, and its creative and inventive practitioners aroused interest and excitement in gastronomy generally and in restaurants specifically. One of its most important results has been the recognition of the chef as a creative artist.

Use of wines and sauces. French gastronomy is distinguished not only by the genius of its chefs but also by well-established culinary practice. One of these practices is the use of fine wines, such as those produced in Bordeaux and Burgundy, as accompaniments to good food. The proper choice of wines—according to vintages, vineyards, shippers—is an indispensable part of French gastronomy.

In the preparation of food, the hallmark of French gastronomy is the delicate sauces that are used to enhance the flavours and textures. Sauces are prepared with stocks, or *fonds de cuisine,* "the foundations of cooking." These stocks are made by simmering meats, bones, poultry or fish trimmings, vegetables, and herbs in water to distill the essence of their flavours.

The basic sauces

There are literally hundreds of French sauces, but among the more familiar ones are the families of white sauces, brown sauces, and tomato sauces, the mayonnaise family, and the hollandaise family. White sauces, which are served with poultry, fish, veal, or vegetables, are prepared by making a white roux, a mixture of butter and flour, which is cooked and stirred to smoothness. Béchamel sauce is prepared by adding milk and seasoning to this thickening agent. Sauce velouté is made by mixing a fish, poultry, or veal stock with the roux. A broad variety of sauces is derived from these basic white sauces. Sauce mornay is simply sauce béchamel with grated cheese and seasonings. Sauce suprême is béchamel with cream. Sauce normande is prepared by mixing a fish velouté with tarragon and white wine or vermouth.

Brown sauces, which are served with red meats, chicken, turkey, veal, or game, are prepared by simmering a meat stock for many hours and then thickening it with a brown roux, a mixture of butter and flour cooked until it turns brown. Among the better known brown sauces are sauce ragout, which is flavoured with bone trimmings or giblets; sauce diable, which is seasoned with lots of pepper; sauce piquant, a brown sauce with pickles and capers, and sauce Robert, which is seasoned with mustard.

The hollandaise family is another important branch of French sauces. Hollandaise is closely related to mayonnaise. It is prepared by delicately flavouring warmed egg yolks with lemon juice and then carefully stirring in melted butter until the mixture achieves a creamy, yellow thickness. Sauce mousseline is made by adding whipped cream to hollandaise, while sauce béarnaise also has an egg and butter base with tarragon, shallots, wine, vinegar, and pepper. Sauce vin blanc is made by adding a white-wine fish stock to the basic hollandaise.

GASTRONOMY IN CHINA

The gastronomic tradition

Apart from the French cuisine, the highest expression of the gastronomic art is generally regarded to be that of the Chinese. It is no accident that China and France should have produced the world's most distinctive and respected cuisines. Both countries were naturally blessed with an abundance and rich variety of raw ingredients. In each of these countries gastronomy traditionally commanded great interest and respect. The intellectual, artistic, political, and financial leaders of China and France traditionally attached great importance to good eating. It has already been noted how this worked in the case of the Bourbon kings of France and with statesmen of such eminence as Talleyrand. In ancient China the preparation and service of food played an important part in court rituals. The first act of many emperors was to appoint a court chef, and once they were on the job these chefs strove mightily to outdo each other.

In ancient China, hunting and foraging supplied much of the food. Wild game, such as deer, elk, boar, muntjac (a small deer), wolf, quail, and pheasant, was eaten, along with beef, mutton, and pork. Vegetables such as royal fern, smartweed, and the leafy thistle (*Sonchus*) were picked off the land. Meats were preserved by salt-curing, pounding with spices, or fermenting in wine. To provide a contrast in flavours the meat was fried in the fat of a different animal.

As Chinese agriculture developed, styles of food were determined to a great degree by the natural resources available in certain parts of the country, thus the vastly different manners of cooking and the development of distinctive regional cuisines of China. As a more varied fare began to emerge, tastes grew more refined. By the time of Confucius (551–479 BC) gastronomes of considerable sophistication had appeared on the scene. Confucius wrote of one of these fastidious eaters,

> For him the rice could never be white enough. When it was not cooked right, he would not eat. When the food was not in season, he would not eat. When the meat was not cut correctly, he would not eat. When the food was not served with the proper sauce, he would not eat.

Emergence of a cuisine. Like all other forms of haute cuisine, classic Chinese cooking is the product of an affluent society. By the 2nd century AD the Chinese court had achieved great splendour, and the complaint was heard that idle noblemen were lounging about all day, feasting on smoked meats and roasts.

By the 10th or 11th century a distinctive cuisine had begun to emerge, one that was developed with great attention to detail. It was to reach its zenith in the Ch'ing dynasty (1644–1911/12). This cuisine was a unique blend of simplicity and elegance. The object of cooking and the preparation of food was to extract from each ingredient its unique and most enjoyable quality.

As in the case of the French cuisine, the hors d'oeuvre set the tone of the meal. "The hors d'oeuvre must look neat," say the Chinese gastronomic authorities Tsuifeng Lin and her daughter Hsiang Ju Lin.

> They are best served in matched dishes, each containing one item. Many people like to garnish the dishes with parsley and vegetables cut in the shape of birds, fish, bats, etc., or even to make baskets of flowers from food. These are all acceptable if kept under control, and if the rest of the meal is served in the same florid style. The worst offense would be to start with a florid display of food and then suddenly change style midway . . .

Common foods and traditions. The theory of balancing *fan* (grains and rice) with *ts'ai* (vegetables and meat) is one of the factors that distinguish Chinese gastronomy from that of all other nations. This refined proportion of harmony and symmetry of ingredients was practiced whenever possible in households throughout the ages and is not limited to formal or high cuisine or to meals served on special occasions.

In addition to taste that pleases (a most elemental requirement in China), astrological, geographical, and personal characteristics had to satisfy the complex system of the *yin–yang* balance of hot and cold, based on Taoist perception of the cosmic equilibrium. According to this theory, every foodstuff possesses an inherent humour; thus, consuming foods and beverages at proper and complementary temperatures can adjust the possible deviation of the normal state of the two intertwining forces.

Certain foods and culinary traditions are prevalent throughout most of the country. Rice is the staple except in the north, where wheat flour takes its place. Fish is extremely important in all regions. Pork, chicken, and duck are widely consumed, as well as large quantities of such vegetables as mushrooms, bamboo shoots, water chestnuts, and bean sprouts. The Chinese season their dishes with monosodium glutamate and soybean sauce, which takes the place of salt. Another distinctive feature of Chinese cooking is the varied and highly imaginative use of fat, which is prepared in many different ways and achieves the quality of a true delicacy in the hands of a talented Chinese cook. The Chinese take tea with their meals, whether green or fermented. Jasmine tea is served with flowers and leaves in small-handled cups.

The great Chinese schools. Traditionally, China is divided into five gastronomic regions, three of which are characterized by the great schools of Chinese cooking, Peking, Szechwan, and Chekiang-Kiangsu. The other two regions, Fukien and Kwangtung, are of lesser importance from a gastronomic point of view.

Peking. Peking is the land of fried bean curd and water chestnuts. Among foods traditionally sold by street vendors are steamed bread and watermelon seeds. Vendors also dispensed buns called *paotse* that were stuffed with pork and pork fat, and *chiaotse,* or crescents, cylindrical rolls filled with garlic, cabbage, pork, scallions, and monosodium glutamate. Wheat cakes wrapped around a filling of scallions and garlic, and noodles with minced pork sauce are also traditional Peking specialties. But the greatest of all delicacies of this region is of course the Peking duck. This elaborate, world-renowned dish requires lengthy preparation and is served in three separate courses. In its preparation, the skin is first puffed out from the duck by introducing air between the skin and the flesh. The duck is then hung out to dry for at least 24 hours, preferably in a stiff, cold breeze. This pulls the skin away from the meat. Then the duck is roasted until the skin is crisp and brown. The skin is removed, painted with Hoisin sauce (a sweet, spicy sauce made of soybeans), and served inside the folds of a bun as the first course. The duck meat is carved from the bones and carefully cut into slivers. Sautéed onions, ginger, and peppers are added to the duck meat and cooked with bean sprouts or bamboo slivers. This forms the second course. The third course is a soup. The duck bones are crushed and then water, ginger, and onion are added to make a broth. The mixture is boiled, then drained, and the residue is cooked with cabbage and sugar until the cabbage is tender.

The preparation of Peking duck

Szechwan. The cooking of Szechwan in central China is distinguished by the use of hot peppers, which are indigenous to the region. The peppers lend an immediate sensation of fiery hotness to the food, but, once this initial reaction passes, a mingled flavour of sweet, sour, salty, fragrant, and bitter asserts itself. Fried pork slices, for example, are cooked with onions, ginger, red pepper, and soy sauce to achieve this aromatic hotness.

Chekiang and Kiangsu. The provinces of Chekiang and Kiangsu feature a broad variety of fish—shad, mullet, perch, and prawns. Minced chicken and bean-curd slivers are also specialties of these provinces. Foods are often arranged in pretty floral patterns before serving.

Fukien. Fukien, which lies farther south, features shredded fish, shredded pork, and *popia,* or thin bean-curd crepes filled with pork, scallions, bamboo shoots, prawns, and snow peas.

Kwangtung. To Americans perhaps, the most familiar form of Chinese cooking is that of Kwangtung, for Canton lies within this coastal province. Mushrooms, sparrows, wild ducks, snails, snakes, eels, oysters, frogs, turtles, and winkles are among the many exotic ingredients of the province. More familiar to Westerners are such Cantonese specialties as egg roll, egg foo yung, and roast pork.

The Cantonese specialties

OTHER CUISINES OF THE WORLD

Japanese. Nowhere has greater care and imagination been given to the presentation of food than in Japan. The delicacy and exquisiteness of Japanese table arrangements are matched only by the fragile beauty of Japanese painting.

Traditionally the Japanese bride received as many as 50 different kinds of dishes as wedding gifts, and she might use a dozen at one meal. She would devote the most painstaking attention to the angle at which a sprig of green vegetable was propped against a lump of crabmeat, or the way a fish was garnished. Meals were served in many small dishes, but the total amounts offered each diner were large.

The waters around Japan abound with fish and shellfish, and Japanese seafood is regarded by many gourmets as the finest in the world. Fish is eaten raw (*sashimi*), broiled, fried in deep fat (*tempura*), or salted and broiled (*shioyaki*). The popular *tempura* method of deep frying food was learned from Portuguese traders who came to Japan in the 16th century. Rice has been the staple; it traditionally accompanied every meal; but in the late 20th century wheat products such as bread have become common, especially as an accompaniment to Western-style food. *Sushi,* or vinegared rice, is served in stylized portions with a variety of accompaniments, including mushrooms, squid, fish, shrimp, and caviar.

The Japanese like clear soups, garnished with eggs, vegetables, or seafood. The thicker "miso" soups are flavoured with fermented soybean paste. Japanese vegetables include bamboo shoots, snow peas, eggplant, mushrooms, and potatoes. The popular sukiyaki consists of beef and vegetables simmered in soy sauce. Pork or chicken may be substituted for the beef. Saké, a fermented beverage made from rice or other grain, is a popular drink, and tea is taken with all meals and at virtually all hours of the day.

The Japanese tea ceremony, or chanoyu, is a highly formalized ritual dating back to the 13th century. The tea is meticulously prepared and is accompanied by a variety of delicate seasonal dishes. Every aspect of the ceremony—the setting, the flavours and textures of foods, the colours and shapes of the containers, even the conversation—is carefully calculated to achieve the most harmonious and satisfying effect.

The Japanese tea ceremony

An outgrowth of the tea ceremony is the *kaiseki,* the *grande cuisine* of Japan; it is the highest form of Japanese dining and perhaps comes as close to dining as an art form as any in the entire world of gastronomy. The food served in *kaiseki* is selected according to the changing seasons and is presented through a series of small dishes with an artful simplicity that brings out the unique tastes of ordinary foods from nearby mountains and sea. Perhaps the key to the composition of the *kaiseki* meal lies in the word *aishoh:* "compatibility."

Indian. Spices are a distinctive feature of the cooking of India and Indonesia. In India, every good cook prepares a curry—a mixture of such fragrant powdered spices as cardamom, cinnamon, cloves, cumin, nutmeg, and turmeric. The spice blend is kept in a jar in the kitchen and is used to season all sorts of foods.

The Hindus of India have developed what is perhaps the world's greatest vegetarian cuisine. They use cereals, pulses (lentils, peas, and beans), and rice with great imagination to produce a widely varied but generally meatless cuisine.

Indian cooks prepare delicious chutneys, highly seasoned vegetables and fruits used as side dishes that must be fresh to be fully appreciated. They also make little delicacies such as *idli*s, cakes of rice and lentils that are cooked by steaming; *pakora*s, vegetables fried in chickpea batter; and *jalebi*s, pretzel-like tidbits made by soaking a deep-fried batter of wheat and chickpea flour in a sweet syrup. *Raytas*, yogurt with fruits or vegetables, are another favourite. Other specialties include *biryānī,* a family of complicated rice dishes cooked with meats or shrimp; *samosa,* a flaky, stuffed, deep-fried pastry; *korma,* lamb curry made with a thick sauce using crushed nuts and yogurt; *masala,* the dry or wet base for curry; and a great variety of breads and hot wafers, including *naan, pappadam, parāṭhā*s, and *chapātī*s.

In southern India and especially in the historical region of Telingana, or Andhra, the food is seasoned with fresh chili peppers and can be fiery hot. Lamb is the most important meat served in northern India. It is prepared in hundreds of different ways as kabobs, curries, roasts, and in rice dishes. In pre-independence days the Mughal cuisine there ranked among the most lavish in the world. The Mughal cuisine developed during the Muslim empire of the great Mughal kingdom. It is based, mostly because of religious and geographic limitations, on lamb. The preparations are mostly roasted, barbecued dishes, also kabobs and the so-called dry curries, versus the stew-type cooking of the south.

In India festivals and holidays are marked by feasting and revelry. Among the more prominent festivals are Ōṇam, a rice harvest celebration; Dīwālī, which marks the beginning of the Hindu New Year; Dashera, which marks the triumph of the good prince Rama over evil; and Holī, the festival of lights, which honours Lord Krishna, an incarnation of the god Vishnu. Feasting and the offering of food to gods and friends are a highlight of these festivals.

The Pacific and Southeast Asia. The cuisine of the Pacific and Southeast Asia is a fascinating melange of raw ingredients, methods, and dishes with a strong influence of the Chinese cuisine. The most important ingredients to tie together this vast area are the coconut, which is used in every one of these countries; rice, which is the basic food everywhere except in the Philippines; and native spices and herbs, especially the omnipresent ginger and chili. The skillful use of condiments and relishes by its inventive cooks makes each of these countries a gastronomically individual entity.

Coconut, rice, spices, and herbs

A Hawaiian staple is the taro bulb, which is the main ingredient for many dishes of the famous luau feasts. Taro may be chopped and steamed alone, or mixed with other ingredients, often wrapped in ti leaves. Poi is made by peeling and cooking the taro root and then mashing it into a paste.

Another famous delicacy is *lomi lomi,* a fresh salmon that is massaged by hand to break down its tissues and remove the salt. Chunks of the fish are mixed with onion and tomatoes. Besides the stone-baked pig, which is always a part of the luau, and several other local specialties, the Hawaiians adapted a number of Chinese, Japanese, Korean, and Indian dishes, together with a great many standard U.S. dishes.

Indonesia consists of several thousand islands, yet its cuisine is almost unified by the use of coconut. It is employed as a vegetable, main course, ingredient, cooking fat, relish, fruit, and even beverage in the popular *tjendol* throughout the islands. Although 300 years of Dutch occupation, a sizable Chinese population, and Portuguese merchants had a very strong influence on the islands' cooking style, Indonesia still can boast of a unique cuisine. Because rice (*nasi*) is the most important part of the meal, all other preparations are actually served to surround and enhance the rice itself. The Dutch themselves created *rijsttafel* (literally, "rice table"), which formalized into an almost endless procession of beautifully arranged, carefully organized dishes, ranging from sweet to sour, from mild to very spicy, from cold to hot.

Each guest was given two plates and was served a long succession of excellent dishes. On one plate a meat or fish preparation would be served, and the other would be filled with rice. The entire meal, with all its courses, took from two to three hours. Since Indonesia gained independence, the *rijsttafel* has been replaced by the *prasmanan,* a lengthy, buffet-style meal also featuring scores of dishes. *Rijsttafel* became popular in The Netherlands, however, and could be ordered in many restaurants, particularly in Amsterdam.

One of the nationally popular preparations is *nasi goreng,* which originates in China's fried-rice concept. In the Indonesian version, however, most of the meats, vegetables, and garnishes surround the pile of fried rice and only the diner mixes them while eating it, allowing many fascinating taste and texture combinations.

Although many dishes are common to all areas, each region has its own specialties and style of cooking. The West Javanese cooking is rather mild and tends to be much simpler than that of Central Java, which favours very hot, rich, and sweet flavours. East Java, on the other hand, is the place where the spicing becomes very complex and subtle, and the Balinese enjoy many of the dishes forbidden to the Muslim population. For instance, the Bali Hindu religion allows the eating of pork, and *saté babi,* the little skewers of charcoal-grilled pork bits, is one of the more interesting of their preparations.

One of the most essential elements of an Indonesian meal is the *sambal*s. These are spicy-hot condiments that are served separately to be mixed with the various foods to make them as "fiery" as the individual desires. *Krupuk,* the deep-fried shrimp wafers, also originated in Indonesia before turning up in other nations' cuisines. Few Indonesian meals are served without *gado-gado,* an interesting melange of cooked and raw vegetables and bean cake with a sauce made of peanuts, coconut, and spices. Sumatra and Malaysia absorbed much of the Arab and Indian culinary influences. *Rendang,* for instance, is a beef stew that absorbs a large amount of coconut milk, using the same technique as some of the so-called dry curries of India. *Gulai* is this area's favourite version of liquid-type curry so common in India.

The Philippine food is much simpler than many of the other Pacific and Southeast Asian cuisines. Although the four centuries of Spanish domination brought considerable influence to this part of the world, Philippine cuisine does have some specialties that can be called its own. Perhaps most typical of these is the fish paste called *bagoong* and the liquid flavouring sauce *patis.* Both are based on fermented seafood and, depending on the area or the household, their variety is almost limitless. Generally speaking, a sour-salty taste is the single most characteristic taste of the Philippines.

Perhaps the strongest Chinese influence can be detected in Vietnam, which was dominated or ruled by China through most of the 1st millennium AD. The degree of influence is discernible even in the manner of eating. For instance, this is the only country in the entire area of the Pacific and Southeast Asia where the food is eaten with chopsticks. *Nuoc mam,* a flavouring sauce, is used in many dishes, and, although it is related to the Philippine *patis,* it really is a specifically Vietnamese flavour, based again on fermented salted fish and spices. Almost every nation's southern inhabitants prefer their food spicier than those in the northern region, and Vietnam is no exception. The tie-in perhaps between the two regions of Vietnam is the use of fish, which is the most important part of the daily diet. The French occupation in Vietnam mostly contributed to the level of the gastronomy of the upper classes, without influencing very much of the average housewife's cooking.

One of the most complex and structured cuisines of the entire area is the cuisine of Thailand. The fact that the Thai lived for much of their history in comparative peace and political independence had beneficial influence on their gastronomy, together with the fact that, just as in China and France, the ruling classes were actively interested in gastronomy. Because the Thai have basically the same ingredients to work with as the Indonesians, Malaysians, or Indians, the categories of the Thai cooking repertoire are not dissimilar, but the subtleties and complexities of flavour and texture are often superior. For instance, *nam prik,* the spicy Thai condiment, has even more varieties than the Indonesian *sambal*s do, with many more ideas employed in their combinations. *Kaeng* is a liquid stew (or perhaps soup-stew) to be mixed with rice. It is very strongly related to the liquid curries, but again the repertoire of *kaeng*s is infinitely larger than almost any other food family in Southeast Asia. Within the formalized gastronomy, the Chinese and Indian influences blend in with such artistry that the emerging cuisine of Thailand is truly its own.

Middle Eastern. Eggplant, olives, and yogurt are widely eaten in all Middle Eastern countries. Chickpeas are toasted or ground. Lamb is the staple meat throughout the region. One of the most characteristic elements of the cuisines of the Middle East is the offering of an almost unlimited array of small hot and cold appetizers. These are called *mazza* (Arabic), *mezethakia* (Greek), or *mezelicuri* (Romanian), and their ingredients and preparation have developed over the centuries as a result of the confluence of many cultures.

Culinary influence of the old Ottoman Empire

The Turkish influence is still dominant in the countries of the old Ottoman Empire: Turkey, Greece, Bulgaria, and other parts of the Balkan region. Vine leaves stuffed with rice and meat are popular. They are called *dolma* in Turkey. *Börek,* a turnover filled with meat or cheese, is another favourite. *Şişkebabi* (shish kebab), skewered mutton or lamb, is enjoyed in all these countries, as is *kofte,* a lamb patty. Yogurt dishes and a sweet known as halvah are commonly found. A favourite dessert is baklava, a rich pastry filled with nuts and layered with honey or syrup. (Baklava was brought by Turkish invaders in the 16th century to Hungary, where it became strudel.)

The Arab states of the Middle East and North Africa share many fine dishes. Among these is the hotly seasoned eggplant dip called *bābā qhanūj.* Other dishes common to the Arab countries include *hummus bī tahīnah,* chickpeas with a sesame paste; *tabbūlah,* a salad of onions, chopped tomatoes, radishes, parsley, and mint; and *kibbi,* a ground mixture of wheat and lamb.

African. The great indigenous dish of North Africa is couscous—steamed wheat or semolina grains—served with meats, poultry, and vegetables piled on top of and around the grain. Another is *brik* (related to the Turkish *börek*), a deep-fried pastry turnover stuffed with fish or meat and a whole egg. A sampler from this continent would include, in East Africa, peanut (groundnut) soup and beef and cassava stew, cooked with coconut, chilies, and coriander; in West Africa, fish *imojo,* a fish and seafood salad; in Ethiopia, *yetemola cheguara,* steamed stuffed whole tripe. South Africans prepare a cinnamon- and clove-flavoured stew, called lamb and pumpkin *bredi,* and date and onion salad. Angola has a yellow coconut pudding in which the colour comes from the predominance of eggs among the ingredients.

Spanish and Portuguese. Spain and Portugal have much in common from a culinary point of view. Olive oil is the cooking fat of both countries. Cod is widely used. The *cocido,* a heavy stew of boiled chicken, meats, and vegetables, is Spain's national dish. In Portugal it is called the *cozido.*

But the two countries also have their own distinctive dishes, which vary greatly from one region to the next. The paella is perhaps Spain's best known dish. It is a colourful combination of rice, chicken, pork, clams, mussels, shrimp, peppers, sausages, and peas. The home of the paella is Valencia, but the dish varies from one province to the next. Another regional specialty is the *zarzuela de mariscos,* a Catalan seafood medley, a stew of fish, lobster, shrimp, scallops, clams, ham, almonds, white wine, and saffron. Fish is popular throughout Spain, especially cod, hake, and red snapper. Many people consider the Basque-style cooking (*à la Vasca*) the best in Spain. It is a surprisingly sophisticated cuisine for one based on ancient shepherds' cooking. *Tapas* are appetizers served in Spanish bars, and often there are several dozen varieties from which to choose. *Jamón serrano,* a mountain-cured ham; chorizo sausages; gazpacho, a cold soup made of pureed vegetables and generally quite spicy; and meat pies called empanadas are some of the highlights of the quite remarkable cuisine of Spain.

The Portuguese kitchen produces somewhat spicier and richer foods, favouring hearty soups, marinated seafoods, braised meats, and such spices as cumin and coriander. The entire Iberian Peninsula is strongly influenced by the honey-almond paste, figs, and dates typically used by the Moors.

Italian. The Italians are especially fond of pasta *asciutta* (an unending variety of dried noodles), the huge assortment of hot and cold appetizers known as antipasti; sausage and salami; *gelati e granite,* ice creams and ices; and *caffè espresso,* coffee made by forcing steam through the coffee grounds.

Italy, like France or China, has many culinary regions, but basically the north's staple is rice and butter and the south lives on pasta and cooks with olive oil. Cooking techniques are less important than the quality of the raw ingredients.

Bologna's rich cooking is perhaps the best of the northern cuisine with its famed *tagliatelle, tortellini,* and other freshly made noodle preparations, egg pastas, sausages, and complex main courses. Piedmont supplies many of the finest chefs to the luxury restaurants around the world. Its local white truffles and Fontina cheese are the base for their *fonduta,* the famous hot melted cheese casserole eaten with bread bits.

Lombardy cooks exclusively with butter, replacing the pasta with rice and cornmeal polenta, and blends successfully the cooking style of several of the northern provinces. Genoese cooking's most characteristic flavour comes from the use of basil leaves pounded into a sauce called *pesto* together with cheese, garlic, pine nuts, and olive oil. Florence is famous for its *Chianina* beef cattle that provide the meat for its *bistecca alla Fiorentina.*

Alla Romana-type cooking produces the best gnocchi, *calamaretti* (baby squid), *abbacchio* (young lamb, usually roasted with rosemary), and vegetable preparations. The cooking of Naples represents the best gastronomy of southern Italy with the use of pasta, crusty white bread, robust tomato sauces, mozzarella, and other types of cheese. Generally speaking, the availability of some of the finest vegetables and fruits of Europe and of fine seafood, and the array and liberal use of fresh herbs, create the best moments of the Italian gastronomy.

Austro-Hungarian. The gastronomic regions of the world existing today do not conform to geographic or political divisions. A good example is the Austro-Hungarian cuisine, a culinary entity the boundaries of which have not been discernible on maps since the end of World War I. This gastronomical region comprises the old Austro-Hungarian Empire. It includes Austria and Hungary, as well as parts of Romania and other areas of the Balkan region, the Czech Republic, and Slovakia. The people of these countries live in different political, economic, and social systems and speak different languages, but their culinary heritage remains as a link between them. *Gulyás,* or goulash, is prepared in varying forms in all of these countries. Wiener schnitzel (breaded veal cutlets, named for the city of Wien, or Vienna) is eaten throughout the area. Coffeehouses are popular throughout this part of the world. In Austria a traveller will encounter *nockerl,* a small dumpling; in Hungary, he may eat *nokedli;* in the Czech Republic and in Slovakia he will find a similar food under the name *noky,* in Serbia under the name *nokla.* In Hungary the *nokedli* would accompany *pörkölt,* a stew made by browning onion in lard and adding paprika, or a *paprikás,* similar to the above, but with the addition of sweet or sour cream. A dessert would be *Rigó Jancsi,* a chocolate square glazed with chocolate and filled with chocolate mousse. Cakes, tortes, and desserts are the glory of this cuisine. Prune dumplings, strudels, the coffee ring called *gugelhupf,* and the Dobos torte, a caramel-topped cake filled with chocolate-cocoa cream, are enjoyed. And one of the greatest glories of Vienna's old empire is Sacher torte, a chocolate sponge cake with a touch of apricot jam, iced with a bittersweet chocolate.

Each section of this gastronomic region developed its own specialties. The people of the Czech-Slovak region, for instance, cook *játernice* (a sausage made with innards), bake *koláĉ* (coffee cake), and make *povidla* (prune jam). Austria offers *Backhendl* (breaded-fried spring chicken), *Tafelspitz* (the boiled beef considered the finest, a cut near the tail of the steer), Linzer torte (a ground-almond and jam lattice cake), *buchteln* (jelly buns), and *Palatschinken* (thin pancakes with filling). In the Yugoslav region popular items are the *čevapčići* (charcoal-grilled meatballs), *gibanica* (cheesecake), *lonac* (a Bosnian meat and vegetable stew), and *šumadija* (a tea made with plum brandy and caramelized sugar).

Slavic. Russia is the mother country of the Slavic cuisine, another culinary entity that does not exist on the map. This cuisine comprises the former Soviet Union, Poland, Albania, and parts of the Yugoslav region and Bulgaria. A Russian-speaking traveller through this region might find it difficult to make himself understood, but he could order the familiar borsch, a beet or cabbage soup, wherever he went. He might dine on blintzes (stuffed pancakes) or *zrazy* (stuffed fried fish or seafood). He could enjoy beef stroganoff, beef cooked with onions in sour cream, or a seafood pie called *rakov*. Wherever he went, vodka would be the most popular drink.

The Russians developed *zakusky*, their equivalent of the French hors d'oeuvres. *Potage Bagration* (cream of veal with asparagus tips) is also part of the French *grande cuisine* together with many other dishes the French chefs learned in the Russian court kitchens. Interesting specialties are the *botvinya* (green vegetable soup with a fish base), *solyanka* (cucumber soup), *pelemeni* (Siberian meat dumplings, boiled, fried, and served with sour cream), *kasha* (buckwheat porridge), *holubtsi* (Ukrainian stuffed cabbage), *bitki* (meatballs or fish balls with strong spices), *paskha* (cottage-cream cheesecake with candied fruits made in a pyramid shape for Easter), and *babka* (a round coffee cake).

German. The emphasis of the cuisine of Germany and its neighbours is on "hearty" foods—roast meats, dumplings, fish dishes, cream sauces, puddings, and rich desserts. The Germans eat sauerbraten, a marinated pot roast with a sweet-and-sour sauce, the earthy hasenpfeffer (hare stew), *Königsberger Klopse* (a fancy meatball), *badischer Hecht* (a sour cream baked pike), and *Schweinebraten mit Pflaumen und Apfeln* (roast pork with prune and apple stuffing). Other favourite foods are sausages; sauerkraut (fermented cabbage); dumplings; thick soups made from potatoes, peas, or lentils; herring; and roast meats, or braten. Popular desserts include puddings, fruit pancakes or dumplings, egg custards, jellies topped with whipped cream, the medieval invention marzipan (an almond paste confection), lebkuchen (a kind of gingerbread), and *Baumkuchen* (the "tree-cake" baked on a special horizontal spit).

Scandinavian. Fish is a mainstay of the Scandinavian diet. It is prepared in many different ways; a favourite appetizer is *gravlax*, salmon marinated in salt and dill and accompanied by a mustard sauce. Swedish pancakes are popular and are served with lingonberries or fruit preserves.

The sumptuous bread-and-butter table

Sweden's great contribution to international eating is the smorgasbord, literally a "bread-and-butter table" but actually a sumptuous feast of three courses. The first course is herring—filleted, pickled, baked, jellied, stewed, or prepared in many other different ways. Cold meats constitute the second course, whereas the third course is made up of Swedish meatballs and other hot dishes.

Danish open sandwiches, called *smørrebrød*, became popular all over the world. Among the many fine dishes in these northern European countries are *nyponsoppe* (a Swedish soup prepared with rose hips, almonds, and whipped cream), *vorshmack* (ground meat, herring, and onion cooked Finnish style), "Jansson's Temptation" (a Swedish potato and anchovy casserole), *frikadeller* (a Danish mixed ground meat hamburger, sautéed in butter), *kalakukko* (a Finnish bird-shaped pie stuffed with fish), *sandkage* (Danish sand cake), and *krumkage* (a Norwegian Christmas cookie). Aquavit is the favourite grain or potato spirit of many in Scandinavia.

British. Favourites among the English are roast beef with Yorkshire pudding, an accompaniment similar in texture to a popover; steak and kidney pie; and veal and ham pie. Fish is served often—plaice (a type of flounder), haddock, mackerel, and smoked kipper—and especially popular are fish-and-chips (deep-fried fish and potatoes). Jellies, jams, marmalade, hot cross buns, crumpets, and scones are served frequently with tea.

Traditional fare in the British Isles would include beef tea (a beef extract), whitebait (miniature fish, fried and eaten as snacks), boxty (Irish potato pancakes), brawn (aspic made with pork bits), cockaleekie (Scottish hen and leek soup), bubble and squeak (chopped, fried leftover meat and vegetables), angels on horseback (grilled oysters wrapped in bacon), kedgeree (a casserole of smoked fish, rice, and eggs), shepherd's pie (ground lamb and beef with onion and topped with mashed potatoes), crumpets, banbury cake (a spiced flat cake made with dried fruits), fool (a fruit custard), and syllabub (a dessert made with whipped cream, lemon, wine, and sugar).

Latin American. Corn (maize) is the culinary common denominator of much of Latin America. Ground into meal, it is used in Mexico to prepare the corn pancakes known as tortillas. Tortillas provide a variety of other Mexican specialties. Enchiladas are tortillas dipped in sauce, then rolled up with a filling of pork or chicken and baked or broiled. *Tostadas* are tortillas fried crisp and sprinkled with onion, chili peppers, grated cheese, or meat. *Quesadillas* are tortillas folded over a filling of meat, beans, cheese, or vegetables. Corn is also used in tamales, which are steamed, filled corn husks.

Chili peppers are widely used to season Latin American dishes. Brazil's national dish, the *feijoada completa,* consists of a bed of rice with black beans, sausages, beef tongue, spareribs, and dried beef, sprinkled with toasted manioc meal, and garnished with orange slices. In Argentina, empanadas are beef-filled turnovers. A favourite Latin American dessert is flan, or caramel custard.

Quick-service and convenience foods

North American. While North American cities such as New York, New Orleans, San Francisco, Chicago, and Montreal have produced many excellent restaurants and hotels, the unique American contribution to gastronomy has been quick-service and convenience foods. The first cafeteria came into being in San Francisco during the Gold Rush of 1849. Automated cafeterias were later introduced in New York and Philadelphia.

The United States is a culinary melting pot. In New York City and many other metropolitan areas, one can find almost any kind of food. Outside the great cities, American food at one time had a distinctive regional character. New England was famous for its clam and lobster dishes, its New England boiled dinner, and its red flannel hash. The South had its fried chicken, barbecued meats, and corn breads. The Far West prided itself on its Dungeness crab, abalone, fish, and shellfish. As a result of easy transportation of fresh, packaged, and frozen foods, once strictly regional dishes have become popular countrywide. A "new" American cooking, combining inventive simplicity and eclectic venturesomeness, offers a challenge to the bastions of European gastronomy.

BIBLIOGRAPHY. PROSPER MONTAGNÉ, *Larousse Gastronomique*. new ed. (1988; originally published in French, rev. and corrected ed., 1967), is the most authoritative contemporary encyclopaedia of food, wine, and cookery, from prehistoric stages to the modern day. It may be supplemented by WAVERLEY ROOT, *Food: An Authoritative and Visual History and Dictionary of the Foods of the World* (1980); JEAN-FRANÇOIS REVEL, *Culture and Cuisine: A Journey Through the History of Food* (1982; originally published in French, 1979); MARGARET VISSER, *The Rituals of Dinner: The Origins, Evolution, Eccentricities, and Meaning of Table Manners* (1991); and MAGUELONNE TOUSSAINT-SAMAT, *A History of Food* (1992; orginally published in French, 1987).

Early works, many of them now classics, include JEAN ANTHELME BRILLAT-SAVARIN, *The Physiology of Taste; or, Meditations on Transcendental Gastronomy*, trans. by M.F.K. FISHER (1949, reissued as *M.F.K. Fisher's Translation of the Physiology of Taste*, 1986; originally published in French, 2 vol., 1826), a classic that set the stage for thinking about dining as an experience and a form of art, in a translation by a distinguished American essayist on gastronomy; ANDRÉ L. SIMON, *A Concise Encyclopaedia of Gastronomy*, 9 vol. (1939–46, reissued in 1 vol., 1981). a complete history; URBAIN DUBOIS and ÉMILE BERNARD, *La Cuisine classique*, 2 vol. (1856), the finest expression of the Golden Age of the French *grande cuisine;* ALEXIS SOYER, *The Pantropheon* (1853, reprinted 1977), a world history of food preparation with many arbitrary but important observations on gastronomy; and ABRAHAM HAYWARD, *The Art of Dining*, ed. by CHARLES SAYLE (1899), on 18th- and 19th-century gastronomy, chefs, and related subjects. Chinese cuisine is treated in PEARL KONG CHEN, TIEN CHI CHEN, and ROSE Y.L. TSENG, *Everything You Want to Know About Chinese Cooking* (1983); and K.C. CHANG (ed.), *Food in Chinese Culture: Anthropological and Historical Perspectives* (1977).

(G.L./Ed.)

Gauss

Carl Friedrich Gauss, who, with Archimedes and Newton, ranks as one of the greatest mathematicians of all time, at an early age overturned the theories and methods of 18th-century mathematics and, following his own revolutionary theory of numbers, opened the way to a mid-19th-century rigorization of analysis. Although he contributed significantly to pure mathematics, he also made practical applications of importance for 20th-century astronomy, geodesy, and electromagnetism. His own dictum, "Mathematics, the queen of the sciences, and arithmetic, the queen of mathematics," aptly conveys his perception of the pivotal role of mathematics in science.

Born on April 30, 1777, in Brunswick, now in Germany, Gauss was the only son of poor parents. Impressed by his ability in mathematics and languages, his teachers and his devoted mother recommended him to the Duke of Brunswick, who granted him financial assistance to continue his education in secondary school and from 1795 to 1798 to study mathematics at the University of Göttingen. In 1799 he obtained his doctorate in absentia from the university at Helmstedt. The subject of his dissertation was a proof of the fundamental theorem of algebra—which was proven only partially before Gauss—which states that every algebraic equation with complex coefficients has complex solutions; moreover, Gauss skillfully formulated and proved this theorem without the use of complex numbers.

Contributions to number theory

At age 24 he published the *Disquisitiones Arithmeticae,* one of the most brilliant achievements in the history of mathematics, in which he formulated systematic and widely influential concepts and methods of number theory—dealing with relationships and properties of integers (−2, −1, 0, +1, +2, . . .)—which, for him, was of paramount importance in mathematics. He dealt extensively with the theory of congruent numbers—(*i.e.,* those numbers that have the same remainder when they are divided by another number (for example, 7 and 9 are congruent modulo the number 2 since there is a remainder of 1 when each is divided by 2); he gave the first proof of the law of quadratic reciprocity, which has to do with the quadratic residues (a is called quadratic residue with respect to b, if there is an integer x such that when a is divided by b, the remainder is the same as x^2 divided by b); and he applied this law to special cases of equations in which he was able to bring together algebraic, arithmetic, and geometric ideas. Using number theory, for example, Gauss proposed an algebraic solution to the geometric problem of constructing a regular polygon that has n sides. Euclid had shown that regular polygons, with 3, 4, 5, and 15 sides and those the sides of which result from doubling the above could be constructed geometrically with compass and ruler. No progress had been made in this subject since then. Gauss developed a criterion based on number theory by which it can be decided whether a regular polygon with any given number of corners can be geometrically constructed: these include, for example, the regular polygon with 17 sides, which he inscribed within a circle using only compass and ruler, the first such discovery since the time of Euclid.

This work on number theory contributed to the modern arithmetical theory of algebraic numbers—that is, to the solution of algebraic equations—in which Gauss introduced the first step—that is, the arithmetic of all complex numbers $a + b\sqrt{-1}$, in which a and b are integers. The complex numbers $a + b\sqrt{-1}$ had been introduced only intuitively before Gauss. In the *Disquisitiones Arithmeticae* Gauss did not hesitate to use complex numbers $a + b\sqrt{-1}$, in which a and b are real numbers. In 1831 (published 1832) he gave a detailed explanation of how an exact theory of complex numbers can be developed with the aid of representation in the x, y plane.

Astronomical and geodetic research

In 1801 Gauss had the opportunity to apply his superior computational skills in a dramatic way and, by so doing, to express gratitude to the Duke for assisting him in obtaining an education. On the first day of the year, a body, subsequently identified as an asteroid and named Ceres, was discovered as it seemed to approach the Sun. Astronomers had been unable to calculate its orbit, although they could observe it for 40 days until lost from view. After only three observations Gauss developed a technique for calculating its orbital components with such accuracy that several astronomers late in 1801 and early in 1802 were able to locate Ceres again without difficulty. As part of his technique, Gauss used his method of least squares, developed about 1794, a method by which the best estimated value is derived from the minimum sums of squared differences in a particular computation. This achievement in astronomy won Gauss prompt recognition. His methods, which he described in his book, in 1809, *Theoria Motus Corporum Coelestium,* are still in use today, and only a few modifications have been required to adapt his methods for modern computers. He had similar success with the asteroid Pallas, for which he refined his calculations to take into account the perturbations of its orbit by planets.

The Duke continued to finance Gauss's research so generously that in 1803 he was able to decline an offer of a professorship in St. Petersburg, where he was by then a corresponding member of the Academy of Sciences. In 1807 he became professor of astronomy and director of the new observatory at the University of Göttingen, where he remained for the rest of his life. His first wife died in 1809, after a marriage of four years and soon after the birth of their third child. From his second marriage (1810–31) were born two sons and a daughter.

About 1820 Gauss turned his attention to geodesy—the mathematical determination of the shape and size of the Earth's surface—to which he devoted much time in theoretical studies and field work. To increase the accuracy of surveying he invented the heliotrope, an instrument by which sunlight could be utilized to secure more accurate measurements. By introducing what is now known as the Gaussian error curve, he showed how probability could be represented by a bell-shaped curve, commonly called the normal curve of variation, which is basic to descriptions of statistically distributed data. He also was interested in determining the shape of the Earth by actual geodetic measurements, which led him back to pure theory. Using data from these measurements, he developed a theory of curved surfaces by which characteristics of a surface could be found solely by measuring the lengths of the curves that lie on the surface. This "intrinsic-surface theory" inspired one of his students, Bernhard Riemann, to develop a general intrinsic geometry of spaces with three or more dimensions. It was the subject of Riemann's inaugural lecture at Göttingen in 1854 and is said to have agitated Gauss. About 60 years later Riemann's ideas formed the mathematical basis for Einstein's general theory of relativity.

Contributions to non-Euclidean geometry and to physics

Gauss was one of the first to doubt that Euclidean geometry was inherent in nature and thought. Euclid was the first to build a systematic geometry. Certain basic ideas in his model are called axioms; they were the points of departure from which his entire system was constructed through pure logic. Of these, the parallel axiom played a prominent role from the beginning. According to this axiom, only one line can be drawn parallel to a given line through any point not on the given line. From this axiom soon arose the supposition that it can be deduced out of the other axioms and thus can be omitted from the system of axioms. All proofs of it, however, contained errors, and Gauss was one of the first to realize how there might be a geometry in which the parallel axiom does not apply. Gradually he came to the revolutionary conclusion that there is indeed such a geometry that is internally consistent and free of contradiction. Because it ran counter to contemporary views, he feared publication (see GEOMETRY: *Non-Euclidean geometry*).

When a Hungarian, János Bolyai, and a Russian, Nikolay Lobachevsky, independently published a non-Euclidean geometry about 1830, Gauss announced that he had made the same conclusions approximately 30 years before. Neither did he publish his work on special complex functions, perhaps because he was unable to derive them from more general principles. Thus, this theory had to be reconstructed by other mathematicians from his calculations in work extending over several decades after his death.

Closely related to his interest in gravitation and magnetism was his published paper in 1840 on real analysis. This paper became the starting point for the modern theory of potential. It is probably the only work he did that failed to meet his own high standards. Only at the beginning of the 20th century was it possible for mathematicians to develop potential theory anew, on the basis of different principles or by finding the conditions under which Gauss's conclusions are completely correct.

About 1830, principles of extremals (maximum and minimum quantities) began to assume a substantial role in his mathematical investigations of physical problems, such as the conditions in which a fluid remains at rest. In his treatment of capillary action, he devised mathematical formulations that took into account the mutual actions of all the particles in a fluid system, the force of gravity, and the interaction of its fluid particles and the particles of solid or fluid with which it is in contact. This work contributed to the development of the principle of the conservation of energy. From 1830, Gauss worked closely with the physicist Wilhelm Weber. Because of their interest in terrestrial magnetism, they organized a worldwide system of stations for systematic observations. The most important result of their work in electromagnetism was the development, by other workers, of electric telegraphy. Because their finances were limited, their experiments were on a small scale; Gauss was rather frightened at the thought of worldwide communication.

Personality

Gauss was deeply religious, aristocratic in bearing, and conservative. He remained aloof from the progressive political currents of his time. In Gauss, apparent contrasts were combined in an effective harmony. A brilliant arithmetician with a phenomenal memory for numbers, he was at once a profound theoretician and an outstanding practical mathematician. Teaching was his only aversion, and, thus, he had only a few students. Instead, he effected the development of mathematics through his publications, about 155 titles, to which he devoted the greatest care. Three principles guided his work: "Pauca, sed matura" ("Few, but ripe"), his favourite saying; the motto "Ut nihil amplius desiderandum relictum sit" ("That nothing further remains to be done"); and his requirement of utmost rigour. It is evident from his posthumous works that there are extensive and important papers that he never published because, in his opinion, they did not satisfy one of these principles. He pursued a research topic in mathematics only when he might anticipate meaningful relationships of ideas and results that were commendable because of their elegance or generality.

The golden anniversary of the granting of the doctorate to Gauss was celebrated in 1849. For this event, he prepared a new edition of his earlier proofs of the fundamental theorem of algebra, which, because of his declining health, was his last publication. The honour that gave him the greatest joy, however, was the bestowal of honorary citizenship on him by the city of Göttingen. On the basis of his outstanding research in mathematics, astronomy, geodesy, and physics, he was elected as a fellow in many academies and learned societies. He declined numerous invitations of other universities to become a professor and remained on the faculty of the University of Göttingen until his death on February 23, 1855. Soon after his death, coins were struck in his honour. The title of *mathematicorum princeps* is a fitting tribute. (H.Re.)

BIBLIOGRAPHY. *Carl Friedrich Gauss Werke,* 12 vol. (1863–1933), presents Gauss's publications, posthumous works, part of his correspondence, and commentaries by the publishers. Biographies include W.K. BÜHLER, *Gauss* (1981); TORD HALL, *Carl Friedrich Gauss,* trans. from Swedish (1970); and W. SARTORIUS VON WALTERSHAUSEN, *Gauss, a Memorial* (1966; originally published in German, 1856), written by a friend as a nonmathematical account of Gauss's life. HANS REICHARDT (ed.), *C.F. Gauss Gedenkband anlässlich des 100. Todestages am 23. Februar 1955* (1957), contains essays on various aspects of Gauss's work, as well as facts on his life and activities; and GEORGE M. RASSIAS (ed.), *The Mathematical Heritage of C.F. Gauss* (1991), includes diverse essays covering theories and problems that Gauss initially set forth. (H.Re./Ed.)

The Principles of Genetics and Heredity

Heredity is the sum of all biological processes by which particular characteristics are transmitted from parents to their offspring. Among organisms that reproduce sexually, progeny are not exact duplicates of their parents but usually vary in many traits. Heredity and variation, two sides of the same coin, are the subject matter of the science of genetics. Genetics may be defined as the study of the way in which genes—the functional units of heritable material—operate and are transmitted from parents to offspring. Modern genetics also involves study of the mechanism of gene action; that is, the way in which the genetic material affects physiological reactions within the cell.

In many languages the same words are used for both the inheritance of biological traits and the inheritance of property. Biological and legal inheritances are, however, very different processes. Inherited objects are actually transferred from one owner to another. Inherited traits are not. Offspring inherit a genetic constitution from their parents. This hereditary endowment, the sum total of the genes that the individual has received from both parents, is called the genotype. The genotype must be contrasted to the phenotype, which is the organism's outward appearance: its bodily structures, physiological processes, behaviour, etc. Although the genotype determines the broad limits of the features an organism may develop, the features that actually develop—*i.e.,* the phenotype—depend upon complex interactions between genes and their environment. Since the environment, both internal and external, of an individual changes continuously, so does the phenotype. Thus the same individual shows different phenotypes in childhood, in adulthood, and in old age. The genotype, on the other hand, does not change during an individual's lifetime. In conducting genetic studies it is crucial to discover the degree to which the observable trait (the phenotype) is attributable to the pattern of genes in the cells (the genotype) and to what extent it arises from environmental influence.

The essence of heredity is the reproduction of the carriers of genetic information, the genes. As a result, biological organisms, including human beings, reproduce organisms resembling themselves; human children are always recognizably human and have phenotypes similar to those of their parents. On the other hand, since the offspring of sexually reproducing organisms receive varying combinations of genetic material from both parents, no two offspring (except for identical twins) have exactly the same genotype. This genetic diversity is always modified by an equally diverse environment, so the resulting phenotype is never exactly the same, even among identical twins.

Genetics is often called the core science of biology. This does not necessarily mean that genetics is the most fundamental among the biological disciplines. It implies only that genetics impinges upon almost every kind of study of life. Anthropology, medicine, biochemistry, physiology, psychology, ecology, systematics, comparative morphology, and paleontology all have intersections with genetics. Like so many basic, or "theoretical," sciences, genetics has many actual and potential practical applications. The understanding and control of hereditary disorders and the breeding of improved crops and livestock are just two such applications.

Knowledge of heredity dates to prehistoric times and has been applied to the breeding of plants and animals for centuries. Most of the mechanisms of heredity, however, remained a mystery until the 20th century. The pioneering work in elucidating the mechanisms of gene action took place even more recently, and the science of genetics is considered as yet in its infancy.

This article examines the discoveries that led to an understanding of heredity and discusses in detail the structure and function of the gene, mutation and other processes by which genetic information is altered, and the science of human genetics, applying some of the aspects mentioned earlier in the article specifically to human inheritance.

The article is divided into the following sections:

BASIC FEATURES OF HEREDITY

Early conceptions of heredity

Heredity was for a long time one of the most puzzling and mysterious phenomena of nature. This was so because the sex cells, which form the bridge across which heredity must pass between the generations, are usually invisible to the naked eye. Only after the invention of microscopes early in the 17th century, and the discovery of the sex cells, could the essentials of heredity be grasped. Before that time, Aristotle (4th century BC) speculated that the relative contributions of the female and the male parents were very unequal—the female was thought to supply what he called the "matter" and the male the "motion." The *Institutes of Manu,* composed in India between AD 100 and 300, consider the role of the female like that of the field and of the male like that of the seed; new bodies are formed "by the united operation of the seed and the field." In reality both parents transmit the heredity pattern equally, and, on the average, children resemble their mothers as much as they do their fathers. Nevertheless, the female and male sex cells may be very different in size and in structure; the mass of an egg cell is sometimes millions of times greater than that of a spermatozoon.

The ancient Babylonians knew that pollen from a male date palm tree must be applied to the pistils of a female tree to produce fruits. Rudolph Jacob Camerarius showed in 1694 that the same is true in corn (maize). Carolus Linnaeus in 1760 and Josef Gottlieb Kölreuter, in a series of works published from 1761 to 1798, described crosses of varieties and species of plants. They found that these hybrids were on the whole intermediate between the parents, although in some characteristics they may be closer to one and in others closer to the other parent. Kölreuter compared the offspring of reciprocal crosses—*i.e.,* of crosses of variety *A* functioning as a female to variety *B* as a male and the reverse, variety *B* as a female to *A* as a male. The hybrid progenies of these reciprocal crosses were usually alike, indicating that, contrary to the belief of Aristotle, the hereditary endowment of the progeny was derived equally from the female and the male parents. Many experiments on plant hybrids were made in the 1800s. These investigations revealed that hybrids were usually intermediate between the parents. They more or less incidentally recorded most of the facts that later led Gregor Mendel (see below) to formulate his celebrated rules and to found the theory of the gene. Apparently, none of Mendel's predecessors saw the significance of the data that were being accumulated. The general intermediacy of hybrids seemed to agree best with the belief that heredity was transmitted from the parents to offspring by "blood," and this belief was accepted by most 19th-century biologists, the evolutionist Charles Darwin being included among these.

Blood theory of heredity

The blood theory of heredity, if this notion can be dignified with such a name, is really a part of the folklore antedating scientific biology. It is implicit in such popular phrases as "half blood," "new blood," "blue blood." It does not mean that heredity is actually transmitted through the red liquid in blood vessels; the essential point is the belief that a parent transmits to each child all its characteristics and that the hereditary endowment of a child is an alloy, a blend of the endowments of its parents, grandparents, and more remote ancestors. This idea appeals to those who pride themselves on having a noble or remarkable "blood" line. It strikes a snag, however, when one observes that a child has some characteristics that are not present in either parent but are present in some other relatives or were present in more remote ancestors. Even more often one sees that brothers and sisters, though showing a family resemblance in some traits, are clearly different in others. How could the same parents transmit different "bloods" to each of their children?

Mendel disproved the blood theory. He showed (1) that heredity is transmitted through factors (now called genes) that do not blend but segregate, (2) that parents transmit only one-half of the genes they have to each child, and they transmit different sets of genes to different children, and (3) that, although brothers and sisters receive their heredities from the same parents, they do not receive the same heredities (an exception is identical twins). Mendel thus showed that, even if the eminence of some ancestor were entirely the reflection of his genes, it is quite likely that some of his descendants, especially the more remote ones, would not inherit these "good" genes at all. In sexually reproducing organisms, humans included, every individual has a unique hereditary endowment.

Lamarckism—a school of thought named for the 19th-century pioneer French evolutionist Jean-Baptiste, chevalier de Lamarck—assumed that characters acquired during an individual's life are inherited by his progeny, or, to put it in modern terms, that the modifications wrought by the environment in the phenotype are reflected in similar changes in the genotype. If this were so, the results of physical exercise would make exercise much easier or even dispensable in a person's offspring. Not only Lamarck but also other 19th-century biologists, including Darwin, accepted the inheritance of acquired traits. It was questioned by August Weismann, whose famous experiments in the late 1890s on amputation of tails in generations of mice showed that such modification resulted neither in disappearance nor even in shortening of the tails in the descendants. Weismann concluded that the hereditary endowment of the organism, which he called the germ plasm, is wholly separate and is protected against the influences emanating from the rest of the body, the somatoplasm or soma. The germ plasm–somatoplasm are related to the genotype–phenotype concepts, but they are not identical and should not be confused with them.

Superstitions regarding heredity

The noninheritance of acquired traits does not mean that the genes cannot be changed by environmental influences: X rays and other mutagens certainly do change them, and the genotype of a population can be altered by selection. It simply means that what is acquired by parents in their physique and their intellect is not inherited by their children. Related to these misconceptions are the beliefs in "prepotency"—that some individuals impress their heredities on their progenies more effectively than others—and in "prenatal influences" or "maternal impressions"—that the events experienced by a pregnant female are reflected in the constitution of the child to be born. How ancient these beliefs are is suggested in the Book of Genesis, in which Laban produced spotted or striped progeny in sheep by showing the pregnant ewes striped hazel rods. Another such belief is "telegony," which goes back to Aristotle; it alleged that the heredity of an individual is influenced not only by his father but also by males with whom the female may have mated and who have caused previous pregnancies. Even Darwin, as late as 1868, seriously discussed an alleged case of telegony: that of a mare that was mated to a zebra and subsequently to an Arabian stallion by whom the mare produced a foal with faint stripes on his legs. The simple explanation for this result is that such stripes occur naturally in some breeds of horses.

All these beliefs, from inheritance of acquired traits to telegony, must now be classed as superstitions. They do not stand up under experimental investigation and are incompatible with what is known about the mechanisms of heredity and about the remarkable and predictable properties of the genetic materials. Nevertheless, some people still cling to these beliefs. Some animal breeders take telegony seriously and do not regard as "pure bred" the individuals whose parents are admittedly "pure" but whose mothers had mated with males of other breeds. The agronomist Trofim Denisovich Lysenko was able for close to a quarter of a century, roughly between 1938 and 1963, to make his special brand of Lamarckism the official creed in the Soviet Union and to suppress most of the teaching and research in orthodox genetics. He and his partisans published hundreds of articles and books allegedly proving their contentions, which effectively deny the achievements of biology for at least a century. The Lysenkoists were officially discredited in 1964.

Mendelian genetics

DISCOVERY AND REDISCOVERY OF MENDEL'S LAWS

Gregor Mendel published his work in the proceedings of the local society of naturalists in Brünn, Austria (now Brno, Czechoslovakia), in 1866, but none of his contemporaries appreciated its significance. It was not until 1900, 16 years after Mendel's death, that his work was rediscovered independently by Hugo de Vries in Holland, Carl Erich Correns in Germany, and Erich Tschermak von Seysenegg in Austria. Like several investigators before him, Mendel experimented on hybrids of different varieties of a plant. Mendel investigated the common pea plant (*Pisum sativum*). His methods differed in two essential respects from those of his predecessors. First, instead of trying to describe the appearance of whole plants with all their characteristics, Mendel followed the inheritance of single, easily visible and distinguishable traits, such as round versus wrinkled seed, yellow versus green seed, purple versus white flowers, etc. Second, he made exact counts of the numbers of plants bearing this or that trait; it was from such quantitative data that he deduced the rules governing inheritance.

Experiments with pea plants

Since pea plants reproduce usually by self-pollination of their flowers, the varieties Mendel obtained from seedsmen were "pure"—*i.e.,* descended for several to many generations from plants with similar traits. Mendel crossed them by deliberately transferring the pollen of one variety to the pistils of another; the resulting first-generation hybrids, denoted by the symbol F_1, usually showed the traits of only one parent. For example, the crossing of yellow-seeded plants with green-seeded ones gave yellow seeds; the crossing of purple-flowered plants with white-flowered ones gave purple-flowered plants, etc. Traits such as the yellow-seed colour and the purple-flower colour Mendel called dominant; the green-seed colour and the white-flower colour he called recessive. It looked as if the yellow and purple "bloods" overcame or consumed the green and white "bloods."

That this was not so became evident when Mendel allowed the F_1 hybrid plants to self-pollinate and produce the second hybrid generation, F_2. Here both the dominant and the recessive traits reappeared, as pure and uncontaminated as they were in the original parents (generation P). Moreover, these traits now appeared in constant proportions: about 3/4 of the plants in the second generation showed the dominant trait and 1/4 showed the recessive, a 3 to 1 ratio. It can be seen in Table 1 that Mendel's actual counts were as close to the ideal ratio as one could expect allowing for the sampling deviations present in all statistical data.

Table 1: Pea Plants with Dominant and Recessive Characters Obtained by Mendel in the Second Generation of Hybrids

number dominant		number recessive		ratio
Round seed	5,474	Wrinkled seed	1,850	2.96 : 1
Yellow seed	6,022	Green seed	2,001	3.01 : 1
Purple flowers	705	White flowers	224	3.15 : 1
Tall plants	787	Short plants	277	2.84 : 1

Mendel concluded that the sex cells, the gametes, of the purple-flowered plants carried some factor that caused the progeny to develop purple flowers, and the gametes of the white-flowered variety had a variant factor that induced the development of white flowers. In 1909 the Danish biologist Wilhelm Ludvig Johannsen proposed to call these factors genes.

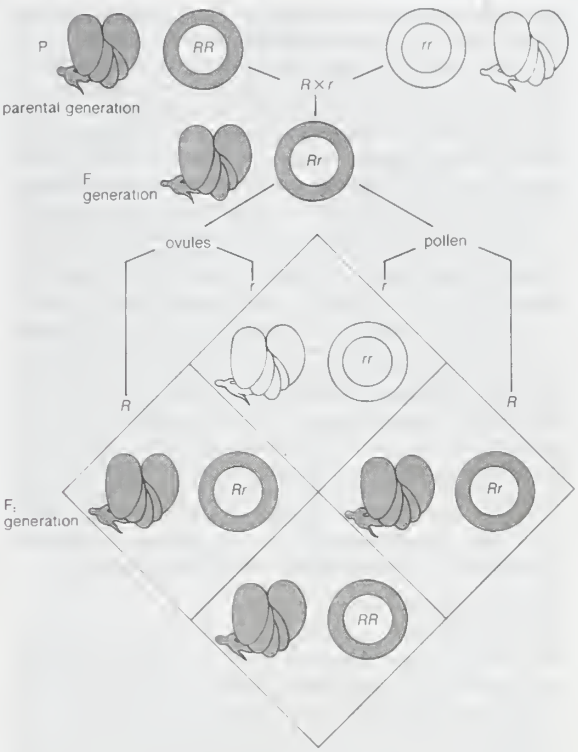

Figure 1: *Mendel's law of segregation.*
Cross of a purple-flowered and a white-flowered strain of peas. *R* stands for the gene for purple flowers and *r* for the gene for white flowers. Dark rings indicate the presence of a dominant gene for purple flowers.
From T. Dobzhansky, *Evolution, Genetics and Man* (1955), John Wiley & Sons, Inc.

First and second laws of Mendel

An example of one of Mendel's experiments will illustrate how the genes are transmitted and in what particular ratios. Let *R* stand for the gene for purple flowers and *r* for the gene for white flowers (dominant genes are conventionally symbolized by capital letters and recessive genes by small letters). Since each pea plant contains a gene endowment half of whose set is derived from the mother and half from the father, each plant has two genes for flower colour. If the two genes are alike, for instance, both having come from white-flowered parents (*rr*), the plant is termed a homozygote (Figure 1). The union of gametes with different genes give a hybrid plant termed a heterozygote (*Rr*). Since the gene *R*, for purple, is dominant over *r*, for white, the F_1 generation hybrids will show purple flowers. They are phenotypically purple, but their genotype contains both *R* and *r* genes, and these alternative (allelic or allelomorphic) genes do not blend or contaminate each other. Mendel inferred that when a heterozygote forms its sex cells, the allelic genes segregate and pass to different gametes. This is expressed in the first law of Mendel, the law of segregation of unit genes. Equal numbers of gametes, ovules, or pollen grains are formed that contain the genes *R* and *r*. Now, if the gametes unite at random, then the F_2 generation should contain about 1/4 white-flowered and 3/4 purple-flowered plants. The white-flowered plants, which must be recessive homozygotes, bear the genotype *rr*. About 1/3 of the plants exhibiting the dominant trait of purple flowers must be homozygotes, *RR*, and 2/3 heterozygotes, *Rr*. The prediction is tested by obtaining a third generation, F_3, from the purple-flowered plants; though phenotypically all purple-flowered, 2/3 of this group of plants reveal the presence of the recessive gene allele, *r*, in their genotype by producing about 1/4 white-flowered plants in the F_3 generation.

Mendel also crossbred varieties of peas that differed in two or more easily distinguishable traits. When a variety with yellow round seed was crossed to a green wrinkled seed variety (Figure 2), the F_1 generation hybrids produced yellow round seed. Evidently yellow (*A*) and round (*B*) are dominant traits, green (*a*) and wrinkled (*b*) are recessive. By allowing the F_1 plants (genotype *AaBb*) to self-pollinate, Mendel obtained an F_2 generation of 315 yellow round, 101 yellow wrinkled, 108 green round, and 32 green wrinkled seeds, a ratio approximately 9 : 3 : 3 : 1. The important point here is that the segregation of the colour (*A–a*) is independent of the segregation of the trait of seed surface (*B–b*). This is expected if the F_1 generation produces equal numbers of four kinds of gametes, carrying the four possible combinations of the parental genes: *AB*, *Ab*, *aB*, and *ab*. Random union of these gametes gives, then, the four phenotypes in a ratio 9 dominant–dominant : 3 recessive–dominant : 3 dominant–recessive : 1 recessive–recessive. Among these four phenotypic classes there must be nine different genotypes, a supposition that can be tested experimentally by raising a third hybrid generation. The predicted genotypes are actually found. Another test is by means of a backcross (or testcross)—the F_1 hybrid (phenotype yellow round seed; genotype *AaBb*) is crossed to a double recessive plant (phenotype green wrinkled seed; genotype *aabb*). If the hybrid gives four kinds of gametes in equal numbers and if all the gametes of the double recessive are alike (*ab*), the predicted progeny of the backcross are yellow round, yellow wrinkled, green round, and green wrinkled seed in a ratio 1 : 1 : 1 : 1. This prediction is realized in experiments. When the varieties crossed differ in three genes, the F_1 hybrid forms 2^3 or eight kinds of gametes (2^n = kinds of gametes, n being the number of genes). The second generation of hybrids, the F_2, has 27 (3^3) genotypically distinct kinds of individuals but only eight different phenotypes. From these results and others Mendel derived his second law, the law of recombination or independent assortment of genes.

UNIVERSALITY OF MENDEL'S LAWS

Although Mendel experimented with varieties of peas, his laws have been shown to apply to the inheritance of many kinds of characters in almost all organisms. In 1902 Mendelian inheritance was demonstrated in poultry and in mice. The following year, albinism became the first human trait shown to be a Mendelian recessive, with pigmented skin the corresponding dominant.

In 1902 and 1909 Sir Archibald Garrod initiated the analysis of inborn errors of metabolism in humans in terms of biochemical genetics. Alkaptonuria, inherited as a recessive, is characterized by excretion in the urine of large amounts of the substance called alkapton, or homogentisic acid, which renders the urine black on exposure to air. In normal (*i.e.*, nonalkaptonuric) persons the homogentisic acid is changed to acetoacetic acid, the reaction being facilitated by an enzyme, homogentisic acid oxidase. Garrod advanced the hypothesis that this enzyme is absent or inactive in homozygous carriers of the defective recessive alkaptonuria gene; hence the homogentisic acid accumulates and is excreted in the urine. Mendelian inheritance of numerous traits in humans has been studied since then (see below *Human genetics*).

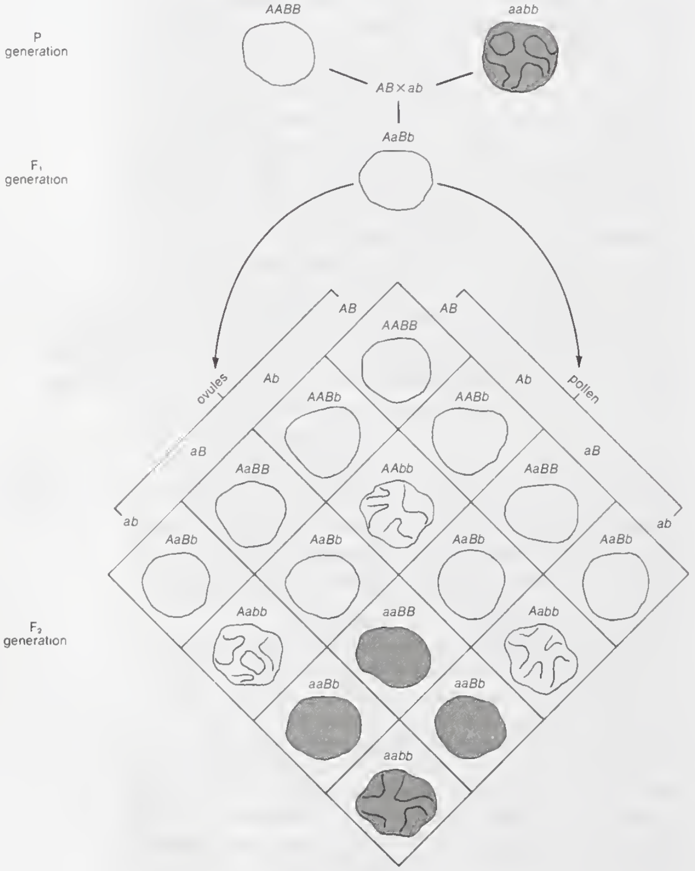

Figure 2: *Mendel's law of independent assortment.*
Cross of peas having yellow and smooth seeds with peas having green and wrinkled seeds. *A* stands for the gene for yellow and *a* for the gene for green; *B* stands for the gene for a smooth surface and *b* for the gene for a wrinkled surface.

In analyzing Mendelian inheritance, it should be borne in mind that an organism is not an aggregate of independent traits, each determined by one gene. A "trait" is really an abstraction, a term of convenience in description. One gene may affect many traits (a condition termed pleiotropic). The gene white in *Drosophila* flies is pleiotropic; it affects the colour of the eyes and of the testicular envelope in the males, the fecundity and the shape of the spermatheca in the females, and the longevity of both sexes. In humans many diseases caused by a single defective gene will have a variety of symptoms, all pleitropic manifestations of the gene.

ALLELIC INTERACTIONS

Dominance relationships. The operation of Mendelian inheritance is frequently more complex than in the case of the traits recorded by Mendel. In the first place, clear-cut dominance and recessiveness are by no means always found. When red- and white-flowered varieties of four-o'clock plants or snapdragons are crossed, for example, the F_1 hybrids have flowers of intermediate pink or rose colour, a situation that seems more explicable by the blending notion of inheritance than by Mendelian concepts. That the inheritance of flower colour is indeed due to Mendelian mechanisms becomes apparent when the F_1 hybrids are allowed to cross, yielding an F_2 generation of red-, pink-, and white-flowered plants in a ratio of 1 red : 2 pink : 1 white. Obviously the hereditary information for the production of red and white flowers had not been blended away in the first hybrid generation, as flowers of these colours were produced in the second generation of hybrids.

Ranges of dominance

The apparent blending in the F_1 generation is explained by the fact that the gene alleles that govern flower colour in four-o'clocks show an incomplete dominance relationship. Suppose, then, that a gene allele R_1 is responsible for red and R_2 for white flowers; the homozygotes R_1R_1 and R_2R_2 are red and white respectively, and the heterozygotes R_1R_2 have pink flowers. A similar pattern of lack of dominance is found in shorthorn cattle. In diverse organisms, dominance ranges from complete (a heterozygote indistinguishable from one of the homozygotes) through incomplete (heterozygotes exactly intermediate) to excessive or over-dominance (a heterozygote more extreme than either homozygote).

Another form of dominance is one in which the heterozygote displays the phenotypic characteristics of both alleles. This is called codominance; an example is seen in the MN blood group system of human beings. MN blood type is governed by two alleles, *M* and *N*. Individuals who are homozygous for the *M* allele have a surface molecule (called the M antigen) on their red blood cells. Similarly, those homozygous for the *N* allele have the N antigen on the red blood cells. Heterozygotes—those with both alleles—carry both antigens.

Multiple alleles. The traits discussed so far all have been governed by the interaction of two possible alleles. Many genes, however, are represented by multiple allelic forms within a population. (One individual, of course, can possess only two of these multiple alleles.) Human blood groups—in this case, the well-known ABO system—again provide an example. The gene that governs ABO blood types has three alleles: I^A, I^B, and I^O. I^A and I^B are codominant, but I^O is recessive. Because of the multiple alleles and their various dominance relationships, there are four phenotypic ABO blood types: type A (genotypes I^AI^A and I^AI^O), type B (genotypes I^BI^B and I^BI^O), type AB (genotype I^AI^B), and type O (genotype I^OI^O).

GENE INTERACTIONS

Many individual traits are affected by more than one gene. For example, the coat colour in many mammals is determined by numerous genes interacting to produce the result. The great variety of colour patterns in cats, dogs, and other domesticated animals is the result of different combinations of complexly interacting genes. The gradual unravelling of their modes of inheritance was one of the active fields of research in the early years of genetics.

Two or more genes may produce similar and cumulative effects on the same trait. In humans, the skin colour difference between so-called blacks and so-called whites is due to several (probably four or more) interacting pairs of genes, each of which increases or decreases the skin pigmentation by a relatively small amount.

Epistatic genes. Some genes mask the expression of other genes just as a fully dominant allele masks the expression of its recessive counterpart. The gene that masks the phenotypic effect of another gene is called the epistatic gene; the gene it subordinates is the hypostatic gene. The gene for albinism (lack of pigment) in humans is an epistatic gene. It is not part of the interacting skin-colour genes described above; rather, its dominant allele is necessary for the development of any skin pigment, and its recessive homozygous state results in the albino condition regardless of how many other pigment genes may be present. Albinism thus occurs in some individuals among people who belong to dark- or intermediate-pigmented groups, such as blacks and American Indians, as well as among whites.

Non-penetrance

The presence of epistatic genes explains much of the variability seen in the expression of such dominantly inherited human diseases as Marfan's syndrome and neurofibromatosis. Because of the effects of an epistatic gene, some individuals who inherit the dominant, disease-causing gene show only partial symptoms of the disease; some, in fact, may show no expression of the disease-causing gene, a condition referred to as nonpenetrance. The individual in whom such a nonpenetrant mutant gene exists will be phenotypically normal but still capable of passing the deleterious gene on to offspring, who may exhibit the full-blown disease.

Examples of epistasis abound in nonhuman organisms. In mice, as in humans, the gene for albinism has two variants: the allele for nonalbino and the allele for albino. The latter allele is unable to synthesize the pigment melanin. Mice, however, have another pair of alleles involved in melanin placement. These are the agouti allele, which produces dark melanization of the hair except for a yellow band at the tip, and the black allele, which produces melanization of the whole hair. If melanin cannot be formed (the situation in the mouse homozygous for the albino gene) neither agouti nor black can be expressed. Hence homozygosity for the albinism gene is epistatic to the agouti/black alleles and prevents their expression.

Complementation. The phenomenon of complementation is another form of interaction between nonallelic genes. For example, there are mutant genes that in the homozygous state produce profound deafness in humans. One would expect that the children of two persons suffering from such hereditary deafness would all be deaf. This is frequently not the case, because the parents' deafness is often caused by different genes. Since the mutant genes are not alleles, the child becomes heterozygous for the two genes and hears normally. In other words, the two mutant genes complement each other in the child. Complementation thus becomes a test for allelism. In the case of congenital deafness cited above, if all the children had been deaf, one could assume that the deafness in each of the parents was due to mutant genes that were alleles. This would be more likely to occur if the parents were genetically related (consanguineous).

Polygenic inheritance. The greatest difficulties of analysis and interpretation are presented by the inheritance of many quantitative or continuously varying traits. Inheritance of this kind produces variations in degree rather than in kind, in contrast to the inheritance of discontinuous traits resulting from single genes of major effect (see above). The yield of milk in different breeds of cattle, egg-laying capacity in poultry, and stature, shape of the head, blood pressure, and intelligence in humans range in continuous series from one extreme to the other and are significantly dependent on environmental conditions. Crosses of two varieties differing in such characters usually give F_1 hybrids intermediate between the parents. At first sight, this situation suggests a blending inheritance through "blood" rather than Mendelian inheritance; in fact, it was probably observations of this kind of inheritance that suggested the folk idea of "blood theory."

Mendelian segregation in polygenes

It has, however, been shown that these characters are polygenic—*i.e.*, determined by several or many genes, each taken separately producing only a slight effect on the phenotype, as small as or smaller than that caused by environmental influences on the same characters. That Mendelian segregation does take place with polygenes, as with the genes having major effects (sometimes called oligogenes), is shown by the variation among F_2 and further generation hybrids being usually much greater than that in the F_1 generation. By selecting among the segregating progenies the desired variants, for example, individuals or families with the greatest yield, the best size, or a desirable behaviour, it is possible to produce new breeds or varieties sometimes exceeding the parental forms. Hybridization and selection are consequently potent methods that can be used for improvement of agricultural plants and animals.

Polygenic inheritance also applies to many of the birth defects (congenital malformations) seen in humans. Although expression of the defect itself may be discontinuous (as in clubfoot, for example), susceptibility to the trait is continuously variable and follows the rules of polygenic inheritance. When a developmental threshold produced by a polygenically inherited susceptibility and a variety of environmental factors is exceeded, the birth defect results (see below *Genetics and human disease*).

Heredity and environment

PREFORMISM AND EPIGENESIS

The homunculus of early microscopists

A notion that was widespread among pioneer biologists in the 18th century was that the fetus, and hence the adult organism that develops from it, is preformed in the sex cells. Some early microscopists even imagined that they saw a tiny "homunculus," a diminutive human figure, encased in the human spermatozoon. The development of the individual from the sex cells appeared deceptively simple—it was merely increase in size and growth of what was already present in the sex cells. The antithesis of the early preformation theories were theories of epigenesis, which claimed that the sex cells were structureless jelly and contained nothing at all in the way of rudiments of future organisms. The naive early versions of preformation and epigenesis had to be given up when embryologists showed that the embryo develops by a series of complex but orderly and gradual transformations (see GROWTH AND DEVELOPMENT, BIOLOGICAL: *Animal development*). Darwin's "Provisional Hypothesis of Pangenesis" was distinctly preformistic; Weismann's theory of determinants in the germ plasm as well as the early ideas about the relations between genes and traits also tended toward preformism.

Heredity has been defined as a process that results in the progeny's resembling their parents. A further qualification of this definition states that what is inherited is a potential that expresses itself only after interacting with and being modified by environmental factors. In short, all phenotypic expressions have both hereditary and environmental components, the amount of each varying for different traits. Thus, a trait that is primarily hereditary (*e.g.*, skin colour in humans) may be modified by environmental influences (*e.g.*, suntanning). And conversely, a trait sensitive to environmental modifications (*e.g.*, weight in humans) is also genetically conditioned. Organic development is preformistic insofar as a fertilized egg cell contains a genotype that conditions the events that may occur and is epigenetic insofar as a given genotype allows a variety of possible outcomes. These considerations should dispel the reluctance felt by many people to accept the fact that mental as well as physiological and physical traits in humans are genetically conditioned. Genetic conditioning does not mean that heredity is the "dice of destiny." At least in principle, but not invariably in practice, the development of a trait may be manipulated by changes in the environment.

HERITABILITY

Although hereditary diseases and malformations are, unfortunately, by no means uncommon in the aggregate, no one of them occurs very frequently. The characteristics by which one person is distinguished from another, such as facial features, stature, shape of the head, skin, eye and hair colours, and voice, are not usually inherited in a clear-cut Mendelian manner, as are some hereditary malformations and diseases. This is not as strange as it may seem. The kinds of gene changes, or mutations, that produce morphological or physiological effects drastic enough to be clearly set apart from the more usual phenotypes are likely to cause diseases or malformations just because they are so drastic.

Variations caused by polygenes

The variations that occur among healthy persons are, as a general rule, caused by polygenes with individually small effects. The same is true of individual differences among members of various animal and plant species. Even brown-blue eye colour in humans, which in many families behaves as if caused by two forms of a single gene (brown being dominant and blue recessive), is often blurred by minor gene modifiers of the pigmentation. Some apparently blue-eyed persons actually carry the gene for the brown eye colour, but several additional modifier genes decrease the amount of brown pigment in the iris. This type of genetic process can influence susceptibility to many diseases (*e.g.*, diabetes) or birth defects (for example, cleft lip—with or without cleft palate).

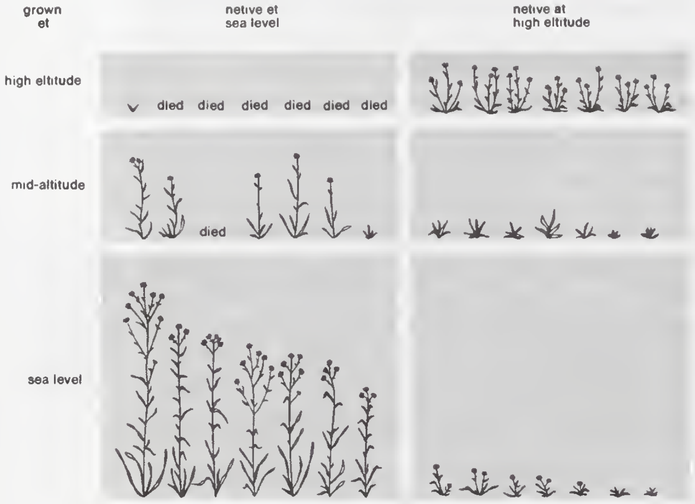

Figure 3: *Genotype–environment interaction.*
Yarrow plants native in different habitats divided and replanted at different elevations.

The question geneticists must often attempt to answer is how much of the observed diversity between persons, or between individuals of any species, is due to hereditary, or genotypic, variations and how much of it is due to environmental influences. Applied to human beings, this is sometimes referred to as the nature–nurture problem. (See *Human genetics* below, for a discussion of this aspect of the subject.) With animals or plants the problem is evidently more easily soluble than it is with people. Two complementary approaches are possible. First, individual organisms, or their progenies, are raised in environments as uniform as can be provided, with food, temperature, light, humidity, etc., carefully controlled. The differences that persist between such individuals or progenies probably reflect genotypic differences. Second, individuals with similar or identical genotypes are placed in different environments. The phenotypic differences then may be ascribed to environmental induction. Experiments combining both approaches have been carried out on several species of plants that grow naturally at different altitudes, from sea level to the alpine zone of the Sierra Nevada of California. Young yarrow plants (*Achillea*) were cut in three parts and the cuttings replanted in experimental gardens at sea level, at midaltitude (4,800 feet [1,460 metres]), and at a high altitude (10,000 feet [3,050 metres]) (Figure 3). The plants native at sea level grow best in their native habitat, grow less well at midaltitudes, and die at high altitudes. On the other hand, the alpine race survives and develops better at the high-altitude transplant station than it does at lower altitudes.

Table 2: Some Heritability Estimates

trait	correlation
Cattle	
Butterfat percentage	0.6
Milk yield	0.3
Pigs	
Body length	0.5
Weight at 180 days	0.3
Litter size	0.15
Poultry	
Egg weight	0.6
Annual egg production	0.3
Body weight	0.2
Viability	0.1
Drosophila melanogaster	
Abdominal bristle number	0.5
Body size	0.4
Ovary size	0.3
Egg production	0.2

Source: D.S. Falconer, *Introduction to Quantitative Genetics*, 1960.

With organisms that cannot survive being cut in pieces and placed in controlled environments, a partitioning of the observed variability into genetic and environmental components may be attempted by other methods. Suppose that in a certain population individuals vary in stature, weight, or some other trait. These characters can be measured in many pairs of parents and in their progenies raised under different environmental conditions. If the variation is due entirely to environment and not at all to heredity, then the expression of the character in the parents and in the offspring will show no correlation at all (heritability = zero). On the other hand, if the environment is unimportant and the character is uncomplicated by dominance, then the means of this character in the progenies will be the same as the means of the parents; with differences in the expression in females and in males taken into account, the heritability will equal unity. In reality, most heritabilities are found to lie between zero and one. Some examples of heritabilities of traits in different animals are given in Table 2.

Heritability estimates

It is important to understand clearly the meaning of heritability estimates. They show that, given the range of the environments in which the experimental animals lived, one could predict the average body sizes in the progenies of pigs better than one could predict the average numbers of piglets in a litter. The heritability is, however, not an inherent or unchangeable property of each character. If one could make the environments more uniform, the heritabilities would rise, and with more diversified environments they would decrease. Similarly, in populations that are more variable genetically the heritabilities increase, and in genetically uniform ones they decrease. In humans the situation is even more complex because the environments of the parents and of their children are in many ways interdependent. Suppose, for example, that one wishes to study the heritability of stature, weight, or susceptibility to tuberculosis. The stature, weight, and liability to contract tuberculosis depend to some extent on the quality of nutrition and generally on the economic well-being of the family. If no allowance is made for this fact, the heritability estimates arrived at may be spurious; such heritabilities have indeed been claimed for such things as administrative, legal, or military talents and for social eminence in general. It is evident that having socially eminent parents makes it easier for the children to achieve such eminence also; biological heredity may have little or nothing to do with this.

A general conclusion from the evidence now available may be stated as follows: diversity in almost any trait, physical, physiological, or behavioral, is due in part to genetic and in part to environmental variables. In any array of environments, individuals with more nearly similar genetic endowments are likely to show a greater average resemblance than the carriers of more diverse genetic endowments. It is, however, also true that in different environments the carriers of similar genetic endowments may grow, develop, and behave in different ways.

THE PHYSICAL BASIS OF HEREDITY

When Mendel formulated his laws of heredity, he postulated a particulate nature for the units of inheritance. What exactly these particles were he did not know. Today scientists understand not only the physical location of hereditary units (*i.e.,* the genes) but their molecular composition as well. The unravelling of the physical basis of heredity makes up one of the most fascinating chapters in the history of biology.

Chromosomes and genes

As has been discussed, each individual in a sexually reproducing species inherits two alleles for each gene, one from each parent. Furthermore, when such an individual forms sex cells, each of the resultant gametes receives one member of each allelic pair. The formation of gametes occurs through a process of cell division called meiosis; it is also known as reduction division, because the amount of hereditary material present in the gametes has been reduced by half. When gametes unite in fertilization, the double dose of hereditary material is restored, and a new individual is created. This individual, consisting at first of only one cell, grows via mitosis, a process of repeated cell divisions. Mitosis differs from meiosis in that each daughter cell receives a full copy of all the hereditary material found in the parent cell.

It is apparent that the genes must physically reside in cellular structures that meet two criteria. First, these structures must be replicated and passed on to each generation of daughter cells during mitosis. Second, they must be organized into homologous pairs, one member of which is parcelled out to each gamete formed during meiosis.

Discovery of chromosomes

As early as 1848, biologists had observed that cell nuclei resolve themselves into small, rodlike bodies during mitosis; later these structures were found to absorb certain dyes and so came to be called chromosomes (coloured bodies). During the early years of the 20th century, cellular studies using ordinary light microscopes clarified the behaviour of chromosomes during mitosis and meiosis, which led to the conclusion that chromosomes are the carriers of genes.

THE BEHAVIOUR OF CHROMOSOMES DURING CELL DIVISION

During mitosis. When the chromosomes condense during cell division, they have already undergone replication. Each chromosome thus consists of two identical replicas, called chromatids, joined at a point called the centromere (see Figure 4). During mitosis the sister chromatids separate, one going to each daughter cell. Chromosomes thus meet the first criterion for being the repository of genes: they are replicated and a full copy is passed to each daughter cell during mitosis.

During meiosis. It was the behaviour of chromosomes during meiosis, however, that provided the strongest evidence for their being the carriers of genes. In 1902 the American Walter S. Sutton reported on his observations of the action of chromosomes during sperm formation in grasshoppers. Sutton had observed that during meiosis, each chromosome (consisting of two chromatids) becomes paired with another, physically similar chromosome. These homologous chromosomes separate during meiosis, with one member of each pair going to a different cell. Assuming that one member of each homologous pair was of maternal origin and the other was paternally derived, here was an event that fulfilled the behaviour of genes postulated in Mendel's first law.

It is now known that the number of chromosomes within the nucleus is usually constant in all individuals of a given species—for example, 46 in humans; 40 in the house mouse; 8 in the vinegar, or fruit, fly (*Drosophila melanogaster*); 20 in corn (maize); 24 in the tomato; 48 in the potato. In sexually reproducing organisms, this number is called the diploid number of chromosomes, as it represents the double dose of chromosomes received from two parents. The nucleus of a gamete, however, contains half this number of chromosomes, or the haploid number. Thus a human gamete contains 23 chromosomes, while a *Drosophila* gamete contains four. Meiosis produces the haploid gametes.

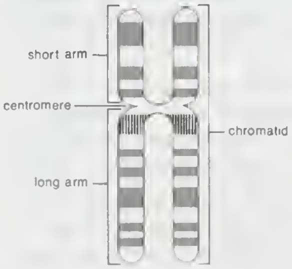

Figure 4: *Structure of the mitotic chromosome.*
Before mitosis, each chromosome has replicated so that it consists of two identical chromatids, which are joined at the centromere. The light and dark bands are produced by Giemsa-trypsin staining; the light bands are the primary sites of unique DNA, and the dark bands are primarily repetitive DNA. The chromatids separate by division through the centromere during mitosis; this division yields two identical chromosomes, one of which goes to each of the two daughter cells produced by mitosis.

The essential features of meiosis are shown in Figure 5. For the sake of simplicity, the diploid parent cell is shown to contain a single pair of homologous chromosomes, one member of which is represented black (from the father) and the other white (from the mother). At the leptotene stage the chromosomes appear as long, thin threads. At pachytene they pair, the corresponding portions of the two chromosomes lying side-by-side. The chromosomes then duplicate and contract into paired chromatids. At this stage the pair of chromosomes is known as a tetrad, as it consists of four chromatids. Also at this stage an extremely important event occurs: portions of the maternal and paternal chromosomes are exchanged. This exchange process, called crossing over, results in chromatids that include both paternal and maternal genes and consequently introduces new genetic combinations. The first meiotic, or reduction, division separates the chromosomal tetrads, with the paternal chromosome (whose chromatids now contain some maternal genes) going to one cell, and the maternal chromosome (containing some paternal genes) going to another cell. During the second meiotic division the chromatids separate. The original diploid cell has thus given rise to four haploid gametes (only two of which are shown in Figure 5). Not only has a reduction in chromosome number occurred, but the resulting single member of each homologous chromosome pair may be a new combination (through crossing over) of genes present in the original diploid cell.

Suppose that the white chromosome shown in Figure 5 carries the gene for albinism, and the black chromosome carries the gene for dark pigmentation. It is evident that

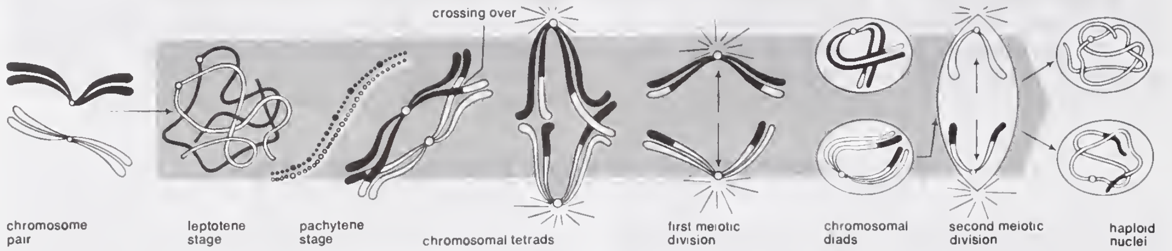

Figure 5: Behaviour of chromosomes at meiosis (see text).
From T. Dobzhansky, *Evolution, Genetics and Man*, (1955), John Wiley & Sons, Inc

the two gene alleles will undergo segregation at meiosis, and that one-half of the gametes formed will contain the albino gene and the other half the pigmentation gene. Following the scheme in Figure 1, random combination of the gametes with the albino and the pigmentation gene will give two kinds of homozygotes and one kind of heterozygote in a ratio 1 : 1 : 2. Mendel's law of segregation is, thus, the outcome of chromosome behaviour at meiosis. The same is true of the second law, that of the independent assortment.

Consider the inheritance of two pairs of genes, such as Mendel's factors for seed coloration and seed surface in peas; these genes are located on different pairs of chromosomes. Since maternal and paternal members of different chromosome pairs are assorted independently, so are the genes they contain. This explains, in part, the genetic variety seen among the progeny of the same pair of parents. As stated above, humans have 46 chromosomes in the body cells and in the cells (oogonia and spermatogonia) from which the sex cells arise. At meiosis these 46 chromosomes form 23 pairs, one of the chromosomes of each pair being of maternal and the other of paternal origin. Independent assortment is, then, capable of producing 2^{23}, or 8,388,608, kinds of sex cells with different combinations of the grandmaternal and grandpaternal chromosomes. Since each parent has the potentiality of producing 2^{23} kinds of sex cells, the total number of possible combinations of the grandparental chromosomes is $2^{23} \times 2^{23} = 2^{46}$. The population of the world is now more than 4,000,000,000 persons, or approximately 2^{32} persons. It is, therefore, certain that only a tiny fraction of the potentially possible chromosome and gene combinations can ever be realized. Yet even 2^{46} is an underestimate of the variety potentially possible. The grandmaternal and grandpaternal members of the chromosome pairs are not indivisible units. Each chromosome carries many genes, and the chromosome pairs exchange segments at meiosis through the process of crossing over. This is evidence that the genes rather than the chromosomes are the units of Mendelian segregation.

LINKAGE OF TRAITS

Simple linkage. As pointed out above, the random assortment of the maternal and paternal chromosomes at meiosis is the physical basis of the independent assortment of genes and of the traits they control. This is the basis of the second law of Mendel. The number of the genes in a sex cell is, however, much greater than that of the chromosomes. When two or more genes are borne on the same chromosome these genes may not be assorted independently; such genes are said to be linked. When a *Drosophila* fly homozygous for a normal gray body and long wings is crossed with one having a black body and vestigial wings, the F_1 consists of hybrid gray, long-winged flies (Figure 6). Gray body (B) is evidently dominant over black body (b), and long wing (V) is dominant over vestigial wing (v). Now consider a backcross of the heterozygous F_1 males to double recessive black-vestigial females ($bbvv$). Independent assortment would be expected to give in the progeny of the backcross the following: 1 gray-long : 1 gray-vestigial : 1 black-long : 1 black-vestigial. In reality only gray-long and black-vestigial flies are produced, in approximately equal numbers; the genes remain linked in the same combinations in which they were found in the parents. The backcross of the heterozygous F_1 females to double recessive males gives a somewhat different result: 42 percent each of gray-long and black-vestigial flies and about 8 percent each of black-long and gray-vestigial classes. In sum, 84 percent of the progeny have the parental combinations of traits, and 16 percent have the traits recombined. The interpretation of these results given in 1911 by the U.S. geneticist Thomas Hunt Morgan laid the foundations of the theory of linear arrangement of genes in the chromosomes.

Linked genes in *Drosophila*

Traits that exhibit linkage in experimental crosses (such as black body and vestigial wings) are determined by genes located in the same chromosome. As more and more genes became known in *Drosophila melanogaster,* they fell neatly into four linkage groups corresponding to the four pairs of the chromosomes this species possesses. One linkage group consists of sex-linked genes, located in the X chromosome (see below); of the three remaining linkage groups, two have many more genes than the remaining one; this corresponds to the presence of two pairs of large

Figure 6: Linkage of genes as illustrated by body colour and wing length in *Drosophila* flies (see text).

chromosomes and one pair of tiny dotlike chromosomes. The numbers of linkage groups in other organisms are equal to or smaller than the numbers of the chromosomes in the sex cells; *e.g.,* 10 linkage groups and 10 chromosomes in corn, 19 linkage groups and 20 chromosomes in the house mouse, 23 linkage groups and 23 chromosomes in human beings.

As seen above, the linkage of the genes black and vestigial in *Drosophila* is complete in heterozygous males, while in the progeny of females there appear about 17 percent of recombination classes. With very rare exceptions, the linkage of all genes belonging to the same linkage group is complete in *Drosophila* males, while in the females different pairs of genes exhibit all degrees of linkage from complete (no recombination) to 50 percent (random assortment). Morgan's inference was that the degree of linkage depends on physical distance between the genes in the chromosome: the closer the genes the tighter the linkage, and vice versa. Furthermore, Morgan perceived that the chiasmata, crosses that occur in meiotic chromosomes, indicate the mechanism underlying the phenomena of linkage and crossing over. As shown schematically in Figure 5, the maternal and paternal chromosomes (represented black and white) cross over and exchange segments, so that a chromosome emerging from the process of meiosis may consist of some maternal (grandmaternal) and some paternal (grandpaternal) sections. If the probability of crossing-over taking place is uniform along the length of a chromosome (which was later shown to be not quite true), then genes close together will be recombined less frequently than those far apart.

Chromosome maps

This realization opened an opportunity to map the arrangement of the genes and the estimated distances between them in the chromosome by studying the frequencies of recombination of various traits in the progenies of hybrids. In other words, the linkage maps of the chromosomes are really summaries of many statistical observations on the outcomes of hybridization experiments. In principle at least, such maps could be prepared even if the chromosomes, not to speak of the chiasmata at meiosis, were unknown. But an interesting and relevant fact is that in *Drosophila* males the linkage of the genes in the same chromosome is complete, and observations under the microscope show that no chiasmata are formed in the chromosomes at meiosis. In most organisms, including humans, chiasmata are seen in the meiotic chromosomes in both sexes, and observations on hybrid progenies show that recombination of linked genes occurs also in both sexes.

The most detailed chromosome maps have been constructed for Morgan's classical material—*Drosophila melanogaster.* Less detailed chromosome maps exist for some other species of *Drosophila* flies, for corn, the house mouse, the bread mold *Neurospora crassa,* and for some bacteria and bacteriophages (viruses that infect bacteria). Until quite late in the 20th century, the mapping of human chromosomes presented a particularly difficult problem: experimental crosses could not be arranged in humans and only a few linkages could be determined by analysis of unique family histories. However, the development of somatic cell genetics (see below) provided new understanding of human genetic processes and new methods of research. Using the techniques of somatic cell genetics, hundreds of genes have been mapped to the human chromosomes and many linkages established.

Sex linkage. The male of many animals has one chromosome pair, the sex chromosomes, consisting of unequal members called X and Y. At meiosis the X and Y chromosomes first pair, then disjoin and pass to different cells. One-half of the gametes (spermatozoa) formed contain the X and the other half the Y chromosome. The female has two X chromosomes, and all egg cells normally carry a single X. The eggs fertilized by X-bearing spermatozoa give females (XX), and those fertilized by Y-bearing spermatozoa give males (XY).

The genes located in the X chromosomes exhibit what is known as sex-linkage or crisscross inheritance. This is due to a crucial difference between the paired sex chromosomes and the other pairs of chromosomes (called autosomes). The members of the autosome pairs are truly homologous; that is, each member of a pair contains a full complement of the same genes (albeit, perhaps, in different allelic forms). The sex chromosomes, on the other hand, do not constitute a homologous pair, as the X chromosome is much larger and carries far more genes than does the Y. Consequently, many recessive alleles carried on the X chromosome of a male will be expressed just as if they were dominant, for the Y chromosome carries no genes to counteract them. The classic case of sex-linked inheritance, described by Morgan in 1910, is that of the white eyes in *Drosophila* (Figure 7). White-eyed females crossed to males with the normal red eye colour produce red-eyed daughters and white-eyed sons in the F_1 generation and equal numbers of white-eyed and red-eyed females and males in the F_2 generation. The cross of red-eyed females to white-eyed males gives a different result: both sexes are red eyed in F_1, the females in the F_2 generation are red eyed, half of the males are red eyed, and the other half white eyed. As interpreted by Morgan, the gene that determines the red or white eyes is borne on the X chromosome, and the allele for red eye is dominant over that for white eye. Since a male receives its single X chromosome from his mother, all sons of white-eyed females also have white eyes. A female inherits one X chromosome from her mother and the other X from her father. Red-eyed females may have genes for red eyes in both of their X chromosomes (homozygotes) or may have one X with the gene for red and the other for white (heterozygotes). In the progeny of heterozygous females one half of the sons will receive the X chromosome with the gene for white and will have white eyes, and the other half will receive the X with the gene for red eyes. The daughters of the heterozygous females crossed with white-eyed males will have either two X chromosomes with the gene for white and hence white eyes or will have one X with white and the other X with the gene for red eyes and will be red-eyed heterozygotes.

Sex-linked genes

In humans, the red-green colour blindness and hemophilia are among many traits showing sex-linked inheritance and consequently are due to genes borne in the X chromosome. Sex-linked human diseases are discussed in detail below (see *Diseases caused by single-factor [Mendelian] inheritance*).

From *Life: An Introduction to Biology* by Simpson, Pittendrigh and Tiffany, Copyright © 1957 by Harcourt Brace Jovanovich Inc. and reproduced with their permission

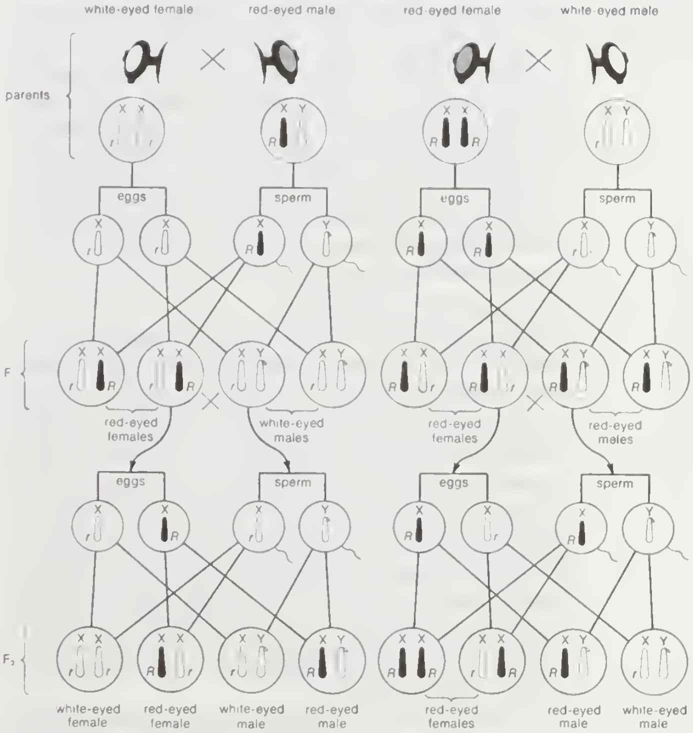

Figure 7: Sex-linked inheritance of white eyes in *Drosophila* flies (see text).

In some animals—birds, butterflies and moths, some fish, and at least some amphibians and reptiles—the chromosomal mechanism of sex determination is a mirror image of that described above. The male has two X chromosomes and the female an X and Y chromosome. Here the spermatozoa all have an X chromosome; the eggs are of two kinds, some with X and others with Y chromosomes, usually in equal numbers. The sex of the offspring is then determined by the egg rather than by the spermatozoon. Sex-linked inheritance is altered correspondingly. A male homozygous for a sex-linked recessive trait, crossed to a female with the dominant one, gives in the F_1 generation daughters with the recessive trait and heterozygous sons with the corresponding dominant trait. The F_2 generation has recessive and dominant females and males in equal numbers. A male with a dominant trait crossed to a female with a recessive trait gives uniformly dominant F_1 and a segregation in a ratio of 2 dominant males : 1 dominant female : 1 recessive female.

Observations on pedigrees or experimental crosses show that certain traits exhibit sex-linked inheritance; the behaviour of the X chromosomes at meiosis is such that the genes they carry may be expected to exhibit sex-linkage. This evidence still failed to convince some skeptics that the genes for the sex-linked traits were in fact borne in certain chromosomes seen under the microscope. An elegant experimental proof was furnished in 1916 by the U.S. geneticist Calvin Blackman Bridges. As stated above, white-eyed *Drosophila* females crossed to red-eyed males usually produce red-eyed female and white-eyed male progeny. Among thousands of such "regular" offspring there are occasionally found exceptional white-eyed females and red-eyed males. Bridges constructed the following working hypothesis. Suppose that during meiosis in the female, gametogenesis occasionally goes wrong, and the two X chromosomes fail to disjoin (Figure 8). Exceptional eggs will then be produced carrying two X chromosomes and eggs carrying none. An egg with two X chromosomes coming from a white-eyed female fertilized by a spermatozoon with a Y chromosome will give an exceptional white-eyed female. An egg with no X chromosome fertilized by a spermatozoon with an X chromosome derived from a red-eyed father will yield an exceptional red-eyed male. This hypothesis can be rigorously tested. The exceptional white-eyed females should have not only the two X chromosomes but also a Y chromosome, which normal females do not have. The exceptional males should, on the other hand, lack a Y chromosome, which normal males do have. Both predictions were verified by examination under a microscope of the chromosomes of exceptional females and males. The hypothesis also predicts that exceptional eggs with two X chromosomes fertilized by X-bearing spermatozoa must give individuals with three X chromosomes; such individuals were later identified by Bridges as poorly viable "superfemales." Exceptional eggs with no Xs, fertilized by Y-bearing spermatozoa, will give zygotes without X chromosomes; such zygotes die in early stages of development.

Verification of sex-linked inheritance

CHROMOSOMAL ABERRATIONS

Two general types of chromosomal abnormalities occur: numerical and structural. Numerical aberrations result from nondisjunction; that is, from the failure of a pair of homologous chromosomes or a pair of sister chromatids to separate during cell division. As described above, when nondisjunction occurs during meiosis two types of germ cells will be formed, those with an extra chromosome and those with a missing chromosome. If one of the former combines with a normal germ cell, the new fertilized egg and all the cells of the individual it produces will have an extra chromosome (trisomy); if one of the latter combines with a normal germ cell, the fertilized egg will lack a chromosome (monosomy). If nondisjunction occurs after fertilization, the resulting individual will be a mosaic and will have two or more populations of cells differing in chromosomal number.

From *Life: An Introduction to Biology* by Simpson, Pittendrigh and Tiffany, Copyright © 1957 by Harcourt Brace Jovanovich, Inc., and reproduced with their permission

Structural aberrations result from chromosome breakages. Chromosomes may break spontaneously, or they may be broken by such environmental agents as radiation, viruses, and toxic chemicals. If a chromosomal segment breaks off and is not rejoined, it may be lost entirely in the gametes or somatic cells that derive, respectively, from meiosis or mitosis. Such a loss is called a deletion. In other instances, the broken-off segment may rejoin its chromosome but with its position inverted 180°; such inversions can alter the sequence of genetic information along the chromosome. In other cases, the segment may become translocated; that is, it may become attached to a different chromosome. When such a rearrangement occurs between two nonhomologous chromosomes without net loss or gain of chromosomal material, it is called a balanced, or reciprocal, translocation, and the individual is not phenotypically affected. If, however, the translocation results in the deletion or duplication of chromosomal material in gametes or somatic cells, the effects may be severe. This is especially true in the event of gametes that carry autosomal translocations; such chromosomal aberrations often produce lethal phenotypic effects.

(T.D./Ar.R.)

Molecular genetics

The data accumulated by the geneticists of the early 20th century provided compelling evidence that chromosomes are the carriers of the genes. But the nature of the genes themselves remained a mystery, as did the mechanism by which they exert their influence. Molecular genetics—the study of the molecular structure of the genes and the methods by which genes control the activities of the cell—provided the answers to these fundamental questions.

Much of the information in molecular genetics has come from the study of microorganisms, particularly the bacterium *Escherichia coli* (a common inhabitant of the human intestine) and its interactions with various bacteriophages. Bacteria have many features that make them especially useful in genetics research. For example, they have an extremely short life cycle, so that many generations can be raised in a brief period of time. Equally important, bacteria have only one basic function—to reproduce. Consequently, their genome is relatively limited. Furthermore, unlike most higher organisms, bacteria are not diploid, so their genome does not include two alleles of each gene. This makes it easy to identify a bacterium that carries a mutant gene, as the effects of the mutation cannot be masked by a normal allele. Although they are not diploid, bacteria can and do occasionally exchange genetic information through a variety of processes. This genetic exchange feature has been important in certain lines of molecular genetics research. Viruses also have advantages in genetics studies. Although they can reproduce only in a living cell, they have the simplest form of genetic material and evidence both genetically controlled properties and the ability to mutate.

Because of the relative simplicity of gene action in microorganisms, their study profoundly influenced early understanding of molecular genetics. Studies of the genetics of microorganisms involves the production of specific gene mutations and the examination of their biochemical effects. These studies have permitted the delineation of the metabolic pathways that produced the mutation in the experimental microorganism, as well as the isolation of the large molecules that contain the genetic information.

Although there are virtues to bacteria as experimental subjects in genetics research, it should be pointed out that bacteria differ from higher organisms in some rather fundamental ways. In fact, bacteria (along with the cyanophytes, or blue-green algae) are sufficiently distinct as to constitute their own kingdom, the Monera. Monerans, unlike protists, plants, and animals, are procaryotic. This means that their cells lack a true, membrane-enclosed nucleus, the cellular structure that contains the chromosomes in all other organisms (which are known as eucaryotes). Perhaps more important in a discussion of genetics, the bacterial chromosome differs in composition from the chromosomes of eucaryotes, so much so that some authorities prefer to avoid the term chromosome in describing the genetic material of bacteria. In eucaryotes, the chromosomes consist primarily of deoxyribonucleic acid (DNA) and a variety of proteins. Bacterial chromosomes have little protein, which proved to be an important clue in determining the chemical nature of the hereditary substance. Finally, all the progeny of a bacterium are identical, whereas the cell progeny of the fertilized egg of a complex, multicellular organism gives rise to many different tissues and organs whose component cells display specific patterns of different gene activities. This latter process is called differentiation.

HEREDITY AND NUCLEIC ACIDS

One of the most impressive and spectacular advances of biology in the 20th century was the discovery of the nature of the genetic material. The way information is encoded in the genes has been clarified and much has been learned about the mechanisms that translate this information into the developmental processes of the organism.

In 1869 a substance containing nitrogen and phosphorus was extracted from cell nuclei. It was originally called nuclein, but is now known as DNA. DNA is the chemical component of the chromosomes that is chiefly responsible for their staining properties in microscopic preparations. As stated above, the chromosomes of eucaryotes contain a variety of proteins in addition to DNA. The question naturally arose whether the nucleic acids or the proteins, or both together, are the carriers of the genetic information, which makes the genes of the same organism and of different organisms specifically different. Until the early 1950s most biologists were inclined to believe that the proteins were the chief carriers of heredity. Nucleic acids contain only four different unitary building blocks, but proteins are made up of 20 different amino acids. Proteins therefore appeared to have a greater diversity of structure, and the diversity of the genes seemed at first likely to rest on the diversity of the proteins.

The evidence that DNA acts as the carrier of the genetic information was first firmly demonstrated by exquisitely simple microbiological studies. One of these seminal studies was performed by the U.S. geneticist Oswald T. Avery and his coworkers in 1944. The background of Avery's study goes back to 1928, to research conducted by Fred Griffith of England, a bacteriologist who was studying the virulence of pneumococci, the bacteria that cause bacterial pneumonia. Griffith knew that the virulence of pneumococci—that is, their ability to cause infection—depends on the presence of an envelope composed of polysaccharides (sugar subunits) surrounding the bacterial cells. When grown on laboratory culture mediums, virulent pneumococci produced large colonies with a smooth, glistening surface.Bacteria from such cultures caused infection in mice. After many transfers to fresh laboratory mediums, however, some of the bacteria lost their polysaccharide envelopes and their ability to infect mice; correlated with these changes was the change to small colonies with rough outlines. The smooth and the rough variants were designated S and R, respectively. Griffith found that mice inoculated with either the living R pneumococci or with heat-killed S pneumococci remained free of infection, but mice inoculated with a mixture of living R and heat-killed S bacteria became infected. He further discovered that living S pneumococcal cultures could be obtained from such animals, proof that the virulent S cells were reconstituted from the mixture inoculated. Some material derived from the dead S bacteria had induced the transformation of R into S strains. Avery and his coworkers showed that the "transforming factor" which conferred the characteristic of virulence upon nonvirulent pneumococci consisted of DNA, which had been transferred from dead virulent pneumococci into living nonvirulent pneumococci. That this newly acquired characteristic was due to a specific genetic activity was demonstrated by its persistence in all of the offspring of the transformed bacteria.

Effect of the DNA of dead bacteria on living bacteria

The DNA of the dead cells evidently accomplishes the transformation of the living ones by penetrating the wall of the living cell. Once a section of the transforming DNA strand is inside the recipient cell, there apparently occurs a pairing between homologous regions of the bacterial chromosome and the transforming DNA. There must follow breakage and subsequent reunion of the bacterial chromosome and the transforming DNA. Thus a portion of the transforming DNA becomes integrated into the bacterial chromosome. If this model is valid, one would expect that genes located near each other on the transforming DNA would appear together more often in a transformed cell than will genes relatively far apart in the transforming DNA. This expectation has been fulfilled, and the principle has been utilized as a means of mapping the donor-cell chromosome. In further research the principles involved in transformation have been confirmed in a more efficient process involving mammalian cells in culture. By means of a process called transfection, defined pieces of DNA enter the cell nucleus and are incorporated into the DNA, thus replacing a particular genetic deficiency formerly exhibited by the cell.

Transfection

In the early 1950s Alfred D. Hershey and Martha Chase obtained evidence confirming that DNA serves as the physical basis of heredity. In their experiment, Hershey and Chase used a bacteriophage that infects *Escherichia coli*, a colon bacteria. This bacteriophage (or simply phage) is an ultramicroscopic tadpole-shaped particle, with a hexagonal head, a cylindrical tail, and an end plate with six tail fibres (see VIRUSES). The entire outer surface consists of protein, but within the interior space of the head there is DNA. When a phage infects *E. coli*, it injects its own genetic material into the bacterial cell. The phage genes then subvert the metabolic machinery of the bacterium, causing the host cell to make phage DNA and phage protein. When a new generation of phage particle is ready inside the host, they destroy (lyse) the bacterium. This lysis releases the new phage particles into the medium, where they can attack other bacterial cells.

Hershey and Chase prepared two populations of phage particles. In one population the phage protein was labelled with a radioactive isotope; in the other the phage DNA was radioactively labelled. After allowing both populations to attack *E. coli* cells, the experimenters analyzed the exterior and the interior of the infected cells for the presence of radioactive material. They discovered that the phage protein had remained outside of the host cell, while the phage DNA had been injected into the bacterium. This ingenious research demonstrated that the genetic material of the phage consists of DNA rather than protein.

The evidence is now overwhelming that the basic material constituting the gene is fundamentally the same in all organisms: it consists of chainlike molecules of nucleic acids—DNA in most organisms and RNA (ribonucleic acid, a close chemical relative of DNA) in certain viruses. As will be discussed later, the gene no longer stands for a discrete unit of heredity of definite and invariable length but is thought of as an operational entity whose properties are more fluid and depend upon the mode of measurement.

STRUCTURE OF NUCLEIC ACIDS

The remarkable properties of the nucleic acids, which qualify these substances to serve as the carriers of genetic information, have claimed the attention of many investigators. The groundwork was laid by pioneer biochemists who found that nucleic acids are long chainlike molecules, the backbones of which consist of repeated sequences of phosphate and sugar linkages—ribose sugar in RNA and deoxyribose sugars in DNA. Attached to the sugar links in the backbone are two kinds of nitrogenous bases: purines and pyrimidines. The purines are adenine (A) and guanine (G) in both DNA and RNA; the pyrimidines are cytosine (C) and thymine (T) in DNA and cytosine (C) and uracil (U) in RNA. A single purine or a pyrimidine is attached to each sugar, and the entire phosphate–sugar–base subunit is called a nucleotide. The nucleic acids extracted from different species of animals and plants have different proportions of the four nucleotides. Some are relatively richer in adenine and thymine, while others have more guanine and cytosine; however, the ratios of A to T, and also of G to C, are equal.

The Watson–Crick model of DNA

With the general acceptance of DNA as the chemical basis of heredity in the early 1950s, many microbiologists turned their attention to determining the molecular structure of this substance. In 1953 James Watson and Francis Crick proposed their now-famous model, which shows DNA as composed of two spirally wound (*i.e.*, helical) chains, in which the A's of one chain are linked by hydrogen bonds to the T's of the other, and the G's in one chain are linked to the C's of the other. The model looks something like a twisted ladder: the sides of the ladder are composed of the sugar and phosphate groups, while the rungs are made up of the paired nitrogenous bases. Watson and Crick based their model largely on X-ray crystallographic studies of DNA, which had been performed by Maurice Wilkins and Rosalind Franklin. This model fulfills the basic requirements—it makes it possible to envisage how genes replicate their precise structures when their copies are synthesized. It also makes it possible to explain how a gene can carry genetic information written in some chemical code. And, finally, it helps to envisage how mutational changes in the genes are produced.

DNA REPLICATION

The Watson–Crick model of the genetic material permits an explanation of the mechanism of precise replication of genes (Figure 9). The paired complementary strands of the DNA molecule may separate as a result of a breakage of the hydrogen bonds between the paired nitrogenous bases. If free nucleotides (base + sugar + phosphate) are present in the medium surrounding the gene, they might pair with the complementary bases on the single strands of DNA. An enzyme, DNA polymerase, functions to form the phosphate bonds between the sugars in the DNA backbone. It has been used in the synthesis of DNA in vitro, in cell-free systems. The enzyme is extracted from rapidly dividing cells of *E. coli*. A supply of the four nucleotides, A, T, G, and C, is provided, as well as a source of energy, adenosine triphosphate (ATP). To start DNA synthesis another key component is added—a trace of DNA to serve as a primer, or template. The kind of DNA that is synthesized depends on the primer. Even though the enzyme came from *E. coli*, if the primer is DNA of some quite different organism, such as cattle, the DNA that is synthesized is not *E. coli* but cattle DNA.

From *Molecular Biology of Bacterial Viruses* by Gunther S. Stent W.H. Freeman and Company, copyright © 1963

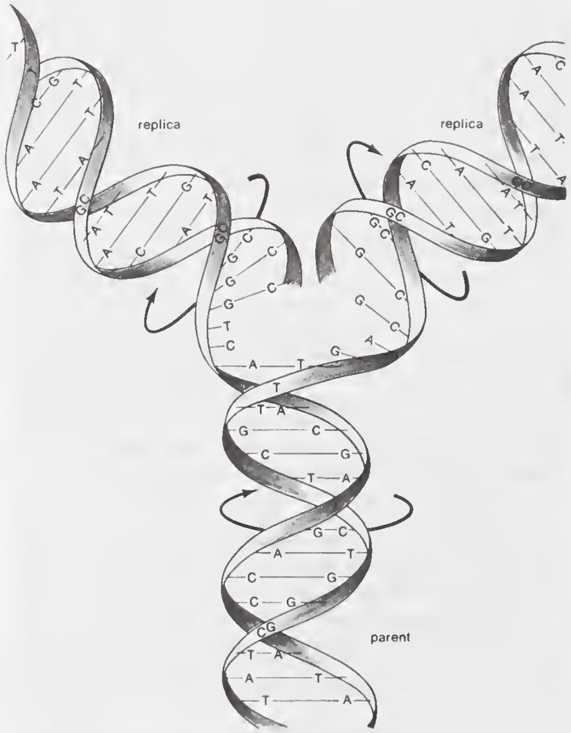

Figure 9: A possible method for the replication of DNA according to Watson and Crick. The arrows indicate the direction of rotation.

The Watson–Crick model of the structure of DNA suggested several different ways that DNA might self-replicate. The experiments of Matthew Meselson and Franklin Stahl on *E. coli* in 1958 suggested that DNA replicates semiconservatively to form two helices, each with one old and one new strand, the old strand acting as a template for the formation of a new strand. J. Herbert Taylor, using cells of higher organisms, confirmed the validity of this interpretation. Synthesis of new DNA occurs while the old chromosome is in the process of uncoiling (see Figure 9).

The DNA in one human cell is approximately two metres long when stretched out. It has been estimated that if all the DNA in a human were stretched out, it would extend from the Earth to the Sun and back again. For the large amount of DNA in one cell to fit, it obviously must be carefully and tightly packaged. About 140 base pairs of the DNA helix wind around a cluster of chromosome proteins (histones) to form a nucleosome, a structure similar to a bead on a string. Between the nucleosome beads is a string (linker region) of 20 to 100 DNA base pairs associated with another histone protein. This structure is flexible enough to permit the coiling and folding necessary to pack the DNA into the cell nucleus in a way that makes it readily available when it becomes genetically active.

DNA AS AN INFORMATION CARRIER: TRANSCRIPTION AND TRANSLATION OF THE GENETIC CODE

As has been stated, the Watson–Crick model provides an explanation of how a gene can carry hereditary information in the form of a chemical code. This section will describe the genetic code and explain how it governs the biochemical processes of the cell.

Before turning to the language of the code, it is necessary to explain what it is that the code specifies. It is now known that genes encode instructions for the production of proteins, which are largely responsible for the structure and function of the organism. Proteins are large, complex molecules consisting of one or more polypeptide chains that, in turn, are composed of amino acids linked together by peptide bonds. Proteins play many roles in organisms. Some proteins make up structural components of the organism; an example is the protein collagen in vertebrate animals. Others perform particular functions; for example, the protein hemoglobin transports oxygen in the blood of mammals, and the proteins of the immune system (immunoglobulins) protect against diseases in many members of the animal kingdom. Still other proteins regulate the rate of specific biochemical reactions in cells. This latter class of proteins, called enzymes, functions as biological catalysts. Enzymes permit chemical reactions to occur with extreme rapidity at temperatures normal to living cells. Without these proteins, the molecular interactions would require much longer periods of time and much higher temperatures, and they would lose their specificity. It is certainly no exaggeration to say that life depends on enzymes.

DNA and RNA: transcription. Among eucaryotes, DNA never leaves the cell nucleus, despite the fact that protein synthesis takes place on the ribosomes, structures that lie in the cytoplasm (*i.e.*, in the portion of the cell outside of the nucleus). Even among procaryotes, which have no membrane-enclosed nucleus, the DNA does not directly carry its instructions to the ribosomes. In both kinds of organisms, this function is performed by a type of RNA that copies the DNA message and carries it to the site of protein synthesis. Aptly enough, this RNA is called messenger RNA, or mRNA for short. The copying of the DNA instructions into messenger RNA is called the transcription function of DNA, to distinguish it from the replication function discussed above.

The sequence of the genetic letters, A (adenine), T (thymine), C (cytosine), and G (guanine), in the DNA is first transcribed into the corresponding sequence of the letters A, U (uracil), C, and G in the messenger RNA. This occurs through the action of the enzyme RNA polymerase. This enzyme synthesizes RNA in a test tube from a mixture of the A, U, C, and G bases, but it does so only in the presence of a primer DNA. The sequence of the bases in the primer is copied in the RNA. The steps involved in this process are as follows: (1) the DNA double helix unwinds by breaking the hydrogen bonds between the corresponding bases in the paired strands; (2) the RNA polymerase forms the bonds between the RNA bases that are complementary to the bases in the DNA; and (3) the messenger RNA thus formed passes into the cytoplasm and becomes attached to a ribosome. Ribosomes consist of proteins and another type of RNA, ribosomal RNA (rRNA).

Protein synthesis: translation. The process of protein synthesis is represented diagrammatically in Figure 10. The information contained in the sequence of the bases (letters) in the messenger RNA is then translated into a sequence of amino acids in a protein. This requires the presence of still another molecule that is capable of recognizing the code for a specific amino acid and selectively making the amino acid available at the right point in the protein synthesis, a soluble RNA fraction within cells that can bind amino acids. Soluble, or transfer, RNA (sRNA, or tRNA) is a single-stranded molecule that forms about 20 percent of the total cellular RNA. If amino acids and a source of energy (usually ATP) are added to a mixture of transfer RNA's, reversible binding of the amino acids to the RNA molecules occurs. Furthermore, each amino acid is bonded to a specific transfer RNA molecule by a specific activating enzyme. There are at least 20 different kinds of transfer RNA's and activating enzymes that correspond to the 20 amino acids commonly found in proteins. The amino acid-transfer RNA complex becomes attached to the ribosome with its messenger RNA molecule; the addition of the amino acid to the growing polypeptide chain then occurs. A sequence of three nitrogenous bases (anticodon) on the transfer RNA molecule pairs with a complementary sequence (codon) on the messenger RNA molecule, which is held in the correct position by the ribosome. Once the recognition has occurred, a peptide bond is formed between the amino acid bound to the transfer RNA and the growing polypeptide chain.

From T. Jukes *Molecules and Evolution* (1966), Columbia University Press

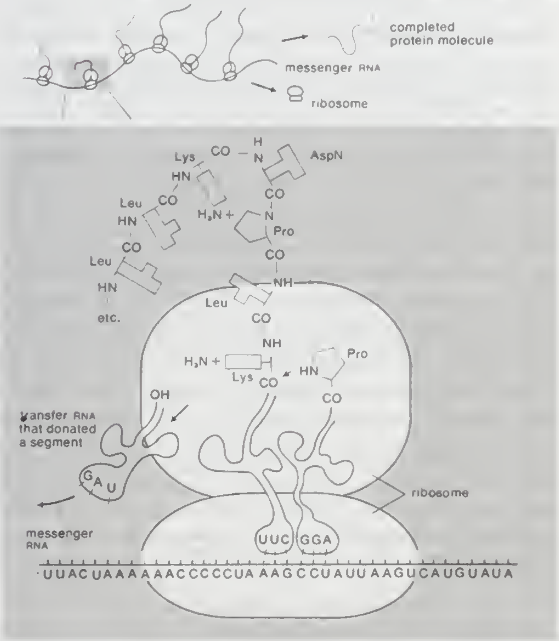

Figure 10: *Synthesis of protein.*
(Top) The messenger RNA shown with a ribosome (in stages) "reading" its message, the translation occurring from left to right, and the polypeptide chain growing as the ribosome proceeds along the messenger RNA. (Bottom) A highly magnified ribosome in the process of "reading" a messenger RNA molecule. The ribosome has just "read" an AAG sequence off the messenger RNA, and a specific transfer RNA molecule (UUC) moves into place carrying the amino acid lysine (Lys), which is then added to the polypeptide chain. Next in position to be read is CCU, which draws a transfer RNA molecule carrying the amino acid proline (Pro) to be transferred to the growing polypeptide chain. The ribosome moves from left to right along the messenger RNA molecule. Each ribosome has two binding sites for transfer RNA: one that holds the growing polypeptide chain and a second for positioning a new transfer RNA molecule for processing.

The accuracy of the model described in Figure 10 has been confirmed by the achievement of protein synthesis in the test tube. This synthesis requires a DNA template (primer DNA), precursor nucleotide molecules, ribosomes, transfer RNA's, amino acids, and a set of enzymes and certain other factors.

The central dogma. The processes of transcription and translation, as described above, can be represented thus: DNA → RNA → protein. Soon after its elucidation, this understanding of the genetic control of protein synthesis became known as "the central dogma" of molecular genetics. Included as part of the dogma was the belief that reverse transfer of information does not occur; in other words, there is no storage of information in the protein molecules and no transcription of protein back into nucleic acids or of RNA back into DNA.

The central dogma has since been modified to accommodate the discovery that reverse transcription of RNA to DNA does occur, as first demonstrated in some viruses. These viruses, called retroviruses, have a genome composed of RNA. When retroviruses enter a host cell, they produce an enzyme called reverse transcriptase. This enzyme permits the transcription of the viral RNA into DNA, which then may become incorporated into the genetic material of the host cell.

A second modification was necessitated by the discovery that not all DNA codes for protein synthesis. As discussed below, some of the noncoding DNA is involved in regulating the biochemical processes of the cell. The amount of noncoding DNA is small in procaryotes, but in eucaryotes it may be most of the cell's DNA.

The words of the genetic code

Reading the code. It is necessary to understand how the four letters—A, T, C, and G—specify, or code, for 20 different amino acids. If a single letter coded for an amino acid, only four amino acids could be specified. If two bases were needed to specify an amino acid, then 16 different combinations could be constructed, again an insufficient number (20 amino acids must be accounted for). Combinations of three letters allow 64 different words to be constructed, more than the necessary minimal number. A three-letter, triplet, code could be constructed in at least three different ways: (1) with words overlapping; (2) with words not overlapping and punctuated; and (3) with words not overlapping and not punctuated. An overlapping code is composed of words that overlap each other—*i.e.*, the letters of any given word may belong to one, two, or three words. The DNA might contain, for example, the sequence

$\underline{A\,G\,\overline{C}}\,\overline{G}\,\underline{\overline{T}\,T\,\overline{A}}\,\overline{C\,G}$; the first word is AGC, the second CGT, and so on. This type of code is improbable, because of the restrictions it would place upon the possible sequence of amino acids in protein. As the example above shows, if the first word is AGC, the second word must begin with C, etc. Examination of amino-acid sequences in a protein such as hemoglobin indicates that any amino acid can follow any other—a possibility not allowed for by an overlapping code.

If the code is nonoverlapping, a problem of distinguishing words from each other arises. DNA contains no spaces separating the words as in written sentences; therefore, there must be other indications of specific starting points for messenger RNA synthesis. The base sequence AGC AGC AGC . . . could be punctuated by the presence of a fourth base, T, between each AGC triplet. This would reduce the number of possible triplets to 27. That a punctuated code of this type is not realized is seen from the evidence of the degeneracy in the code for some amino acids. The degeneracy means that some amino acids are coded for by more than one triplet, and a punctuated code does not allow enough words. A second objection to this type of code comes from a consideration of the effects of mutation on the coding sequence. If one of the punctuation marks mutates to another base, or a coding base mutates to a punctuation mark, the resulting sequence will be complete nonsense functionally.

The third possibility is a nonoverlapping, nonpunctuated code, in which the reading starts from a specific point. In all organisms studied in this respect this is the method of coding used. A knowledge of the base sequence in the messenger RNA and the resulting amino-acid sequence in protein reveals the code for each amino acid. The triplet UUU, for example, is the code for the amino acid phenylalanine, corresponding to the sequence AAA in the DNA. Poly-A (AAA) and poly-C (CCC) are messenger RNA's codes for lysine and proline, respectively.

Other triplets were tested for their coding abilities by synthesizing messenger RNA molecules with varying proportions of the two bases. If, for example, a mixture of the two bases U and C in a 5 : 1 proportion are synthesized into RNA, the possible triplets and their probable frequency in the synthetic messenger RNA can be easily determined. The triplet UUU will be most common and will appear with the frequency 5/6 × 5/6 × 5/6; the triplets UUC, UCU, and CUU will appear in the frequencies of 5/6 × 5/6 × 1/6; the triplets UCC, CUC, and CCU will be the next most frequent and will appear with a frequency of 5/6 × 1/6 × 1/6; while the triplet CCC should appear only 1/216 of the time. A messenger RNA of this composition should result in the incorporation into protein of eight different amino acids. In fact, only four amino acids were present in the protein produced; this means that several of these triplets encode for the same amino acid and therefore that the code is degenerate.

The RNA code triplets (or codons) and the amino acids for which they stand are shown in Table 3. Triplets have been discovered that encode for starting and for stopping the synthesis of protein chains in *E. coli.* Many proteins of *E. coli* begin with the amino acid methionine. Two different transfer RNA's for methionine are known to exist, only one of which functions to initiate protein synthesis. After synthesis of the protein, an enzyme may remove a portion of the beginning of the chain to eliminate the obligatory methionine molecule. The second transfer RNA for methionine allows this amino acid to be incorporated into the middle of a polypeptide.

Termination of the synthesis of a polypeptide chain is signalled by three different RNA codons that do not specify an amino acid: UAA, UAG, and UGA. These triplets were discovered as nonsense mutations that produced premature cessation of protein synthesis in many different genes. Specific proteins called release factors can read these codons and release the polypeptide chain from the ribosome.

MUTATIONS IN THE CODE

The DNA content of the cell must accurately replicate itself prior to mitosis or meiosis. Given the complexity of the DNA molecule and the vast number of cell divisions that take place within the lifetime of a multicellular organism, it is obvious that copying errors are likely to occur. If unrepaired, such errors change the linear order of the DNA bases and produce mutations in the genetic code. Many mutations arise from unknown causes. In addition to these so-called spontaneous mutations, researchers have demonstrated that a variety of environmental agents—including ionizing radiation, toxic chemicals, and certain viruses—can induce mutations. The effects of these mutagenic agents on human health are discussed below in the section *Human genetics.*

Table 3: The Genetic Code: Nucleotide Triplets (Codons) Specifying Different Amino Acids in Protein Chains*

DNA triplet	RNA triplet	amino acid	DNA triplet	RNA triplet	amino acid
AAA	UUU	phenylalanine	ACA	UGU	cysteine
AAG	UUC		ACG	UGC	
AAT	UUA	leucine	ACC	UGG	tryptophan
AAC	UUG		ATA	UAU	tyrosine
GAA	CUU		ATG	UAC	
GAG	CUC		ATT	UAA	(termination: end of specification)
GAT	CUA		ATC	UAG	
GAC	CUG		ACT	UGA	
AGA	UCU	serine	GCA	CGU	arginine
AGG	UCC		GCG	CGC	
AGT	UCA		GCT	CGA

* The columns may be read: the DNA triplet is transcribed into an RNA triplet, which then directs the production of an amino acid.

Kinds of mutations. The addition or deletion of one or more bases results in a frame-shift mutation, so named because the reading frame of the gene, and thus its message, is altered from that point forward. Suppose that a DNA message read from left to right reveals the triplets GAC, TCA, and TTA (which are transcribed in the RNA code as CUG, AGU, and AAU). Deletion of the first T alters the reading frame so that triplets GAC, CAT, TA . . . will be read. The first triplet is unchanged, but all the remaining triplets may specify wrong amino acids. The chemical addition of a base to the sequence likewise shifts the reading frame; such a mutant will also specify wrong amino acids beyond the point of the base addition. If an original mutant resulted from the deletion of a base from the DNA, the addition of a base at a point beyond the first mutation would restore the reading frame of the DNA sequence and would result in nearly normal function. For example, assume that the original DNA sequence reads ACT GGC TAG CTG TCA TCG . . . . Deletion of the C in the second triplet results in the following triplets being read: ACT, GGT, AGC, TGT, CAT, CG . . . . The subsequent addition of a base (A) between the third and fourth mutant triplets results in the following sequence: ACT GGT AGC ATG TCA TCG . . . . Note that the first, fifth, and sixth triplets are identical to those in the original sequence. Only the second, third, and fourth triplets are altered, and the reading of the code from the fifth triplet on will be identical to that in the original message. Frequently, suppressor mutations occur in proximity to other mutations and restore the reading frame of the DNA sequence, thereby allowing a sequence of amino acids differing only slightly from the original one to be formed in the protein.

Mutations in which one base is exchanged for another are called base substitutions, or point mutations. A base substitution may result in the incorporation of one wrong amino acid into the polypeptide chain encoded by the gene. What effect this has on the functioning of the protein of which the chain is part depends on the type and position of the wrong amino acid. In many cases, the effects are minor, but there are exceptions. The human disease sickle-cell anemia, for example, is the product of a single base substitution inherited from both parents. Sometimes a base substitution results in a codon for an amino acid being changed to one of the termination triplets. This type of point mutation will cause premature termination of protein synthesis and, probably, complete loss of function in the finished protein.

Thus far distinctions have been made between mutations in terms of their effects on the nucleotide sequence of DNA. It is also useful to differentiate between mutations that affect germ cells (*i.e.*, eggs and sperm) and those that affect somatic cells. When a mutation occurs in a germ cell, it can be passed on to offspring, where it will be carried in every cell of the new individual. Mutations in somatic cells, on the other hand, are not passed on to offspring, and they affect only a certain population of cells (the original mutant cell and its mitotic descendants) within the affected individual. (Ro.R./T.D./Ar.R.)

Mutation rates. Detectable results of germinal mutation among people are only very rarely encountered. Thus, the actual rate of mutation in human chromosomes defies full measurement. A major reason for this is that most mutations seem to be recessive and thus tend to be masked for generations. Efforts to measure mutation rate therefore are most conveniently directed toward selected dominant or codominant mutations for which phenotypic recognition is easier. Indirect (inferential) methods of measurement are still required.

Studies of achondroplasia

One dominant gene that is useful for studying human mutation rates produces the form of dwarfism called achondroplasia. When an affected child appears in a family in which both parents are normal, the properly diagnosed condition can be ascribed to the occurrence of one new mutation. The frequency of such an event is customarily calculated on the basis of the number of gametes (egg and sperm cells) produced by the parents in one generation; for human achondroplasia, the mutation rate has been inferred to be 4.2 per 100,000 gametes. Analyses of a number of different gene loci in humans and in such experimental organisms as corn and the *Drosophila* fly show that the average mutation rate among living beings is on the order of one in 100,000 gametes (10^{-5}). Nevertheless, each gene studied shows its unique mutational probability; the neurological disorder called Huntington's chorea shows only about 0.5 mutation per 100,000 gametes, whereas the figure for neurofibromatosis (a disorder with soft tumours distributed over the whole body) has been stated to be somewhat higher. The general average in humans is considered to be about the same as for achondroplasia, roughly four per 100,000 gametes. (H.L.C.)

It may well be, however, that mutation rates are considerably higher than this figure for the following reasons: (1) there undoubtedly are "silent" mutations that do not change the biological function of the gene product (protein) in a way that will change the phenotype; (2) some mutations may be so harmful as to be lethal early in embryonic development; and (3) different mutations can produce the same abnormal phenotype, a situation known as genetic heterogeneity. It follows from the above that more accurate mutation rates in humans will result only from DNA analysis that reveals changes in the specific nucleotides of the DNA chain.

DNA repair. A variety of agents in the cell's environment, both chemical and physical, can damage DNA. Organisms have developed a variety of mechanisms for repairing copying errors produced by damaged DNA, usually by enzymatically excising them. The enzyme DNA polymerase then catalyzes the replacement of the excised segment with the correct nucleotides, using the undamaged DNA strand as a template. Eucaryotic cells have a greater variety of DNA repair mechanisms than do bacteria. Malfunctioning of the repair mechanisms can lead to genetic disease, abnormal function, or cancer. Xeroderma pigmentosum, a lethal human disease that is recessively inherited, involves several defective repair mechanisms.

REGULATION OF GENES

The evidence accumulated in genetics makes it virtually certain that not all the genes present in a cell are active in directing the specific processes of protein synthesis. Gene action can be switched on or off in response to the cell's stage of development and external environment. In multicellular organisms, moreover, each cell has a complete copy of the organism's genetic instructions, though different kinds of cells come to express different parts of the genome. That is to say that a skin cell, a nerve cell, and a bone marrow cell from the same person all contain the same genes; the differences in structure and function among these cells result from the selective expression and repression of certain genes.

In bacteria. In 1961 the French molecular biologists François Jacob and Jacques Monod proposed a model for genetic regulation in *E. coli*. When grown on a minimum culture of carbohydrates and sulfur, these bacteria can synthesize all of their necessary amino acids. To accomplish this amino-acid synthesis, the bacteria must produce various enzymes, the activities of which can be detected in a growing culture. If certain amino acids are added to the culture medium, the bacteria stop producing the enzymes required for the synthesis of these amino acids. This phenomenon is known as repression, and the enzymes affected are repressible enzymes. The pathway for the synthesis of the amino acid arginine in *E. coli* is a good example of how these repressible enzymes work. This synthesis involves three steps and three separate enzymes:

$$\text{glutamic acid} \xrightarrow{\text{enzyme A}} \text{ornithine} \xrightarrow{\text{enzyme B}} \text{citrulline} \xrightarrow{\text{enzyme C}} \text{arginine.}$$

When arginine is present in the medium, none of the three enzymes involved in this process is detected, but if arginine is removed, all three enzymes rapidly appear. The end product of this pathway, arginine, controls the production of the intermediate enzymes, since the addition of either ornithine or citrulline to the medium has no effect. A related process involves the production of enzymes whose substrates are not always present in cells. The presence of lactose in the medium, for example, induces the synthesis of three enzymes that procced to degrade lactose; this phenomenon is termed induction.

The classes of genes involved in regulating the expression of a bacterial gene—repressing its action or inducing it—are shown in Figure 11. The part of the chromosome containing the genes concerned is divided into two regions, one of which includes the structural genes (*i.e.*, those genes that code for protein synthesis) and the operator gene. This region is termed an operon. The other part contains only the regulator gene. The regulator gene need not be located close to the operon. The regulator gene produces some substance, a repressor, which affects a second gene, an operator. There are several lines of evidence that suggest that the repressor substance is a protein molecule. It would be necessary for such a molecule to have at least two areas or sites that interact with the operator gene or a metabolite or both in order to influence structural genes (repress or induce their action, depending on given conditions).

From F Jacob and J Monod, *Journal of Molecular Biology* (1961), Academic Press Inc

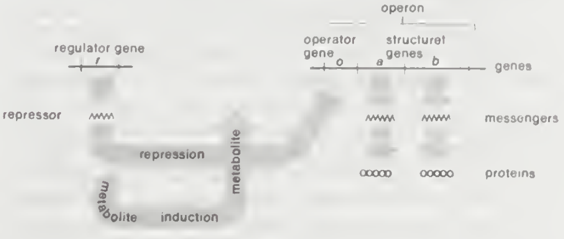

Figure 11: Model of the operon and its relation to the regulator gene.

In higher organisms. Although the operon model has proved a useful description of gene regulation in bacteria, evidence indicates that different regulatory mechanisms are employed in eucaryotes. The series of events associated with gene expression in higher organisms is much more complex than in procaryotes, requiring multiple levels of regulation. This is particularly true in multicellular organisms, in which cell differentiation takes place.

The regulation of gene expression in eucaryotes is not fully understood, but research in the fields of somatic cell genetics and recombinant DNA have yielded at least partial explanations as to how this process occurs. (The techniques involved in such research are discussed below.) What this research has indicated may be the mechanisms of gene regulation in higher organisms.

Eucaryotic DNA comprises three different classes: (1) unique, or single copy, DNA, which contains the structural genes (protein coding sequences); (2) moderately repetitive DNA, some forms (families) of which are dispersed throughout the chromosomes in small clusters and which may contain some functional genes, such as those that code for certain forms of RNA; and (3) the highly repetitive DNA, which contains nucleotide sequences repeated up to 1,000,000 times. This last class of DNA is usually clustered near the centromeres and is often known as satellite DNA. The function of the families of satellite DNA is unknown. There is no indication that their remarkably constant sequences are ever transcribed.

Since a very small percent of the DNA in higher organisms codes for proteins, the assumption is that the majority of DNA is involved in the control of gene action. If all the human structural genes functioned simultaneously, for example, metabolic chaos would ensue. Mechanisms exist for switching gene activity on and off at the appropriate time in development and in appropriate tissues, thus permitting the differentiation of the organs at various stages of development. Much of this regulation in higher organisms occurs during the processing of the RNA copies transcribed from DNA. Following the transcription of the DNA into this nuclear, or heterogenous, RNA, a process of editing and splicing takes place. The nuclear RNA contains long and often multiple noncoding intervening sequences of nucleotides. These sequences, called introns, are cut out, and the remaining coding regions, called exons, are spliced together to form the functional messenger RNA that can leave the nucleus to direct protein synthesis in the cytoplasm (see Figure 12). Because the nuclear RNA, including its introns, is a mirror image of its DNA template, it follows that many genes of eucaryotes are discontinuous and may be characterized as mosaics of coding and noncoding regions. The role of the introns is not firmly established, but some evidence points to their possible involvement in regulating gene action. For example, researchers have shown that several forms of thalassemia (a common disease of hemoglobin) stem from intron mutations that interfere with the splicing action.

With the discovery of introns, molecular geneticists realized that it is impossible to determine the nucleotide sequence of a eucaryotic structural gene simply by analyzing the amino-acid sequence of its polypeptide product. This is so because the amino-acid sequence will not reflect the introns present in the native DNA. What is possible is to reconstruct the complementary DNA (CDNA), the DNA sequences consisting only of exons. As will be seen later, this has become an important part of recombinant DNA technology.

The analysis of nucleotide sequences has revealed a number of other mechanisms that help in the regulation of gene expression. Molecular geneticists have discovered small DNA sequences, about 100 base pairs in length, that interact with other constituents of the cell to produce specific regulatory effects on adjacent genes. These regulatory sites—called promoters, enhancers, or modulators—have been sequenced, and their effects studied on the quantitative expression of the products of a "standard" gene cloned by recombinant DNA techniques. Of particular interest is the enhancer site which may be involved in turning on specific genes in specific tissues at specific stages in development. In addition to illuminating the mysterious problems associated with normal development, chromosomal translocations may move these sites to abnormal positions where they can disturb cell multiplication and produce malignancy.

CYTOPLASMIC, OR EXTRANUCLEAR, DNA

Some characteristics of organisms do not show Mendelian segregation and, among higher organisms, are inherited through the maternal line only. For example, the cells of green plants contain cytoplasmic bodies called chloroplasts, which carry the green pigment chlorophyll. In corn, variants are known whose leaves are striped green and yellow because of the absence of chlorophyll in the chloroplasts of some cells. Since no chloroplasts are present in pollen grains, the conclusion is that chloroplasts are self-replicating bodies in egg cells and in part control their own characteristics.

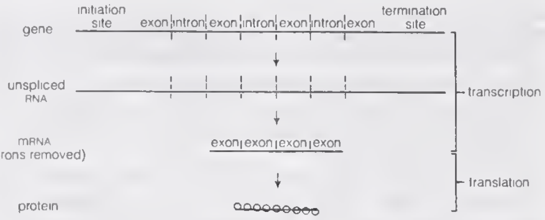

Figure 12: The steps in the processing of a gene in eucaryotes (see text).

In the 1960s the existence of DNA within chloroplasts (in plants) and mitochondria (in complex animal cells) was demonstrated. The subsequent discoveries of ribosomes, transfer RNA's, and enzymes within mitochondria and chloroplasts have demonstrated that these cytoplasmic bodies synthesize part, but not all, of their own proteins.

The usual procedure for testing for extranuclear inheritance is to look at the progeny of reciprocal crosses of two different strains. Chromosomal (nuclear) inheritance predicts that offspring of the cross male A × female B should not differ phenotypically from those of the cross male B × female A. Cytoplasmic inheritance, on the other hand, is entirely maternal, as only the female gamete contributes chloroplasts or mitochondria to the zygote. Hence the offspring of male B × female A differ from those of male A × female B for traits controlled by extranuclear DNA. There is little evidence of cytoplasmic inheritance in humans. A large pedigree, however, has been reported of a family with a disease characterized by abnormal muscle fibres and abnormal mitochondria. In every case the disease was inherited from an affected mother, suggesting the presence of mutant mitochondrial DNA and cytoplasmic inheritance.

THE BIOCHEMICAL PRODUCTS OF GENE EXPRESSION

As stated above, the central function of genes (and hence of DNA) is to direct the production of proteins. The conceptual union of biochemistry and genetics, now called biochemical genetics, was first envisaged by Garrod, an English physician who has been called "the father of chemical genetics." In lectures delivered in 1908, Garrod described four hereditary diseases (alkaptonuria, cystinuria, albinism, and pentosuria) that involve an enzyme deficiency. He dubbed these diseases "inborn errors of metabolism," a name that persists to this day. Garrod stressed the unusual frequency of consanguineous matings in the parents of these patients. At a time when Mendel's laws were just being rediscovered, Garrod gave the first detailed description of recessive inheritance in humans, a point quickly appreciated by a pioneer in genetics, William Bateson.

Although the relationship between gene and enzyme was implicit in Garrod's work, it was more than 30 years before George W. Beadle and Edward L. Tatum of the United States made it explicit by their classical studies on genetic control of biochemical reactions in the bread mold *Neurospora crassa.* This work, for which Beadle and Tatum received the Nobel Prize for Physiology or Medicine for 1958, resulted in the formulation of the "one gene–one enzyme" hypothesis.

Most strains of *N. crassa* produce enzymes that enable the mold to grow on a minimal medium of sugar, inorganic salts, and the vitamin biotin. From these sources, *N. crassa* can synthesize all the amino acids, vitamins, and other substances necessary for its survival and reproduction. If, however, a genetic mutation results in the production of a chemically defective enzyme, the affected strain will not grow on the minimal medium unless the product of the now-defective enzymatic reaction is added. Let a metabolic pathway consist of a chain of reactions $A \xrightarrow{(1)} B \xrightarrow{(2)} C \xrightarrow{(3)} D$, in which each reaction is mediated by a specific enzyme (1, 2, and 3, respectively). If the gene for enzyme 2 is mutated, C cannot be synthesized and the reaction stops. If, however, C is added to the medium, the reaction proceeds and D is formed. Meanwhile, however, B will accumulate in large amounts, which may be toxic.

The existence of metabolic pathways composed of successive steps, each of which is controlled by a single gene, appears to be a general phenomenon in the living world. One of the experimental techniques of somatic cell genetics (see below) has been to produce single-gene mutations that cause a nutritional defect in the experimental cell line. Through these abnormalities geneticists can elucidate the normal metabolic pathways of the cell and can map the gene to a specific chromosomal site. A similar phenomenon, of course, operates in the inborn errors of metabolism. Well over 100 different inborn errors of human metabolism are understood as defects in specific enzymes, secondary to specific gene mutations.

It was not, however, until the work of the U.S. biochemist Linus Pauling and his associates (1949) that the molecular basis for the relationship between a mutant gene and its protein product began to be understood. This was accomplished by the use of electrophoresis, a technique that separates different proteins by their movement through a liquid under the influence of an electric field. Pauling's electrophoretic separation of normal hemoglobin (hemoglobin A) from the hemoglobin of sickle-cell anemia (hemoglobin S) made it apparent for the first time that genetic disease could be understood in molecular terms. The hemoglobin molecule consists of two pairs of polypeptide chains, an alpha chain and a beta chain. Of fundamental importance was the determination by Vernon M. Ingram that the electrophoretic difference between hemoglobins A and S is due to the change of a single amino acid—glutamic acid being replaced by valine in position six of the beta chain. This results from a single base change in the DNA triplet responsible for the amino acid in position six: GAA is changed to GUA. The beta chain has 146 amino acids, but this one change disturbs the structure of the hemoglobin sufficiently to produce a most serious disease, sickle-cell anemia, in the homozygote.

Information resulting from this and other hemoglobin diseases demands that the "one gene–one enzyme" hypothesis be modified to the "one gene–one polypeptide" hypothesis or even more accurately to the "one structural gene–one polypeptide" principle. This has the advantage also of broadening the concept of inborn errors of metabolism to include any inherited deficiency of a protein, whether the protein is involved in enzymatic activity, transport, or structure. (Ro.R./T.D./Ar.R.)

SOMATIC CELL GENETICS

The development of molecular biology represented a fusion of biochemistry and genetics. As has been discussed, most of the pioneer research in this field utilized microorganisms. The great strides made in genetic-biochemical analysis resulted basically from the ability to place an experimental organism on a culture dish containing agar (a jellylike substance) and a nutrient medium supporting cell multiplication. The cells multiplied to produce discrete colonies. All the cells in a particular colony formed a clone; that is, they all had the same genetic constitution as the founding cell. By selecting a founding cell with a phenotypically observable mutation, researchers could easily establish clones with the mutant genotype. The biochemical products of these mutant cells could then be studied and compared to those of normal colonies.

By contrast, the study of genetics in higher organisms was, for many years, limited to the analysis of the genetic effects of experimental matings. In human genetics, even this technique was not available, as the experimental mating of human beings is not only morally unjustifiable but also unworkable due to the long generation time (about 30 years) of the species. These obstacles precluded the observation of the segregation of human genes over multiple generations except by the classical methods of retrospective analysis of large family pedigrees.

During the late 1950s, molecular biologists learned to grow single mammalian somatic cells in culture, a feat hitherto thought impossible. This ability to treat "the mammalian cell as a microorganism" (a phrase coined by the U.S. molecular biologist Theodore T. Puck) has made it possible to study the genetics of higher organisms with techniques similar to those used in *E. coli.* Somatic cell genetics has permitted researchers to analyze mammalian cells in terms of their growth requirements and their responses to a variety of environmental agents and especially to study, at the molecular and cellular level, the processes of heredity in these cells. Because of such research, the characteristics of mammalian cells in culture can be analyzed in simple, quantifiable terms. In the study of human genetics, somatic cell techniques have revolutionized the diagnosis of genetic disease (including prenatal diagnosis), have made possible the analysis of the human chromosomes, and have elucidated some of the processes of normal and abnormal differentiation, including those involved in producing cancer.

Mammalian cells can be cultured from many different tissues (*e.g.,* white cells from the blood, fibroblasts from the skin, marrow cells from the bone) for a variety of purposes. These include (1) studies of the chromosomes (cytogenetics), (2) biochemical assays to look for enzymatic defects associated with human diseases, (3) examination of DNA and the processes of replication, (4) interspecific and intraspecific somatic cell hybridization to gain information about the position of genes on the human chromosomes, and (5) the study of the structure and function of the cells and their organelles (constituent parts). These cells, with the exception of lymphocytes (white blood cells), can be kept in culture for long periods or stored in a frozen state to be thawed out and recultured later. The human lymphocyte, readily available from a peripheral blood sample, can be kept in culture for only several days. It can, however, be transformed into a permanent culture that can be frozen and reactivated at a later time by infecting it with certain viruses, particularly the Epstein–Barr virus.

The ability to fuse two cells, either of the same or of different mammalian species, has proved to be one of the most powerful tools of somatic cell genetics. Researchers accomplish such fusion by treating the cultured cells with an irradiated, killed virus (the sendai virus) or with particular chemical agents; in response the cytoplasm and nuclei of the cells merge to form a hybrid cell with a single, large nucleus that contains the genome of both "parent" cells.

The hybridization of two cells from the same species—each cell having been exposed to radiation or chemical agents to produce a desired phenotypic mutation—is useful in complementation analysis. Consider, for example, the fusion of two mutant cells (A and B) whose DNA has been damaged by a point mutation so that neither cell can grow in a medium lacking glycine. If the hybrid cell can grow in the absence of glycine, the two mutant genomes have complemented each other. In short, the defect in the DNA present in cell A involves a different gene at a different location than that in cell B, and the combined genome is able to compensate for each mutation. If, however, A and B have mutations at the same DNA locus, they cannot produce a glycine-independent hybrid. When complementation occurs, researchers can analyze the biochemical products of the "parent" cells to elucidate the nature of the mutation that exists in each cell.

The fusion of cells of two different species (*e.g.,* of a human cell and a Chinese hamster cell) produces a hybrid cell that, when cultured, undergoes extensive chromosome loss, primarily of the species whose cultured cells have the longer generation time. In the case of the human–Chinese hamster hybrid, human chromosomes are lost. If a mutant hamster cell with a nutritional deficiency (*e.g.,* one that cannot grow in the absence of glycine) is hybridized with a human cell without the deficiency, the hybrid cell will not show the deficiency (in this instance the hybrid will be able to grow in a medium without glycine). The hybrid cells will then produce clones showing extensive loss of the human chromosomes. The one human chromosome the hybrid cannot lose is the one that carries the human gene that compensates for the hamster cell mutation, for without that gene the cell would die. By employing this technique, researchers can identify the human chromosome on which a particular gene is located. In fact, by using a series of X rays or other manipulations to break the human chromosome, geneticists can locate the segment of the chromosome possessing the gene. Hundreds of human genes have been mapped to a specific chromosome, in many cases to a specific chromosomal region, by this method. Using increasingly small chromosome deletions, researchers have succeeded in locating the genes in their proper order on the chromosomes. By studying the recombination frequency between these genes (a task made simpler by the methods of recombinant DNA discussed below), the distances between them on the chromosome have been mapped. The ability to locate the human genes on the 23 pairs of chromosomes is of tremendous practical importance for understanding human genetics. When large numbers of genes are mapped, investigators can identify which are absent or supernumerary in the many diseases involving the human chromosomes. Mapping also helps geneticists elucidate the nature of gene control in mammals, which, as has been discussed, is significantly more complex than the relatively simple operon system in bacteria. Insights into gene regulation in mammals can increasingly be applied to understanding of cellular biochemical control in normal development and in human disease.

RECOMBINANT DNA TECHNOLOGY

Since the focus of all genetics is the gene, the fundamental goal of geneticists is to isolate, characterize, and manipulate genes. Although it is relatively easy to isolate a sample of DNA from a collection of cells, finding a specific gene within this DNA sample can be compared to finding a needle in a haystack. Consider the fact that each human cell contains approximately two metres (approximately six feet) of DNA. Therefore, a small tissue sample will contain many kilometres of DNA. However, recombinant DNA technology has made it possible to isolate one gene or any other segment of DNA, enabling researchers to determine its nucleotide sequence, study its transcripts, mutate it in highly specific ways, and reinsert the modified sequence into a living organism.

DNA CLONING

In biology, a clone is a group of individual cells or organisms all descended from one progenitor. This means that the members of a clone are genetically identical because cell replication produces identical daughter cells each time. The use of the word *clone* has been extended to recombinant DNA technology. If it were possible to produce many copies of a single fragment of DNA, such as a gene, these identical copies would constitute a DNA clone. Indeed, this is now possible. In practice, the procedure is carried out by inserting a DNA fragment into a small DNA molecule and then allowing this molecule to replicate inside a simple living cell such as a bacterium. The small replicating molecule is called a DNA vector (carrier). The most commonly used vectors are plasmids, circular DNA molecules that originated from bacteria, viruses, and yeast cells. Plasmids are not a part of the main cellular genome, but they can carry genes that provide the host cell with useful properties such as drug resistance, mating ability, and toxin production. They are small enough to be conveniently manipulated experimentally, and furthermore they will carry extra DNA that is spliced into them. The process of gene cloning is illustrated in Figure 13.

Restriction enzymes

Creating the clone. The steps in cloning are as follows. DNA is extracted from the organism under study and is cut into small fragments of a size suitable for cloning. Most often this is achieved by cleaving the DNA with a restriction enzyme. Restriction enzymes are extracted from several different species and strains of bacteria, in which they act as defense mechanisms against viruses. They can be thought of as "molecular scissors," cutting the DNA at specific target sequences. The most useful restriction enzymes make staggered cuts; that is, they leave a single-stranded overhang at the site of cleavage. These overhangs are very useful in cloning because the unpaired nucleotides will pair with other overhangs made using the same restriction enzyme. So, if the donor DNA and the vector DNA are both cut with the same enzyme, there is a strong possibility that the donor fragments and the cut vector will splice together because of the complementary overhangs. The resulting molecule is called recombinant DNA. It is recombinant in the sense that it is composed of DNA from two different sources. Thus, it is a type of DNA that would be impossible naturally and is an artifact created by DNA technology.

The next step in the cloning process is to cut the vector with the same restriction enzyme used to cut the donor DNA. Vectors have target sites for many different restriction enzymes, but the most convenient ones are those that occur only once in the vector molecule. This is because the restriction enzyme then merely opens up the vector ring, creating a space for the insertion of the donor DNA segment. Cut vector DNA and donor DNA are mixed in a test tube, and the complementary ends of both types of DNA unite randomly. Of course, several types of unions are possible: donor fragment to donor fragment, vector fragment to vector fragment, and, most important, vector fragment to donor fragment. There are special ways of selecting for vector molecules with donor inserts, as described below. Recombinant DNA associations form spontaneously in the above manner, but these associations are not stable because, although the ends are paired, the sugar-phosphate backbone of the DNA has not been sealed. This is accomplished by the application of an enzyme called DNA ligase, which seals the two segments, forming a continuous and stable double helix.

The mixture should now contain a population of vectors each containing a different donor insert. This solution is mixed with live bacterial cells that have been specially treated to make their cells more permeable to DNA. Recombinant molecules enter living cells in a process called transformation. Usually, only a single recombinant molecule will enter any individual bacterial cell. Once inside, the recombinant DNA molecule replicates like any other plasmid DNA molecule, and many copies are subsequently produced. Furthermore, when the bacterial cell divides, all of the daughter cells receive the recombinant plasmid, which again replicates in each daughter cell.

The original mixture of transformed bacterial cells is spread out on a surface of a growth medium in a flat dish

(Petri dish), so that the cells are separated from one another. These individual cells are invisible to the naked eye, but as each cell undergoes successive rounds of cell division, visible colonies form. Each colony is a cell clone, but it is also a DNA clone because the recombinant vector has now been amplified by replication during every round of cell division. Thus, the Petri dish, which may contain many hundreds of distinct colonies, represents a large number of clones of different DNA fragments. This collection of clones is called a DNA library. By considering the size of the donor genome and the average size of the inserts in the recombinant DNA molecule, a researcher can calculate the number of clones needed to encompass the entire donor genome, or, in other words, the number of clones needed to constitute a genomic library.

Types of genetic libraries

Another type of library is a complementary DNA (cDNA) library. Creation of a cDNA library begins with mRNA instead of DNA. These mRNA molecules are treated with the enzyme reverse transcriptase, which is used to make a DNA copy of an mRNA. The resulting DNA molecules are called cDNA. A cDNA library represents a sampling of the transcribed genes, whereas a genomic library includes untranscribed regions.

Both genomic and cDNA libraries are made without regard to obtaining functional cloned donor fragments. Genomic clones do not necessarily contain full-length copies of genes. Furthermore, genomic DNA from eukaryotes contains introns, which cannot be processed by bacterial cells, so even full-sized genes would not be translated. In addition, eukaryotic regulatory signals are different from those used by prokaryotes. However, it is possible to produce expression libraries by slicing cDNA inserts immediately adjacent to a bacterial promoter region on the vector; in these expression libraries, eukaryotic proteins are made in bacterial cells, which allows several important technological applications that are discussed below in DNA sequencing.

Several bacterial viruses have also been used as vectors. The most commonly used is lambda phage. The central part of the lambda genome is not essential for the virus to replicate in *E. coli,* so this can be excised using an appropriate restriction enzyme, and inserts from donor DNA are spliced into the gap. In fact, when the phage repackages DNA into its protein capsule, it includes only DNA fragments the same length of the normal phage genome.

Vectors are chosen depending on the total amount of DNA that must be included in a library. Cosmids are vectors that are hybrids of plasmid and phage and can carry larger inserts than either alone. Bacterial artificial chromosomes (BACs) are vectors based on F-factor (fertility factor) plasmids of *E. coli* and can carry much larger amounts of DNA. Yeast artificial chromosomes (YACs) are vectors based on autonomously replicating plasmids of *Sacchromyces cerevisieae* (baker's yeast). In yeast (a eukaryotic organism), a YAC behaves like a yeast chromosome and segregates properly into daughter cells. These vectors can carry the largest inserts of all and are used extensively in cloning large genomes such as the human genome.

Isolating the clone. In general, cloning is undertaken in order to obtain the clone of one particular gene or DNA sequence of interest. The next step after cloning, therefore, is to find and isolate that clone among other members of the library. If the library encompasses the whole genome of an organism, then somewhere within that library will be the desired clone. There are several ways of finding it, depending on the specific gene concerned. Most commonly, a cloned DNA segment that shows homology to the sought gene is used as a probe. For example, if a mouse gene has already been cloned, then that clone can be used to find the equivalent human clone from a human genomic library. Bacterial colonies constituting a library are grown in a collection of Petri dishes. Then a porous membrane is laid over the surface of each plate, and cells adhere to the membrane. The cells are ruptured, and DNA is separated into single strands—all on the membrane. The probe is also separated into single strands and labeled, often with radioactive phosphorus. A solution of the radioactive probe is then used to bathe the membrane. The single-stranded probe DNA will adhere only to the DNA of the clone that contains the equivalent gene. The membrane is dried and placed against a sheet of radiation-sensitive film, and somewhere on the film a black spot will appear, announcing the presence and location of the desired clone. The clone can then be retrieved from the Petri dishes.

DNA SEQUENCING

Once a segment of DNA has been cloned, its nucleotide sequence can be determined. The nucleotide sequence is the most fundamental level of knowledge of a gene or genome. It is the blueprint that contains the instructions for building an organism, and no understanding of genetic function or evolution could be complete without obtaining this information.

Uses. Knowledge of the sequence of a DNA segment has many uses, and some examples follow. First, it can be used to find genes. If a region of DNA has been sequenced, it can be screened for characteristic features of genes. For example, open reading frames (ORFs), long sequences that begin with a start codon and are uninterrupted by stop codons (except for one at its termination), suggest a protein-coding region. Also, human genes are generally adjacent to clusters of cytosine and guanine nucleotides (CpG islands). If a gene with a known phenotype (such as a disease gene in humans) is known to be in the chromosomal region sequenced, unassigned genes in the region will become candidates for that function. Second, homologous DNA sequences of different organisms can be compared to plot evolutionary relatedness both within and between species. Third, a gene sequence can be screened for functional regions. In order to determine the function of a gene, various domains can be identified that are common to proteins of similar function. For example, certain amino acid sequences within a gene are always found in proteins that span a cell membrane; such amino acid stretches are called transmembrane domains. If a transmembrane domain is found in a gene of unknown function, it suggests that the encoded protein is located in the cellular membrane. Other domains characterize DNA-binding proteins. Several public databases of DNA sequences are available for analysis by any interested individual.

Methods. The two basic sequencing approaches are the Maxam-Gilbert method and the Sanger method. In the most commonly used method, the Sanger method, DNA chains are synthesized on a template strand, but chain growth is stopped when one of four possible dideoxy nucleotides, which lack a 3′-hydroxyl group, is incorporated, preventing the addition of another nucleotide. A population of nested, truncated DNA molecules results that represents each of the sites of that particular nucleotide in the template DNA. These molecules are separated in a procedure called electrophoresis (Figure 14), and the inferred nucleotide sequence is deduced using a computer.

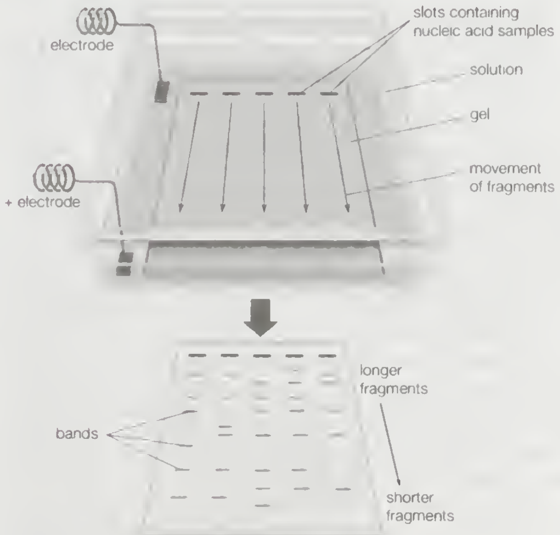

Figure 14: Electrophoresis is a technique that allows for the isolation and identification of nucleic acid samples.
Encyclopædia Britannica, Inc

In vitro mutagenesis. Another use of cloned DNA is in vitro mutagenesis. Mutations are useful to geneticists in enabling them to investigate the components of any biological process. However, traditional mutational analysis relied on the occurrence of random spontaneous mutations—a hit-or-miss method in which it was impossible to predict the precise type or position of the mutations obtained. In vitro mutagenesis, however, allows specific mutations to be tailored for type and for position within the gene. A cloned gene is treated in the test tube (in vitro) to obtain the specific mutation desired, and then this fragment is reintroduced into the living cell, where it replaces the resident gene.

One method of in vitro mutagenesis is oligonucleotide-directed mutagenesis. A specific point in a sequenced gene is pinpointed for mutation. An oligonucleotide, a short stretch of synthetic DNA of the desired sequence, is made chemically. For example, the oligonucleotide might have an adenine in one specific location instead of the wild-type guanine. This oligonucleotide is hybridized to the complementary strand of the cloned gene; it will hybridize despite the one base pair mismatch. Various enzymes are added to allow the oligonucleotide to prime the synthesis of a complete strand within the vector. When the vector is introduced into a bacterial cell and replicates, the mutated strand will act as a template for a complementary strand that will also be mutant, and thus a fully mutant molecule is obtained. This fully mutant cloned molecule is then reintroduced into the donor organism, and the mutant DNA replaces the resident gene.

Another version of in vitro mutagenesis is gene disruption, or gene knockout. Here, the resident functional gene is replaced by a completely nonfunctional copy. The advantage of this technique over random mutagenesis is that specific genes can be knocked out at will, leaving all other genes untouched by the mutagenic procedure.

Designer organisms

Transgenesis. The ability to obtain specific DNA clones using recombinant DNA technology has made it possible to add the DNA of one organism to the genome of another. The added gene is called a transgene. The transgene inserts itself into a chromosome and is passed to the progeny as a new component of the genome. The resulting organism carrying the transgene is called a transgenic organism or a genetically modified organism. In this way, a "designer organism" is made that contains some specific change required for an experiment in basic genetics or for improvement of some commercial strain. Several transgenic plants have been produced. Genes for toxins that kill insects have been introduced in several species, including corn and cotton. Bacterial genes that confer resistance to herbicides also have been introduced into crop plants. Other plant transgenes aim at improving the nutritional value of the plant.

Gene therapy. Gene therapy is the introduction of a normal gene into an individual's genome in order to repair a mutation that causes a genetic disease. When a normal gene is inserted into a mutant nucleus, it most likely will integrate into a chromosomal site different from the defective allele; although this may repair the mutation, a new mutation may result if the normal gene integrates into another functional gene. If the normal gene replaces the mutant allele, there is a chance that the transformed cells will proliferate and produce enough normal gene product for the entire body to be restored to the undiseased phenotype. So far, human gene therapy has been attempted only on somatic (body) cells. Somatic cells cured by gene therapy may reverse the symptoms of disease in the treated individual, but the modification is not passed on to the next generation. Germinal gene therapy aims to place corrected cells inside the germ line (*e.g.*, cells of the ovary or testis). If this is achieved, these cells will undergo meiosis and provide a normal gametic contribution to the next generation. Germinal gene therapy has been achieved experimentally in animals but not in humans.

Reverse genetics. Recombinant DNA technology has made possible a type of genetics called reverse genetics. Traditionally, genetic research starts with a mutant phenotype and, by Mendelian crossing analysis, a researcher is able to attribute the phenotype to a specific gene. Reverse genetics travels in precisely the opposite direction. Researchers begin with a gene of unknown function and use molecular analysis to determine its phenotype. One important tool in reverse genetics is gene knockout. By mutating the cloned gene of unknown function and using it to replace the resident copy or copies, the resultant mutant phenotype will show which biological function this gene normally controls.

Diagnostics. Recombinant DNA technology has led to powerful diagnostic procedures useful in both medicine and in forensics. In medicine, these diagnostic procedures are used in counseling prospective parents as to the likelihood of having a child with a particular disease, and they are also used in the prenatal prediction of genetic disease in the fetus. Researchers look for specific DNA fragments that are located in close proximity to the gene that causes the disease of concern. These fragments, called restriction fragment length polymorphisms (RFLPs) often serve as effective "genetic markers." In forensics, DNA fragments called variable number tandem repeats (VNTRs), which are highly variable between individuals, are employed to produce what is called a "DNA fingerprint." A DNA fingerprint can be used to determine if blood or semen left at the scene of a crime belongs to a suspect.

DNA fingerprinting

Genomics. The genetic analysis of entire genomes is called genomics. Such a broad-scale analysis has been made possible by the development of recombinant DNA technology. In humans, knowledge of the entire genome sequence has facilitated searching for genes that produce hereditary diseases. It is also capable of revealing a set of proteins, produced at specific times, in specific tissues, or in specific diseases, that might be targets for therapeutic drugs. Genomics also allows the comparison of one genome with another, leading to insights into possible evolutionary relationships between organisms.

Genomics has two subdivisions, structural genomics and functional genomics. Structural genomics is based on the complete nucleotide sequence of a genome. Each member of a library of clones is physically manipulated by robots and sequenced by automatic sequencing machines, enabling a very high throughput of DNA. The resulting sequences are then assembled by a computer into a complete sequence for every chromosome. The complete DNA sequence is scanned by computer to find the positions of ORFs, or prospective genes. The sequences are then compared to the sequences of known genes from other organisms, and possible functions are assigned. Some ORFs remain unassigned, awaiting further research.

Functional genomics attempts to understand function at the broadest level (the genomic level). In one approach, gene functions of as many ORFs as possible are assigned as above in an attempt to obtain a full set of proteins encoded by the genome (called a proteome). The proteome broadly defines all the cellular functions used by the organism. Function in relation to specific developmental stages also is assessed by trying to identify the "transcriptome," the set of mRNA transcripts made at specific developmental stages. The practical approach ultilizes microarrays, glass plates the size of a microscope slide imprinted with tens of thousands of ordered DNA samples, each representing one gene (either a clone or a synthesized segment). The mRNA preparation under test is labeled with a fluorescent dye, and the microarray is bathed in this mRNA. Fluorescent spots appear on the array indicating which mRNAs were present, thus defining the transcriptome.

Protein manufacture. Recombinant DNA procedures have been used to convert bacteria into "factories" for the synthesis of foreign proteins. This technique is useful not only for preparing large amounts of protein for basic research but also for producing valuable proteins for medical use. For example, the genes for human proteins such as growth hormone, insulin, and blood-clotting factor can be commercially manufactured. Another approach to producing proteins via recombinant DNA technology is to introduce the desired gene into the genome of an animal, engineered in such a way that the protein is secreted in the animal's milk, facilitating harvesting.

HEREDITY AND EVOLUTION

The gene in populations

Influences on heredity

In the study of heredity the first question that arises is how the genotype of an individual is formed from the constituents of the genotypes of his parents. This is the genetics of individuals or basic genetics. One may also inquire how the genotype in a fertilized egg cell influences the developmental pattern of the organism and thus realizes its potentialities. This is developmental genetics. An individual, at least an individual of a sexually reproducing species, is not, however, biologically complete in itself. Its biological role is actualized through its membership in a reproductive community, a Mendelian population. A Mendelian population consists of individuals among whom matings may or do occur. An individual is mortal and temporary; a Mendelian population has a continuity through time. The genetic processes in Mendelian populations are the subject matter of population genetics.

THE GENE POOL

A Mendelian population is said to have a gene pool. The gene pool is the sum total of the genes carried by the individual members of the population. The gene pool also continues through time. The genes of the individuals of the generation now living come from a sample of the genes of the previous generation; if these individuals reproduce, their genes will pass into the gene pool of the following generations. The Mendelian population and its gene pool in humans have a very complex structure. Individuals born and living close together are more likely to meet and to mate than those living far apart. In a widely distributed species such as *Homo sapiens,* the likelihood of mating of individuals born on different continents was, until the development of modern means of travel, very small. The gene pool of the human species is, accordingly, divided into the smaller gene pools of populations living in different regions. Aside from the geographic divisions, there are also linguistic, religious, social, economic, and educational barriers that break the gene pools into further, often overlapping, subdivisions. The smallest subdivision is referred to as an isolate or panmictic unit; it consists of a relatively limited number of persons (or animals or plants) that may be regarded as potential mates. Few of these divisions may be sharp enough to decide where one gene pool subdivision ends and the other begins, and yet these subdivisions are biologically meaningful.

A biological species, in sexually reproducing organisms, is defined as the most inclusive Mendelian population. The gene pool of *Homo sapiens* is an entity the limits of which are not in doubt, since no gene exchange between the human and any other related species takes place. Nor does the intraspecific differentiation impair the unity. There may never have been a marriage of, for example, an Eskimo and a Melanesian, but genetic communications between the Eskimo gene pool and the Melanesian gene pool occur through the chains of geographically intermediate populations. A genetic change arising anywhere in the world, if favourable, may spread throughout humanity. This is how genetic changes may have transformed the ancestral prehuman species into the present one. This genetic unity makes any genetic damage (*e.g.,* that caused by exposure to high-energy radiation) a concern of all people, regardless of whether the damage is inflicted more heavily on one portion of the human population than on another.

THE HARDY–WEINBERG PRINCIPLE

The basis for population genetics

In 1908, Godfrey Harold Hardy and Wilhelm Weinberg independently formulated a theorem that became the foundation of population genetics. According to the Hardy–Weinberg principle, two or more gene alleles will have the same frequency in the gene pool generation after generation, until some agent acts to change that frequency. Consider a population that is, as most human populations actually are, a mixture of individuals with M, N, and MN blood types. An individual witn M blood is a homozygote with two *M* alleles (*MM*), an N individual has two *N* alleles (*NN*), and an MN individual is a heterozygote (*MN*). Suppose that a population consists of 49 percent of individuals with M, 42 percent with MN, and 9 percent with N bloods. The frequencies of the blood types in the next and the following generations can be calculated. Assume for simplicity that (1) marriages are at random with respect to the blood groups, (2) people with different blood groups have neither advantages nor disadvantages in survival or in reproduction, (3) the alleles *M* and *N* do not change frequently by mutation, (4) there is no migration into or out of the population, and (5) the population is large enough so that chance fluctuations may be ignored. Also assume that all individuals produce equal numbers of sex cells with each of the pair of alleles they carry and that the sex cells of the parents combine at random in fertilization.

Persons with M blood produce sex cells with the allele *M,* and these sex cells will amount to 49 percent of the total. Persons with MN blood produce equal numbers of *M*- and of *N*-bearing sex cells—*i.e.,* 21 percent of each. Finally, persons with N blood will give *N*-bearing sex cells, 9 percent of the total. The gene pool will, therefore, contain $49 + 21 = 70$ percent of *M*- and $21 + 9 = 30$ percent of *N*-type sex cells, or, using decimals, 0.7 *M* and 0.3 *N,* respectively. These sex cells will combine to produce the following blood types in individuals: $0.7 \times 0.7 = 0.49$, or 49 percent of M; 0.3×0.3, or 9 percent of N; and $2 \times 0.7 \times 0.3$, or 42 percent of MN. Generalizing, if the proportions of *M* and *N* genes in the gene pool are p and q, respectively, the frequencies of the blood groups will be, generation after generation:

$$p^2 + 2pq + q^2 = 1.$$

(In this expression p^2 represents the genotype *MM,* q^2 the genotype *NN,* and pq the genotype *MN.*) This expression is the Hardy–Weinberg formula, which describes the genetic equilibrium status in populations. The genetic composition of a population can meaningfully be described in terms of the frequencies of various alleles of the genes in the gene pool. Different populations of the same species are likely to differ in the frequencies of some, probably of many, genes. If the gene frequencies are different, the populations are distinct; if the differences are large, one may decide to give these populations different subspecific names.

CHANGES IN GENE FREQUENCIES

The Hardy–Weinberg principle predicts that gene frequencies will remain constant from generation to generation within a population that meets certain assumptions. It further predicts that if mating is random in regard to genetic traits, then the frequencies of genotypes will also remain constant in succeeding generations. Yet if all gene frequencies remained constant in populations indefinitely, evolution could not take place. Evolution is, in the last analysis, change of gene frequencies.

Evolution

The assumptions that underlie the Hardy–Weinberg principle are, in fact, theoretical considerations that are never met in natural populations. Mutations and migrations can affect gene frequencies. Many natural populations are small enough that chance fluctuations can significantly alter gene frequencies. Moreover, in many cases matings may be selective rather than random in regard to certain genetic traits; this will alter the frequencies of genotypes in succeeding generations. The effects of these phenomena are described in this section.

Finally, and most importantly in considering the genetics of evolution, a certain genotype may offer an advantage in terms of reproduction or survival over its counterparts. Such advantageous genotypes, and their constituent alleles, will increase in frequency in succeeding generations. This phenomenon, called selection, is dealt with at length below (see *Selection as an agent of change*).

Mutations. As has been discussed, under most circumstances newly formed chromosomes and their genes are perfect reproductions of the originals. This remarkably stable copying process is the basis of the continuity of living species, generation after generation, for each specific characteristic encoded by the genes.

It also has been shown, however, that mutations—in the form of chromosomal aberrations and miscopying of DNA—do occur. Mutations produce the potential for new traits. Even when only a single gene in one cell is mutated, the copying process tends faithfully to reproduce the changed DNA in all the descendants of that particular cell. Indeed, mutation appears to be a basic cellular mechanism underlying evolution.

That mutations can arise in response to environmental agents was first demonstrated by Hermann J. Muller, who in 1926 demonstrated that *Drosophila* flies exposed to X rays suffer high rates of mutation. It is now known that other forms of radiation, as well as a variety of chemicals, can serve as potent mutagenic agents, producing both chromosomal aberrations and changes in the DNA of individual genes. The implications of these findings are discussed below in *Human genetics.*

In discussing mutation in the context of gene frequencies and evolution, it is imperative to recall the difference between germinal mutations and somatic mutations. Only the former are passed on to offspring, who will then "breed true" for the altered or defective trait. It is germinal mutations, then, that can produce the greatest effect in altering gene frequencies in succeeding generations of a population.

Gene flow. Migrations of individuals into a population can introduce new alleles or can increase the frequencies of those already present; similarly, migration out of a population can remove alleles or decrease their frequencies. This gene flow may be negligible in a highly isolated population, such as one on a remote island, but it operates freely among adjacent populations of species that occupy large ranges. Gene flow is most readily appreciated in human and other animal populations made up of mobile individuals; it occurs in plants as well, however, as pollen may be carried by wind or by animals from one population to another.

Genetic drift. This term refers to the effects of chance fluctuations on gene frequencies in small populations. Consider a small population in which there are two alleles—*a* and *A*—for a particular gene. If the frequency of one of these alleles, say *a,* is low to begin with, a chance event that has nothing to do with the selective value of that allele could result in its complete elimination from the population. The population would then consist entirely of *AA* individuals. Such an event is referred to as a fixation for gene *A*. Conversely, a chance event could result in the loss of several *AA* individuals from the population; in this case, the frequency of *a* would increase.

Founder effect

Genetic, or random, drift is most obviously manifested in what is known as the "founder effect." This occurs when a small group of individuals—or even just one pregnant female—migrates into a new region, or when a small group becomes reproductively isolated from its parent population without migration. The genes carried by the founders of the new population will often be small, atypical, and unbalanced samples of the gene pool of the population whence they came. In the case of a new, small population established by migration, the subsequent frequencies of alleles will depend not only on the chance distributions carried by the founders but also on the environmental influences (*i.e.,* the selection pressures) of the new location. In the case of reproductive isolation without migration, the situation depends more on the chance distribution of alleles in the small group at the time of isolation and the relative degree of consanguinity among those mating. These factors might explain the increased frequency of a relatively rare autosomal recessively inherited disease, Tay-Sachs, among Jews of eastern European origin. For many years these people were forced to live in small isolates and were socially ostracized by the population around them. As a result, a mutant gene present in the original small group had the opportunity to express itself as a lethal disease among homozygotes.

Selective mating. Mating may be selective rather than random with respect to a given gene. Suppose that persons with M, MN, and N bloods prefer to marry individuals with a blood group the same as themselves. Selective mating will not, by itself, change the gene frequencies, but it will disturb the Hardy–Weinberg equilibrium in another way. The relative frequencies of the homozygotes (*MM* and *NN*) will increase from generation to generation, while those of the heterozygotes (*MN*) will decrease. Eventually the population will consist of homozygotes only. Preferential mating of unlike genotypes will, on the contrary, increase the incidence of the heterozygotes, but it will not, no matter how long continued, eliminate the homozygotes.

Selection as an agent of change

NATURAL SELECTION AND DARWINIAN FITNESS

Sexual reproduction under simple (Mendelian) inheritance is a conservative force that tends to maintain the genetic status quo in a population. If a gene frequency is 1 percent in a population, it tends to remain at 1 percent indefinitely unless some force acts to change it. Outside of the laboratory, the most powerful force for changing gene frequencies is natural selection.

The carriers of some genes may survive more often or be more fecund than the carriers of other genes. When the carriers of different genes are not equally efficient in transmitting these genes to the succeeding generations, the result is natural selection. When the inequality of the transmission rates of the genes is imposed by human will, the result is artificial selection. In general, the genes that confer on their possessors a superior reproductive efficiency will increase in frequencies from generation to generation, and the reproductively inferior genes will become less frequent.

Imagine a population that carries two alleles—A_1 and A_2—for a particular gene. Suppose that the relative numbers of the surviving progeny left by the carriers of the genotypes A_1A_1 and A_2A_2 are in the ratio $1 : 1 - s$ (the value s is called the selection coefficient). If for every 100 offspring of A_1A_1 parents only 90 surviving offspring are left by A_2A_2 parents, then $s = 1/10$ or 0.1. The heterozygotes, A_1A_2, may leave as many progeny as A_1A_1 (if A_1 is dominant) or as many as A_2A_2 (if A_2 is dominant) or an intermediate number (if neither is dominant). Alternatively, the heterozygotes may exhibit the quality of hybrid vigour (heterosis); that is, they may be reproductively superior to both homozygotes A_1A_1 and A_2A_2. And finally (though this is rare except in species hybrids) the heterozygotes may be at a disadvantage compared to both homozygotes. The situation is simplest if the heterozygotes (A_1A_2) are equal in reproductive efficiency to one of the homozygotes or intermediate between the two.

Hybrid vigour

Whichever gene, A_1 or A_2, confers a superior reproductive efficiency on its possessors will increase in frequency in the population. The increase will continue generation after generation; given enough time (*i.e.,* enough generations) the more efficient gene will eliminate and supplant the less efficient one entirely. How rapid or slow the gene frequency changes will be depends on the magnitude of the selection coefficients. Table 4 gives several examples for a dominant allele, for a recessive allele, and for no dominance—*i.e.,* for the case in which the fitness of the heterozygote is intermediate between the two homozygotes. The two alleles in the population with which the selection starts are assumed to be equally frequent, $p = q = 0.5$. The selection coefficients of one (lethal), 0.5, 0.1, and 0.01 are considered, and the gene frequencies after one, two, five, 10, 20, 50, and 100 generations of such selection are given.

The homozygotes for a recessive gene allele may not reproduce at all. With natural selection this may happen because they are inviable (lethal) or sterile; with artificial selection the same result is accomplished if the breeder kills them or does not use them as parents. The recessive allele is then opposed by a selection $s = 1$. Table 4 shows that a gene with an initial frequency of 0.5 will decrease to 0.33 after one generation, to 0.25 after two, and to 0.01 after 100 generations. With weaker selection (s smaller than unity) the decrease of the recessive allele will, of course, be slower. Note, however, that in all cases the frequency change is more rapid when the gene is common than when

Table 4: The Decrease of the Frequencies of Genes Discriminated Against by Different Selection Pressures
(the frequency of the gene in the initial population is 0.5)

50	—	—	0.07	0.438
100	—	—	0.006	0.377

it is rare. A dominant allele opposed by a selection s = 1 (a dominant lethal) disappears in a single generation, and even weaker selections against dominants are more efficient than similar selections against recessives. A selection in favour of a recessive is, of course, just the reverse of that against a dominant, and vice versa. The frequencies can be read from Table 4 by subtracting the frequencies given from unity. When the dominance is absent, the efficiency of selection is, as shown in Table 4, intermediate between those for recessives and for dominants.

The attainment of balanced polymorphism

A most interesting, and at first sight paradoxical, outcome of selection arises if the heterozygote is superior to both homozygotes. Neither the gene A_1 nor A_2 is allowed to crowd the other out or to disappear entirely. Instead, a genetic equilibrium is reached, and the population attains the state of the so-called balanced polymorphism. All three genotypes continue to occur in the population, with frequencies dependent on the relative magnitudes of the selection coefficients s_1 and s_2. This will be true even if one of the homozygotes is seriously incapacitated, inviable, or sterile. The possible importance of this in human populations is considered below.

Darwin's description of the process of natural selection as the survival of the fittest in the struggle for life is a metaphor. "Struggle" does not necessarily mean contention, strife, or combat; "survival" does not mean that ravages of death are needed to make the selection effective; and "fittest" is virtually never a single optimal genotype but rather an array of genotypes that collectively enhance population survival rather than extinction. All these considerations are most apposite to consideration of natural selection in humans. Decreasing infant and childhood mortality rates do not necessarily mean that natural selection in the human species no longer operates. Theoretically, natural selection could be very effective if all the children born reached maturity. Two conditions are needed to make this theoretical possibility realized: first, variation in the number of children per family. and, second, variation correlated with the genetic properties of the parents. Neither of these conditions is far-fetched.

Darwinian fitness is sometimes referred to also as the adaptive value or the selective value; these terms are best treated as synonyms, although they may have somewhat different connotations. The Darwinian fitness of a genotype, or of a group of genotypes, is measured as the contribution of their carriers to the gene pool of the succeeding generation, relative to the contributions of other genotypes present in the same population. In the example given above, the Darwinian fitness of the genotype A_1A_1 was taken to be unity and the fitness of A_2A_2 as 1 − s or less than unity. The fitness is, of course, subject to change in different environments; the carriers of a genotype A_1A_1 may leave more surviving progeny than A_2A_2 in a certain environment, but the reverse may be the case in another environment. Darwinian fitness is reproductive fitness; bodily or mental vigour, health, and energy obviously contribute to this fitness but only insofar as they result in a superior reproductive capacity. Mules, no matter how strong and resistant, must be ranked zero in Darwinian fitness because they are sterile. The emphasis on reproductive success rather than on survival is characteristic of the modern concept of natural selection, as distinguished from the classical one. The difference is not, however, so great as it may seem at first glance; the carriers of a genotype evidently must survive in order to reproduce, and they must reproduce in order to survive in the next generation.

VARIETIES OF NATURAL SELECTION

Normalizing selection

There are several kinds of natural selection, rather different in their biological consequences and in their importance to humans. The simplest of them is the normalizing selection, which was already known before Darwin but, of course, not under this name. Normalizing selection counteracts the accumulation in populations of hereditary diseases, malformations, and weaknesses. Suppose that a gene allele A_1, the carriers of which have a high Darwinian fitness, mutates to a state A_2, which lowers the fitness. If A_2 is a dominant lethal or a gene that renders its carriers sterile, then (as shown in Table 4, column s = 1.0) all the A_2 mutants will be eliminated in the same generation in which they arise. A new crop of mutants will, of course, appear in the next generation. If, however, the selection is not so completely efficient, some mutant genes will escape its dragnet and will be transmitted to the next generation. That generation will contain all the newly arisen mutants, a part of the mutants that arose in the preceding generation, a smaller part of those having arisen two generations ago, etc. How great a "genetic load" of uneliminated mutants a population can accumulate will depend principally on two factors—how often the mutation arises and how much it lowers the Darwinian fitness.

Simple formulas have been worked out to describe the situations that arise. Suppose that a deleterious mutation from $A_1 \rightarrow A_2$ occurs at a rate u per generation. Suppose further that the mutant is discriminated against by a selection coefficient s. If, then, the mutant A_2 is dominant to the original state, A_1, the frequency of A_2 in the gene pool will be u/s. If A_2 is recessive to A_1, its accumulated frequency will be much higher, namely $\sqrt{u/s}$. The reason deleterious recessive mutants are allowed to attain higher frequencies than equally deleterious dominants is simple: a recessive mutant may be carried in many heterozygotes, in which it does not express itself, and is consequently protected, or sheltered, from the weeding-out action of natural selection. With mutants that are neither dominant nor recessive, the accumulation will be intermediate between u/s and $\sqrt{u/s}$.

All human populations doubtless carry genetic loads consisting of harmful mutant genes. This cannot be blamed entirely on culture, civilization, or on any other specifically human attributes. Populations of *Drosophila* flies and of other sexually reproducing organisms also carry genetic loads. The accumulation of the genetic loads is a necessary consequence of the occurrence of mutations, most of which are harmful but not always harmful enough to be eliminated immediately after they are produced. Harmful mutations are accumulated until the numbers of the respective mutant genes become equal to the numbers eliminated by natural selection in the same population. The population is then said to be in the state of "genetic equilibrium." Muller has termed the elimination of harmful mutants "genetic death." Genetic "death" is sometimes cruel, sometimes rather benign. The death of a child from a severe hereditary disease and the genetically conditioned failure to have one more child are both genetic deaths. The higher the mutation rates, the more harmful are the mutants produced and the more frequent are the genetic deaths. In populations that have reached genetic equilibrium, the total number of genetic deaths will be equal to the total number of the mutations subject to normalizing natural selection.

Heterotic balancing selection

A very different form of natural selection is heterotic balancing selection. It occurs when the Darwinian fitness of a heterozygote exceeds the fitness of both homozygotes, a situation mentioned above. Heterotic balancing selection also leads to genetic equilibrium but not to an equilibrium between mutation and the normalizing selection. The balanced polymorphism that is established is due to the selection favouring the heterozygotes against the homozygotes. In a sexually reproducing population the heterozygotes tend, however, to produce a fresh crop of homozygotes in every generation. The maintenance in human populations of the grave hereditary disease sickle-cell anemia is apparently due to this form of selection. The sickling gene (Hb^S) produces a specific type of hemoglobin, while normal hemoglobin is related to another allele (Hb^A). Accordingly, the possible genotypes are Hb^AHb^A, Hb^AHb^S, and Hb^SHb^S. The latter individuals are homozygous for the sickle-cell gene and will develop severe anemia. While the condition is not lethal before birth, such individuals rarely survive long enough to exhibit more than minimal fitness in the Darwinian sense of capacity to reproduce. On these grounds it might be concluded that natural selection eventually should drive the frequency of the Hb^S gene to complete elimination or at least down to the one in 100,000 level of the mutation rate. One would theorize a transient polymorphism; that is, one on the way out, toward fixation of the favoured allele.

Evidence, however, seems to contradict theory since, in a number of African tribes living in their ancestral tropical lowlands where the falciparum form of malaria is widespread, the Hb^S (sickling) gene is very common indeed. On the other hand, the same gene is rare in genetically related but isolated tribes living in highlands that are free of mosquitoes that transmit this type of malaria. This discrepancy between lowland and highland people has led to the hypothesis that the Hb^AHb^S heterozygote is fitter and capable of leaving more offspring than is the homozygous normal Hb^AHb^A in a highly malarious environment. This extra measure of protection is evidently provided by the sickle-cell hemoglobin (Hb^S), which is detrimental to the malaria parasite. In malarial environments, populations that contain the sickle-cell gene, therefore, have advantages over populations free of this gene. The former populations are in less danger from the ravages of malaria, although they "pay" for this advantage by sacrificing in every generation some individuals who die of anemia. The lethal disease caused by homozygosity for the sickle-cell gene certainly brings about some genetic deaths; it is a part of the genetic load of the populations. But this genetic load, due to a disadvantage of being homozygous for certain genes, is very different from the mutational load controlled by the normalizing selection. The former is maintained by the heterotic balancing selection, while the latter is maintained by recurrent mutation.

Diversifying selection

Another form of natural selection is diversifying, or disruptive, selection. In many discussions and mathematical analyses of selection this simplifying assumption is adopted: that the environment in which a population lives is uniform and that the selection advantages and disadvantages of different genotypes are independent of their frequencies in the population. This simplification, however, flies in the face of reality. Many animals can subsist on a variety of foods; many plants grow on different soils; humans have to fill many different employments, functions, professions, and social roles. It is most likely that some genotypes will be fitter in some environments than they are in other environments. Diversifying selection will then favour different genotypes in different subenvironments, or ecological niches, that occur in the population.

A special form of selection occurs in mammals due to the incompatibility of certain maternal genotypes with those of their unborn children. The best studied case in humans is that of a Rhesus-positive fetus in a Rhesus-negative mother (see below *The genetics of human blood*). This selection should, theoretically, make the entire population either Rhesus positive or Rhesus negative. For reasons that have not been clarified, it does not appear to be doing this. Another special kind of selection is that due to so-called meiotic drives, disturbances of the Mendelian segregation mechanisms, which result in sex cells carrying certain gene alleles being more or less frequent than expected on a random basis.

Directional selection

The last to be mentioned, but in the long run possibly the most important form of selection, is directional selection. Suppose that the climate becomes warmer or cooler, that there appears a new source of food or a new predator or disease, or that there occur some other prominent environmental changes. Some genotypes will, then, become more favourable and others less favourable. Directional natural selection will operate to reconstruct the gene pool of the population in accord with the demands of the new environment.

NATURAL SELECTION IN OPERATION

When the antibiotic streptomycin is added in a sufficient concentration to a culture of colon bacteria, only the streptomycin-resistant mutants are able to reproduce, while the streptomycin-sensitive cells are eliminated. If experimenters add the streptomycin to a culture in order to obtain resistant strains of the bacteria, they are effecting artificial selection. Natural selection acts, however, very much in the same fashion. Widespread and often rather indiscriminate utilization of antibiotics against various infectious microorganisms led to quite unintended consequences—the appearance of numerous "drug-fast" infections. In some instances (as with gonorrhea in some countries) the treatment with penicillin, originally very effectual, became less reliable or even useless as selection brought about a drug-resistant strain of gonococci.

Genetic resistance to DDT

Essentially the same process took place with more complex organisms, various insect pests, in response to the introduction of certain potent insecticides. The first such insecticide, DDT, was used on a large scale during and after World War II. The discovery of DDT, followed by invention of many other insecticides of similar or even greater potency, led to hope of eradication of all insect pests. This enthusiasm was short lived, since by 1947 DDT-resistant populations of the housefly were recorded in Italy and soon thereafter in other countries. It apparently takes the fly only two to three years to evolve a genetically conditioned resistance to DDT, and similar resistances arise against other insecticides as well. During the Korean War DDT-resistant lice emerged. Attempts to eradicate malaria-bearing mosquitoes by DDT sprays resulted in DDT-resistant mosquito populations. Laboratory experiments with *Drosophila* and with houseflies have shown that one can artificially select for insecticide resistance. Moreover, there are apparently genetically different resistant strains, some differing from the sensitive ones by a single gene with a strong effect and others by accumulation of several genetic changes, each increasing the resistance only slightly but giving strong resistance in the aggregate.

Industrial melanism

Colour changes in moth populations provide another example of natural selection. A black mutant of the peppered moth (*Biston betularia*) was found at Manchester, England, in 1848. Until that time the prevalent form of this species was light gray with dark speckles. The frequency of the black variant rapidly increased in the immediate area and reached about 99 percent by 1898. Dark coloration, melanism, has arisen and spread in many species of British moths belonging to different genera and families. The spread of the melanic forms was most rapid in and near industrial areas, where the foliage and the tree trunks are blackened with soot and other atmospheric pollutants. The spread of the dark forms is consequently known as industrial melanism. The light form of *Biston betularia* is protectively coloured when resting on tree trunks covered with lichens but conspicuous on blackened trunks on which the lichens have been largely destroyed by pollution. The selective agents are the insectivorous birds that feed on the moths; they find the light moths easily on dark tree bark and the black moths easily on light tree trunks. H.B.D. Kettlewell has verified the hypothesis by exposing known numbers of light and of melanic moths in localities with blackened and with unpolluted vegetation. A greater proportion of the blacks than of the whites remained alive and were recaptured on dark vegetation, and the opposite was observed on the unpolluted vegetation. Genetically, the difference between the light and the melanic forms has been shown to be due to a single gene, the allele for melanism being dominant to that for the light coloration.

Plants that grow in habitats created or modified by human activities are often different from their wild relatives and different in ways that adapt them to survive and reproduce in their respective habitats. *Camelina sativa,* a plant of the mustard family, is a common weed in fields of cultivated flax in Europe. The *Camelina* that contaminates the flax fields is, however, genetically different in several ways from that growing outside the fields. *Camelina* outside flax fields is a low-growing, branched plant with small seeds; that growing in flax fields is much taller, unbranched, and with larger seeds that resemble those of the flax in size and in specific gravity. The characteristics of *Camelina* growing in flax fields are such that it is harvested together with the flax, and its seeds remain with those of flax during the winnowing process. The variety in the flax fields is doubtless derived from the original form now found growing freely; the remarkable adaptations that are found in the former have, then, developed since farmers started to plant flax on fairly large scales. Genetically, the varieties of *Camelina* differ from each other in several, probably in many, genes. The process of natural selection—incidentally abetted by the human activity of flax cultivation—has, thus, created a new adaptive genetic system.

The examples of drug resistance in bacteria, pesticide resistance in insects, and industrial melanism in moths all involve directional natural selection, which, if continued long enough, leads to replacement of old gene alleles by new ones. Balancing natural selection has a different biological function—it maintains genetic diversity, or polymorphism, in populations. Selection pressures involved in balancing selection in nature are sometimes quite high. This is very useful to those engaged in research on selection, since it is evidently easier to detect strong selection than weak selection.

GENETICS OF SPECIES DIFFERENCES

The nature and origin of species are dealt with in the article EVOLUTION, THE THEORY OF, particularly in the section *Species and speciation.* Here it is necessary to consider only the genetic composition of species differences in sexually reproducing and outbreeding organisms. In general, species are considered to be populations of organisms between which breeding is impossible or significantly limited under natural conditions. (This limitation does not hold for the mating [hybridization] of cells of different species by the methods of somatic cell genetics [see above].

An individual belongs to only one species, unless that individual is a species hybrid. Mules, hybrids between the horse and donkey, are sterile because of abnormalities in the processes of sex-cell formation in their gonads. Sterility of hybrids between species, if viable hybrids between them can be obtained at all, is observed very frequently, though some experimentally obtained species hybrids have proved to be fertile.

The origin of distinct populations

Scientists have asked what causes the development of the gene-frequency differences between populations that live in different territories, or, in other words, what makes these populations distinct. The probable explanation is that genetic differences between populations arise in most cases through natural selection in response to the local environments that prevail in the territories they inhabit. It is, however, very difficult to verify this explanation in many concrete instances of race differentiation. For example, it is probable that the dark skin pigmentation of many human populations that live, or have until recently lived, in tropical and subtropical countries protects them from sunburns. It is probable also that the light skin colours of the natives of Europe facilitate the acquisition of vitamin D in regions with deficient sunshine. The evidence for even these hypotheses is not as conclusive as might be desired. But when it comes to human traits such as hair form and shapes of the nose, lips, and cheekbones, no acceptable evidence of adaptive significance is available. The situation is no better with animals and plants: for most physical differences the adaptive significance is unknown.

Attempts have been made to envisage factors other than natural selection that could be responsible for genetic differentiation of populations. Appeals are frequently made to pleiotropism of the gene action; a visible difference may in itself be neither adaptive nor unadaptive, yet it may be only an outward sign of an underlying physiological difference that is adaptively important. An elegant example is the coloration of onions—red and purple bulbs are resistant to the attacks of a smudge fungus, while white bulbs are highly susceptible. A trait may also be important as a sexual recognition mark, or it may play a role in the courtship ritual.

A most interesting possibility that should be seriously considered is that some differences between populations may be due to random genetic drift. As was discussed above, genetic drift acts on small populations. Suppose that a species lives in many isolated colonies, some of them consisting of only tens or perhaps hundreds of individuals. Chance events may cause the gene frequencies in the different colonies to drift apart. How important this random genetic drift may be in race differentiation is controversial. That genetic drift does occur is certain; a simple example is that in small villages a sizable fraction of the inhabitants sometimes have the same surname, and different surnames are frequent in different villages. Increasing or decreasing frequencies of the surnames evidently go together with increases or decreases of the frequencies of certain genes that the ancestors of the people with these surnames carried. As discussed, genetic drift can also arise from the founder effect. When the populations of new colonies founded by a small number of individuals expand, they will be found to differ genetically from each other and from the ancestral population. Natural selection will then come into operation, giving rise to new balanced gene pools. The founder effect was probably important in the development of some human populations. Many groups may be the descendants of small numbers of original migrants and settlers. Whether the random genetic drift alone can explain the origin of the gene complexes that differentiate species is very doubtful. The point is, however, that genetic drift and natural selection are not mutually exclusive alternatives; it is not one or the other but the interaction of both that brings about differentiation. The founder effect is a special case of random genetic drift. The gene pool of a colony derived from a single immigrant or several pairs of immigrants may need a restructuring by natural selection to become properly adapted to the new environment.

OUTBREEDING AND INBREEDING

Human beings make up an outbreeding species. Marriage between close relatives is forbidden by custom and by law in most human societies. Whether the proscription initially was based on biological or social considerations is a matter of question. The prohibition may seem reasonable, however, in view of the evidence accumulated by practical breeders and geneticists. In normally outbreeding species, the progeny of matings in which the parents are close relatives tend to be less vigorous than the offspring of unrelated parents. This is a consequence of the genetic loads of deleterious recessive genes carried in populations. A recessive gene is more or less innocuous in the heterozygous condition, but its chances of becoming homozygous are greater in the offspring of parents who are close relatives (and therefore have more similar genotypes) than in families where the parents are not closely related.

The effects of outbreeding and inbreeding

It is worthwhile to stress at this point that the effects of outbreeding and inbreeding on the vigour, viability, and fertility of the offspring depend upon the reproductive biology of the species or the population in which they occur. Outbreeding is not invariably or necessarily invigorating, nor is inbreeding invariably or necessarily debilitating. Wheat is an example of a plant that is predominantly self-pollinating. Self-pollination is, of course, the closest possible form of inbreeding, but this inbreeding does not progressively weaken the vigour of a wheat strain. The converse, however, is observed with corn. Inbreeding decreases the yield, and the intercrossing of inbred lines restores hybrid vigour in the progeny. One may say that hybrid vigour (heterosis) is the normal state of a corn population, while inbreeding and a prevalence of homozygosis is the normal state in wheat. In species and populations in which the reproductive biology is adjusted to outbreeding, consanguinity leads to a decline in the average vigour and to the appearance of relatively many individuals with hereditary diseases and malformations. Just what kind of a malformation or ill health, if any, will appear in a given progeny depends on what deleterious recessive genes were carried by the common ancestor of the relatives who mate. This will certainly be different in different families. The histories of the reigning houses of Egypt and the Peruvian Incas, where the monarchs allegedly married their sisters, are not sufficiently well documented to conclude that in these instances the incestuous marriages resulted in no weakening of the progeny. High childhood mortality may have gone unrecorded; furthermore, "sister" may have been, in some instances, a title bestowed upon a person rather than indicative of an actual relationship.

It is important to study how much inbreeding depression will occur in a given species or population, and a great deal of information in this direction is being accumulated. With rare exceptions, the highest degree of consanguinity that occurs in human populations with appreciable frequency is marriage of first cousins, resulting in homozygosis of 6.25 percent of the genes in the progeny. A genetic counselor would hardly be justified in discouraging all marriages of people known to be relatives, and yet he may point out that the chance of genetic weaknesses in the progeny of such marriages is measurably greater than when unrelated persons marry.

GENETIC LOAD AND HYBRID VIGOUR

How hereditary variability is maintained in populations of sexually reproducing species is an unsettled and controversial question. The classical theory assumes that the pressure of mutation generating detrimental genetic variants is the main factor. The balance theory, while not denying that some variability is maintained by recurrent mutation, considers that a far from negligible portion of the variability is preserved by natural selection. These two theories, though they are not incompatible alternatives, have interestingly different theoretical and even philosophical implications.

According to the classical theory, a majority of the genes a species has are fixed, uniform, and homozygous in most, or even in all, individuals. The minority of the genes that are not fixed are represented by two or more variant alleles. One allele of each gene is "normal," and it confers a high fitness on its possessors; the others are mutant, abnormal, and more or less deleterious. This view is logically connected with the conception of the "optimal" genotype. The optimal genotype is the one that contains only normal genes. Any deviation from the optimum genotype will be detrimental. Nevertheless, the process of mutation unrelentingly generates detrimental mutant genes, lowers fitness, and creates a genetic load. A genetic load can, in this view, be defined as the deviation of the observed fitness from that produced by the optimum genotype. The weakness of this definition is obvious: the optimum genotype is operationally elusive; it cannot be located and its fitness cannot be measured.

The balance theory of population structure

The balance theory of population structure takes a somewhat more optimistic view. Not all genetic variability present in populations is a regrettable departure from the optimal genotype. Some of this variability is, on the contrary, an adaptive device that permits the population to secure a firmer hold on its environment. The environment is never uniform; it has a greater or lesser variety of ecological niches, opportunities for living that members of the population can exploit. A living species or population faces many diverse environments, not a single environment. Two genetic strategies are possible to cope with environmental complexity. First, there may be genotypes that react favourably in several environments. Second, there may be a variety of more or less specialized genotypes to match the variety of environments.

Nature has used both strategies in the evolutionary process. A sexually reproducing population contains a variety of hereditary endowments. Most, and perhaps all, individuals may be heterozygous for many genes; it is now known, for example, that humans are heterozygous at a minimum of 30 percent of the genetic loci responsible for the serum proteins. Any gene that is rare will be carried in heterozygotes much more frequently than in homozygotes (except in highly inbred or self-fertilizing species). Natural selection operates in sexual populations chiefly with heterozygotes. It will tend to make the heterozygotes highly fit, even if the corresponding homozygotes are low in fitness. In other words, natural selection promotes hybrid vigour or heterosis and maintains the variant genes in a state of balanced polymorphism. It takes a variety of genetic endowments to make a world worth living in.

Natural selection cannot prevent the appearance of some individuals of inferior fitness. In a population in which no two individuals carry the same genes, it is not possible to describe the genetic load as the deviation from the optimal genotype. This latter will be represented by a single individual or not at all. An operationally meaningful measure of fitness is that of the average or norm for a given population. The pronounced negative deviants from this average may be considered as constituents of the genetic load and the positive deviants as the genetic elite. Between the genetic load and the genetic elite there is the adaptive norm comprising a majority of the genotypes that are formed. The division lines between the load, the adaptive norm, and the elite can only be established by a convention. For most purposes, the load and the elite should probably refer to fairly extreme negative or positive deviations from the population mean. One may, however, foresee that some genetic processes will cause these deviations to become more or less frequent. For example, a genetic radiation damage or a greater incidence of marriages between relatives would increase the expressed genetic load compared to what it is at present.

The most impressive success scored to date, in attempts to utilize the genetic elite of an agricultural plant for increasing yields of a useful product, is represented by hybrid corn. Hybrid corn is obtained by artificially crossing inbred corn strains in order to exploit the phenomenon of hybrid vigour or heterosis.

ARTIFICIAL SELECTION

Hybrid corn is the most impressive but not the only achievement of genetics in agriculture. General accounts of animal and plant breeding can be found in the article FARMING. This section is concerned only with the genetic basis of the methods used in breeding programs. It should be kept in mind that the inbreeding-heterosis technique is most likely to succeed with species that are normally cross-fertilizing and outbred and less so in habitually inbreeding or self-pollinating forms (like wheat and barley).

In practicing artificial selection, the breeder seeks to identify and propagate those genotypes that, when placed in suitable and economically feasible environments, induce in their carriers the desired qualities. The improvement methods used in the breeding work must evidently be appropriate to the reproductive biology, the genetic population structure, and the economic value of the form to be improved. It is evidently impossible, for example, with large domestic animals such as cattle or horses to raise numbers of individuals from which selection is made comparable to that practicable with field crops. Collections of pedigrees, published in stud books for horses and in herd books for some breeds of cattle, are still regarded by commercial breeders as important in the choice of most prized animals. Progeny and sib testing are often used as aids for evaluation of the breeding worth of individual animals. A quite different situation is encountered with some useful plants in which cross-pollination happens only rarely, and the normal method of propagation is self-pollination (as in most cereals, peas, beans, and tomatoes) or parthenogenesis or asexual reproduction (sugarcane, bluegrass, bananas, and many citrus fruits). Here the problem is to identify the individual, or a small group of individuals, with a desired combination of traits and to propagate them to form pure lines (progenies obtained by self-pollination) or clones (progenies obtained asexually). Some of the most valuable varieties of wheats are descended from a single seed progenitor.

Selection, artificial as well as natural, can operate only if genetic diversity exists among the materials available. In a genetically uniform pure line or a clone, selection is without effect. Provision of genetic variability is the prime concern for a breeder. A powerful means of inducing genetic variability is hybridization and Mendelian segregation in the hybrid progenies. Two lines, neither of which is particularly good, may produce valuable genotypes in segregating hybrid progenies. This is the reason that modern breeders frequently endeavour to collect primitive varieties from far-off lands and use them as materials for hybridization followed by selection. Many, if not most, breeds and varieties, from thoroughbred horses to cultivated strawberries, are descended from hybrids of two or more ancient breeds or even of distinct species. The cultivated roses have genes from at least four wild ancestral species in their gene pool.

A technique to speed up the improvement of useful plants and animals is induction of mutations that increase the amount of genetic variability available for selection. Although a decided majority of mutants are harmful, some exceptional ones may be useful. (T.D./Ar.R.)

EUGENICS

Breeders have been quite successful in improving, for human benefit, the genetic endowments of domesticated animals, cultivated plants, and even microorganisms. The question inevitably presents itself whether humans can succeed equally well in directing the evolution of their own species toward goals regarded as good and desirable. The term eugenics has been applied to theories and practices ostensibly designed to improve the human condition from the genetic point of view. The intention of so-called negative eugenics is to improve the human species by identifying individuals and couples at risk of perpetuating "inferior" genes and to prevent such persons from reproducing. On the other hand, positive eugenics attempts to identify "good" genes and thereby improve the species by encouraging the reproduction of those persons who are thought to carry them. All too often, however, the identification of desirable or undesirable hereditary human traits is a subjective and controversial matter, in which the opinions of one, often self-serving, group become the basis of reproductive decisions imposed upon another group. Furthermore, the concept of eugenics tends to ignore the sizable role that environment plays in the establishment of human characteristics.

The idea of applying knowledge of heredity to the improvement of the human race goes back to earliest times. References to eugenic ideals appear in the Old Testament, and Plato's *Republic* idealizes a society in which there is constant selection for the improvement of the human stock. A British economist, Thomas Robert Malthus, noted the struggle for existence; Darwin saw in it the means of evolution. It remained for Francis Galton, a scientist of many talents and a cousin of Darwin, to see that the theory of evolution implied that humans might in part direct their own evolutionary future. Galton's first important work, *Hereditary Genius* (1869), contained the results of his studies of the families of eminent men as evidence for his belief that "it would be quite practical to produce a highly gifted race of men by judicious marriages during several consecutive generations." In 1883 he published *Inquiries into Human Faculty,* in which he coined the term eugenics. In *Natural Inheritance* (1889), Galton pioneered the development and application of advanced statistical methods to the study of man.

While Galton's thinking was much ahead of his time, he retained some of the prejudices of an English gentleman of his day in regard to social class and race. In his studies of the families of eminent men, Galton underestimated the effects of a favourable environment. But his faults in this respect were far less than those of many of his followers. He developed many of the statistical methods for the study of populations and was the first to recognize the value of the study of twins for research in heredity. He repudiated the Lamarckian view, then widely held, that acquired characteristics were inherited. Although Galton attached religious significance to the eugenic movement, he did not think of it in revolutionary terms but rather as "the new duty which is supposed to be exercised concurrently with and not in opposition to, the old ones upon which the social fabric depends." For all his ability, Galton was not able to gain wide acceptance for eugenics, largely because much of the scientific and technical foundation was lacking.

Galton had endowed a research fellowship in eugenics in 1904 and, in his will, provided funds for a chair of eugenics at University College, London University. The fellowship and later the chair at University College were both occupied by Karl Pearson, a brilliant mathematician who helped to create the science of biometry, the statistical aspects of biology. Pearson was a controversial figure who believed that environment had little to do with the development of mental or emotional qualities. He felt that the high birth rate of the poor was a threat to civilization and that the "higher" races must supplant the "lower." His views gave countenance to those who believed in racial and class superiorities. Thus, Pearson shares the blame for the discredit later brought on eugenics in the United States and for making possible the dreadful misuse of the word eugenics in Adolf Hitler's propaganda. The English Eugenics Society, founded by Galton in 1907 as the Eugenics Education Society, opposed Pearson's views but was itself slow in throwing off the prevalent biases of that time.

Eugenics discredited by early racist views

In the United States the American Eugenics Society was founded in 1926 by men who believed that the white race was superior to other races and, further, that the "Nordic" white was superior to other whites. They thought of races as "pure" groups, quite separate from each other. They did not know that all races are mixtures of many types, the distribution of genes among the races varying in proportions rather than in kind, as evidenced by the distribution of the various blood groups among all of the races. They did not realize that environments are so uncontrollable that scientists cannot reasonably put forward views on the genetic differences in the performance of different races. Furthermore, they believed that the upper classes had superior hereditary qualities that justified their being the ruling class.

The science of that day supported extreme views on "feeblemindedness" and "criminal types." Intelligence tests, introduced in the early 1900s by the French psychologist Alfred Binet, were thought, contrary to Binet's views, to be measures of innate, genetic intelligence. People whose test performance (*e.g.,* intelligence quotient, or IQ) gave them a mental age of 12 or less were classified as feebleminded or morons. Criminality was generally considered a concomitant of feeblemindedness. Studies on degenerate family stocks were taken to prove that hundreds of persons in each of these families were feebleminded or criminal types because of the inheritance they received from a single ancestor five or six generations back. Claims were made that immigrants from southern and eastern Europe, besides being socially inferior, included criminal and defective stocks. There was much in the intellectual atmosphere of the United States that fostered an extreme hereditarian racist view.

Even before 1905 eugenists had been active in the effort to restrict immigration. Their arguments, along with those of others who advocated restrictions for different reasons, culminated with the passage of the Immigration Act of 1924, which limited quota immigrants to about 150,000 annually, with no more than 2 percent of each nationality according to the number of persons of their national origin in the United States as of 1890, and providing that, beginning July 1, 1929, the quota of any country should have the same ratio to 150,000 as the number of persons of that national origin living in the United States had to the total U.S. population in the 1920 census. In later years it became clear that the material the eugenists had presented to congressional hearings had little scientific foundation.

Eugenists at this time laid great stress on the importance of sterilizing defective persons. By 1931 sterilization laws had been enacted by 27 states in the United States, and by 1935 sterilization laws had been passed in Denmark, Switzerland, Germany, Norway, and Sweden. Most of these laws provided for the voluntary or compulsory sterilization of certain classes of people thought to be insane, mentally retarded, or epileptic; some applied equally to habitual criminals and sexual deviants. In most cases the purpose was clearly eugenic, though some laws tacitly permitted sterilization for social rather than genetic reasons. In the United States most states did not generally enforce these rather extreme measures, and the number of sterilizations was seldom more than 100 per year. Exceptions were California, where sterilizations averaged more than 350 cases per year, with a total of 9,931 by 1935, and some of the southern states, with fairly high sterilization rates relative to their populations.

Unquestionably the greatest abuse of the concept of eugenics took place in Hitler's Germany, when as a rationale for producing a "master race" the Nazis murdered millions of people considered to have inferior genes.

As a result of these misuses, modern society has been disinclined to admit any validity to eugenic concepts. However, the practice of modern genetic counseling (see below) is in a special sense a eugenic activity, in that it attempts to prevent the conception or birth of individuals with most serious forms of maldevelopment that would be tragic burdens to themselves and to their families. This form of negative eugenics identifies individuals and couples at risk of perpetuating genes that lead to heritable diseases and disorders that contribute to a significant amount of human tragedy. Of importance is the fact that information on these risks is given to couples so that they can make informed and personal decisions about reproduction without societal pressure. (F.H.O./Ar.R.)

HUMAN GENETICS

The study of human heredity occupies a central position in genetics. Much of this interest stems from a basic desire to know who humans are and why they are as they are. At a more practical level, an understanding of human heredity is of critical importance in the prediction, diagnosis, and treatment of diseases that have a genetic component. The quest to determine the genetic basis of human health has given rise to the field of medical genetics. In general, medicine has given focus and purpose to human genetics, so that the terms medical genetics and human genetics are often considered synonymous.

General aspects

THE HUMAN CHROMOSOMES

A new era in cytogenetics, the field of investigation concerned with studies of the chromosomes, began in 1956 with the discovery by Jo Hin Tjio and Albert Levan that human somatic cells contain 23 pairs of chromosomes. Since that time the field has advanced with amazing rapidity and has demonstrated that human chromosome aberrations rank as major causes of fetal death and of tragic human diseases, many of which are accompanied by mental retardation. Since the chromosomes can be delineated only during mitosis, it is necessary to examine material in which there are many dividing cells. This can usually be accomplished by culturing cells from the blood or skin, since only the bone marrow cells (not readily sampled except during serious bone marrow disease such as leukemia) have sufficient mitoses in the absence of artificial culture. After growth, the cells are fixed on slides and then stained with a variety of DNA-specific stains that permit the delineation and identification of the chromosomes. The Denver system of chromosome classification, established in 1959, identified the chromosomes by their length and the position of the centromeres. Since then the method has been improved by the use of special staining techniques that impart unique light and dark bands to each chromosome. These bands permit the identification of chromosomal regions that are duplicated, missing, or transposed to other chromosomes.

Figure 15 shows the karyotypes (*i.e.,* the physical appearance of the chromosomes) of a male and female. In these micrographs the 46 human chromosomes (the diploid number) are arranged in homologous pairs, each consisting of one maternally derived and one paternally derived member. The chromosomes are all numbered except for the X and the Y chromosomes, which are the sex chromosomes. In humans, as in all mammals, the normal female has two X chromosomes and the normal male has one X chromosome and one Y chromosome. The female is thus the homogametic sex, as all her gametes normally have one X chromosome. The male is heterogametic, as he produces two types of gametes—one type containing an X chromosome and the other containing the Y chromosome. There is good evidence that the Y chromosome in humans, unlike that in *Drosophila,* is necessary (but not sufficient) for maleness.

FERTILIZATION, SEX DETERMINATION, AND DIFFERENTIATION

A human individual arises through the union of two cells, an egg from the mother and a sperm from the father. Human egg cells are barely visible to the naked eye. They are shed, usually one at a time, from the ovary into the oviducts (fallopian tubes), through which they pass into the uterus. Fertilization, the penetrance of an egg by a sperm, occurs in the oviducts. This is the main event of sexual reproduction and determines the genetic constitution of the new individual.

Human sex determination is a genetic process that depends basically on the presence of the Y chromosome in the fertilized egg. This chromosome stimulates a change in the undifferentiated gonad into that of the male (a testicle). The gonadal action of the Y chromosome is mediated by a gene located near the centromere; this gene codes for the production of a cell surface molecule called the H-Y antigen. Further development of the anatomic structures, both internal and external, that are associated with maleness is controlled by hormones produced by the testicle. The sex of an individual can be thought of in three different contexts: chromosomal sex, gonadal sex, and anatomic sex. Discrepancies among these, especially the latter two, result in the development of individuals with ambiguous sex, often called hermaphrodites. Homosexuality is of uncertain cause and is unrelated to the above sex-determining factors. It is of interest that in the absence of a male gonad (testicle) the internal and external sex anatomy is always female, even in the absence of a female ovary. A female without ovaries will, of course, be infertile and will not experience any of the female developmental changes normally associated with puberty. Such a female will often have Turner's syndrome (see below).

If X-containing and Y-containing sperm are produced in equal numbers, then according to simple chance one would expect the sex ratio at conception (fertilization) to be half boys and half girls, or 1 : 1. Direct observation of sex ratios among newly fertilized human eggs is not yet feasible, and sex-ratio data are usually collected at the time of birth. In almost all human populations of newborns there is a slight excess of males; about 106 boys are born for each 100 girls. Throughout life, however, there is a slightly greater mortality of males; this slowly alters the sex ratio until, beyond the age of about 50 years, there is an excess of females. Studies indicate that male embryos suffer a relatively greater degree of prenatal mortality, so that the sex ratio at conception might be expected to favour males even more than the 106 : 100 ratio observed at birth would suggest. Firm explanations for the apparent excess of male conceptions have not been established; it is possible that Y-containing sperm survive better within the female reproductive tract, or that they may be a little more successful in reaching the egg in order to fertilize it. In any case, the sex differences are small, the statistical expectation for a boy (or girl) at any single birth still being close to one out of two.

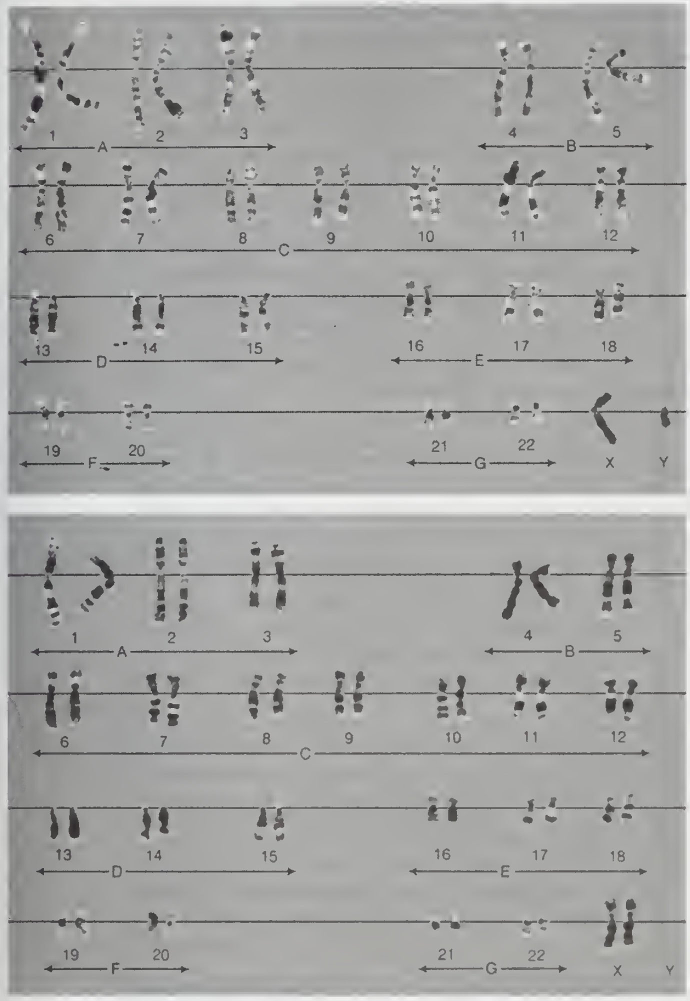

Figure 15: *Human karyotypes of the (top) male and female.* The chromosomes have been stained with Giemsa stain. Individual chromosomes are characterized by their size, position of centromere, and unique distribution of light and dark bands.

From the Cytogenetics Laboratory of Dr. Arthur Robinson, National Jewish Hospital and Research Center/National Asthma Center Denver, Colorado

During gestation—the period of nine months between fertilization and the birth of the infant—a remarkable series of developmental changes occur. Through the process of mitosis, the total number of cells changes from one (the fertilized egg) to about 2×10^{11}. In addition, these cells differentiate into hundreds of different types with specific functions (liver cells, nerve cells, muscle cells, etc.). A multitude of regulatory processes, both genetically and environmentally controlled, accomplish this differentiation. Elucidation of the exquisite timing of these processes remains one of the great challenges of human biology.

IMMUNOGENETICS

Immunity is the ability of an individual to recognize the "self" molecules that make up one's own body and to distinguish them from such "non-self" molecules as those found in infectious microorganisms and toxins. This process has a prominent genetic component. Knowledge of the genetic and molecular basis of the mammalian immune system has increased in parallel with the explosive advances made in somatic cell and molecular genetics.

Lymphocytes

There are two major components of the immune system, both originating from the same precursor "stem" cells. The bursa component provides B lymphocytes, a class of white blood cells that, when appropriately stimulated, differentiate into plasma cells. These latter cells produce circulating soluble proteins called antibodies or immunoglobulins. Antibodies are produced in response to substances called antigens, most of which are foreign proteins or polysaccharides. An antibody molecule can recognize a specific antigen, combine with it, and initiate its destruction. This so-called humoral immunity is accomplished through a complicated series of interactions with other molecules and cells; some of these interactions are mediated by another group of lymphocytes, the T lymphocytes, which are derived from the thymus gland. Once a B lymphocyte has been exposed to a specific antigen, it "remembers" the contact so that future exposure will cause an accelerated and magnified immune reaction. This is a manifestation of what has been called immunological memory.

The thymus component of the immune system centres on the thymus-derived T lymphocytes. In addition to regulating the B cells in producing humoral immunity, the T cells also directly attack cells that display foreign antigens. This process, called cellular immunity, is of great importance in protecting the body against a variety of viruses as well as cancer cells. Cellular immunity is also the chief cause of the rejection of organ transplants. The T lymphocytes provide a complex network consisting of a series of helper cells (which are antigen specific), amplifier cells, suppressor cells, and cytotoxic (killer) cells, all of which are important in immune regulation.

The genetics of antibody formation. One of the central problems in understanding the genetics of the immune system has been in explaining the genetic regulation of antibody production. Immunobiologists have demonstrated that the system can produce well over 1,000,000 specific antibodies, each corresponding to a particular antigen. It would be difficult to envisage that each antibody is encoded by a separate gene—such an arrangement would require a disproportionate share of the entire human genome. Recombinant DNA analysis has illuminated the mechanisms by which a limited number of immunoglobulin genes can encode this vast number of antibodies.

Each antibody molecule consists of several different polypeptide chains—the light chains (L) and the longer heavy chains (H). The latter determine to which of five different classes (IgM, IgG, IgA, IgD, or IgE) an immunoglobulin belongs. Both the L and H chains are unique among proteins in that they contain constant and variable parts. The constant parts have relatively identical amino acid sequences in any given antibody. The variable parts, on the other hand, have different amino acid sequences in each antibody molecule. It is the variable parts, then, that determine the specificity of the antibody.

Recombinant DNA studies of immunoglobulin genes in mice have revealed that the light-chain genes are encoded in four separate parts in germ-line DNA: a leader segment (L), a variable segment (V), a joining segment (J), and a constant segment (C). These segments are widely separated in the DNA of an embryonic cell, but in a mature B lymphocyte they are found in relative proximity (albeit separated by introns). The mouse has more than 200 light-chain variable region genes, only one of which will be incorporated into the proximal sequence that codes for the antibody production in a given B lymphocyte. Antibody diversity is greatly enhanced by this system, as the V and J segments rearrange and assort randomly in each B-lymphocyte precursor cell. The mechanisms by which this DNA rearrangement takes place are not clear, but transposons are undoubtedly involved. Similar combinatorial processes take place in the genes that code for the heavy chains; furthermore, both the light-chain and heavy-chain genes can undergo somatic mutations to create new antibody-coding sequences. The net effect of these combinatorial and mutational processes enables the coding of millions of specific antibody molecules from a limited number of genes. It should be stressed, however, that each B lymphocyte can produce only one antibody. It is the B lymphocyte population as a whole that produces the tremendous variety of antibodies in humans and other mammals.

Plasma cell tumours (myelomas) have made it possible to study individual antibodies since these tumours, which are descendants of a single plasma cell, produce one antibody in abundance. Another method of obtaining large amounts of a specific antibody is by fusing a B lymphocyte with a rapidly growing cancer cell. The resultant hybrid cell, known as a hybridoma, multiplies rapidly in culture. Since the antibodies obtained from hybridomas are produced by clones derived from a single lymphocyte, they are called monoclonal antibodies.

The genetics of cellular immunity. As has been stated, cellular immunity is mediated by T lymphocytes that can recognize infected body cells, cancer cells, and the cells of a foreign transplant. The control of cellular immune reactions is provided by a linked group of genes, known as the major histocompatibility complex (MHC). These genes code for the major histocompatibility antigens, which are found on the surface of almost all nucleated somatic cells. The major histocompatibility antigens were first discovered on the leukocytes (white blood cells) and are, therefore, usually referred to as the HLA (human leukocyte group A) antigens.

The advent of the transplantation of human organs in the 1950s made the question of tissue compatibility between donor and recipient of vital importance, and it was in this context that the HLA antigens and the MHC were elucidated. Investigators found that the MHC resides on the short arm of chromosome 6, on four closely associated sites designated HLA-A, HLA-B, HLA-C, and HLA-D. Each locus is highly polymorphic—*i.e.,* each is represented by a great many alleles within the human gene pool. These alleles, like those of the ABO blood group system, are expressed in codominant fashion. Because of the large number of alleles at each HLA locus, there is an extremely low probability of any two individuals (other than siblings) having identical HLA genotypes. (Since a person inherits one chromosome 6 from each parent, siblings have a 25 percent probability of having received the same paternal and maternal chromosomes 6 and thus of being HLA matched.)

Although HLA antigens are largely responsible for the rejection of organ transplants, it is obvious that the MHC did not evolve to prevent the transfer of organs from one person to another. Indeed, information obtained from the histocompatibility complex in the mouse (which is very similar in its genetic organization to that of the human) suggests that a primary function of the HLA antigens is to regulate the number of specific cytotoxic T killer cells, which have the ability to destroy virus-infected cells and cancer cells. (Ar.R.)

THE GENETICS OF HUMAN BLOOD

More is known about the genetics of the blood than about any other human tissue. One reason for this is that blood samples can be easily secured and subjected to biochemical analysis without harm or major discomfort to the person being tested. Perhaps a more cogent reason is that many chemical properties of human blood display relatively simple patterns of inheritance.

Blood types. Certain chemical substances within the red blood cells (such as the ABO and MN substances noted above) may serve as antigens. When cells that contain specific antigens are introduced into the body of an experimental animal such as a rabbit, the animal responds by producing antibodies in its own blood.

In addition to the ABO and MN systems, geneticists have identified about 14 blood-type gene systems associated with other chromosomal locations. The best known of these is the Rh system. The Rh antigens are of particular importance in human medicine. Curiously, however, their existence was discovered in monkeys. When blood from the rhesus monkey (hence the designation Rh) is injected into rabbits, the rabbits produce so-called Rh antibodies that will agglutinate not only the red blood cells of the monkey but the cells of a large proportion of human beings as well. Some people (Rh-negative individuals), however, lack the Rh antigen; the proportion of such persons varies from one human population to another. Akin to data concerning the ABO system, the evidence for Rh genes indicates that only a single chromosome locus (called *r*) is involved and is located on chromosome 1. At least 35 Rh alleles are known for the *r* location; basically the Rh-negative condition is recessive.

Rh incompatibility

A medical problem may arise when a woman who is Rh-negative carries a fetus that is Rh-positive. The first such child may have no difficulty, but later similar pregnancies may produce severely anemic newborn infants. Exposure to the red blood cells of the first Rh-positive fetus appears to immunize the Rh-negative mother, that is, she develops antibodies that may produce permanent (sometimes fatal) brain damage in any subsequent Rh-positive fetus. Damage arises from the scarcity of oxygen reaching the fetal brain because of the severe destruction of red blood cells. Measures are available for avoiding the severe effects of Rh incompatibility by transfusions to the fetus within the uterus; however, genetic counselling before conception is helpful so that the mother can receive Rh immunoglobulin immediately after her first and any subsequent pregnancies involving an Rh-positive fetus. This immunoglobulin effectively destroys the fetal red blood cells before the mother's immune system is stimulated. The mother thus avoids becoming actively immunized against the Rh antigen and will not produce antibodies that could attack the red blood cells of a future Rh-positive fetus.

Serum proteins. Human serum, the fluid portion of the blood that remains after clotting, contains various proteins that have been shown to be under genetic control. Study of genetic influences has flourished since the development of precise methods for separating and identifying serum proteins. These move at different rates under the impetus of an electrical field (electrophoresis), as do proteins from many other sources (*e.g.,* muscle or nerve). Since the composition of a protein is specified by the structure of its corresponding gene, biochemical studies based on electrophoresis permit direct study of tissue substances that are only a metabolic step or two away from the genes themselves.

Electrophoretic studies have revealed that at least one-third of the human serum proteins occur in variant forms. Many of the serum proteins are polymorphic, occurring as two or more variants with a frequency of not less than 1 percent each in a population. Patterns of polymorphic serum protein variants have been used to determine whether twins are identical (as in assessing compatibility for organ transplants) or whether two individuals are related (as in resolving paternity suits). Whether or not the different forms have a selective advantage is not generally known.

Much attention in the genetics of substances in the blood has been centred on serum proteins called haptoglobins, transferrins (which transport iron), and gamma globulins (a number of which are known to immunize against infectious diseases). Haptoglobins appear to relate to two common alleles at a single chromosome locus; the mode of inheritance of the other two seems more complicated, about 18 kinds of transferrins having been described. Like blood-cell antigen genes, serum-protein genes are distributed worldwide in the human population in a way that permits their use in tracing the origin and migration of different groups of people.

Hemoglobin. Hundreds of variants of hemoglobin have been identified by electrophoresis, but relatively few are frequent enough to be called polymorphisms. Of the polymorphisms, the alleles for sickle-cell and thalassemia hemoglobins produce serious disease in homozygotes, whereas others (hemoglobins C, D, and E) do not. As was discussed earlier (see above *Varieties of natural selection*), the sickle-cell polymorphism confers a selective advantage on the heterozygote living in a malarial environment; the thalassemia polymorphism provides a similar advantage.

INFLUENCE OF THE ENVIRONMENT

As stated earlier in this article, gene expression occurs only after modification by the environment. A good example is the recessively inherited disease called galactosemia, in which the enzyme necessary for the metabolism of galactose—a component of milk sugar—is defective. The sole source of galactose in the infant's diet is milk, which in this instance is toxic. The treatment of this most serious disease in the neonate is to remove all natural forms of milk from the diet (environmental manipulation) and to substitute a synthetic milk lacking galactose. The infant will then develop normally but will never be able to tolerate foods containing lactose. If milk were not a major part of the infant's diet, however, the mutant gene would never be able to express itself, and galactosemia would be unknown.

The interaction of heredity and environment

Another way of saying this is that no trait can exist or become actual without an environmental contribution. Thus, the old question of which is more important, heredity or environment, is without meaning. Both nature (heredity) and nurture (environment) are always important for every human attribute.

But this is not to say that the separate contributions of heredity and environment are equivalent for each characteristic. Dark pigmentation of the iris of the eye, for example, is under hereditary control in that one or more genes specify the synthesis and deposition in the iris of the pigment (melanin). This is one character that is relatively independent of such environmental factors as diet or climate; thus, individual differences in eye colour tend to be largely attributable to hereditary factors rather than to ordinary environmental change.

On the other hand, it is unwarranted to assume that other traits (such as height, weight, or intelligence) are as little affected by environment as is eye colour. It is very easy to gather information that tall parents tend, on the average, to have tall children (and that short parents tend to produce short children), properly indicating a hereditary contribution to height. Nevertheless, it is equally manifest that growth can be stunted in the environmental absence of adequate nutrition. The dilemma arises that only the combined, final result of this nature–nurture interaction can be directly observed. There is no accurate way (in the case of a single individual) to gauge the separate contributions of heredity and environment to such a characteristic as height. An inferential way out of this dilemma is provided by studies of twins.

Fraternal twins. Usually a fertile human female produces a single egg about once a month. Should fertilization occur (a zygote is formed), growth of the individual child normally proceeds after the fertilized egg has become implanted in the wall of the uterus (womb). In the unusual circumstance that two unfertilized eggs are simultaneously released by the ovaries, each egg may be fertilized by a different sperm cell at about the same time, become implanted, and grow, to result in the birth of twins.

Twins formed from separate eggs and different sperm cells can be of the same or of either sex. No matter what their sex, they are designated as fraternal twins. This terminology is used to emphasize that fraternal twins are genetically no more alike than are siblings (brothers or sisters) born years apart. Basically they differ from ordinary siblings only in having grown side by side in the womb and in having been born at approximately the same time.

Split embryos

Identical twins. In a major nonfraternal type of twinning, only one egg is fertilized; but during the cleavage of this single zygote into two cells, the resulting pair somehow become separated. Each of the two cells may implant in the uterus separately and grow into a complete, whole individual. In laboratory studies with the zygotes of many animal species, it has been found that in the two-cell stage (and later) a portion of the embryo, if separated under the microscope by the experimenter, may develop into a perfect, whole individual. Such splitting occurs spontaneously at the four-cell stage in some organisms (*e.g.*, the armadillo) and has been accomplished experimentally with the embryos of salamanders, among others.

The net result of splitting at an early embryonic stage may be to produce so-called identical twins. Since such twins derive from the same fertilized egg, the hereditary material from which they originate is absolutely identical in every way, down to the last gene locus. While developmental and genetic differences between one "identical" twin and another still may arise through a number of processes (*e.g.*, mutation), these twins are always found to be of the same sex. They are often breathtakingly similar in appearance, frequently down to very fine anatomic and biochemical details (although their fingerprints are differentiable).

Diagnosis of twin types. Since the initial event in the mother's body (either splitting of a single egg or two separate fertilizations) is not observed directly, inferential means are employed for diagnosing a set of twins as fraternal or identical. The birth of fraternal twins is frequently characterized by the passage of two separate afterbirths. In many instances, identical twins are followed by only a single afterbirth, but exceptions to this phenomenon are so common that this is not a reliable method of diagnosis.

The most trustworthy method for inferring twin type is based on the determination of genetic similarity. By selecting those traits that display the least variation attributable to environmental influences (such as eye colour and blood types), it is feasible, if enough separate chromosome loci are considered, to make the diagnosis of twin type with high confidence.

Inferences from twin studies. *Metric (quantitative) traits.* By measuring the heights of a large number of ordinary siblings (brothers and sisters) and of twin pairs, it may be shown that the average difference between identical twins is less than half the difference for all other siblings (see Figure 16). Any average differences between groups of identical twins are attributable with considerable confidence to the environment. Thus, since the sample of identical twins (given in Figure 16) who were reared apart (in different homes) differed little in height from identicals who were raised together, it appears that environmental–genetic influences on that trait tended to be similar for both groups.

Twins reared together and apart

Yet, the data for like-sexed fraternal twins reveal a much greater average difference in height (about the same as that found for ordinary siblings reared in the same home at different ages). Apparently the fraternal twins were more dissimilar than identicals (even though reared together) because the fraternals differed more among themselves in genotype. This emphasizes the great genetic similarity among identicals. Such studies can be particularly enlightening when the effects of individual genes are obscured or distorted by the influence of environmental factors on quantitative (measurable) traits (*e.g.*, height, weight, and intelligence).

Any trait that can be objectively measured among identical and fraternal twins can be scrutinized for the particular combination of hereditary and environmental influences that impinge upon it. The effect of environment on identical twins reared apart (Figure 16) is suggested by their relatively great average difference in body weight as compared with identical twins reared together. Weight appears to be more strongly modified by environmental variables than is height.

Study of comparable characteristics among farm animals and plants suggests that such quantitative human traits as height and weight are affected by allelic differences at a number of chromosome locations; they are not simply affected by genes at a single locus. Investigation of these gene systems with multiple locations (polygenic systems) is carried out largely through selective-breeding experiments among large groups of plants and lower animals. Human beings select their mates in a much freer fashion, of course, and polygenic studies among people are thus severely limited.

Intelligence

Intelligence is a very complex human trait, the genetics of which has been a subject of controversy for some time. Much of the controversy arises from the fact that intelligence is so difficult to define. Information has been based almost entirely on scores on standardized IQ tests constructed by psychologists; in general such tests do not take into account cultural, environmental, and educational differences. As a result, the working definition of intelligence has been "the general factor common to a large number of diverse cognitive (IQ) tests." Even roughly measured as IQ, intelligence shows (Figure 16) a strong contribution from the environment. Fraternal twins, however, show relatively great dissimilarity in IQ, suggesting an important contribution from heredity as well. In fact, it has been estimated that on the average between 60 and 80 percent of the variance in IQ test scores could be genetic. It is important to note that intelligence is polygenically inherited and that it has the highest degree of assortative mating of any trait; in other words, people tend to mate with people having similar IQ's. Moreover, twin studies involving psychological traits should be viewed with caution; for example, since identical twins tend to be singled out for special attention, their environment should not be considered equivalent even to that of other children raised in their own family.

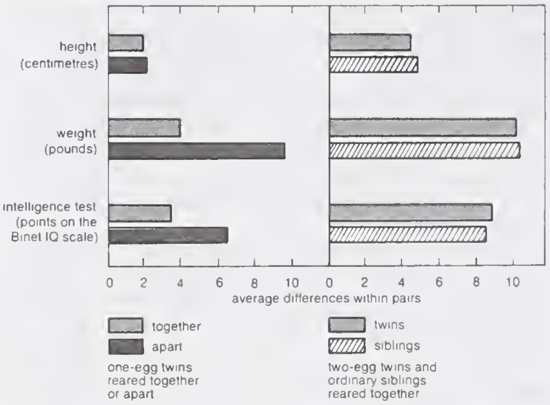

Figure 16: Measured differences between identical (one-egg) twins, between like-sexed fraternal (two-egg) twins, and between like-sexed ordinary siblings.

Adapted from H.L. Carson, *Heredity and Human Life* (1963), Columbia University Press

Other traits. For traits of a more qualitative (all-or-none) nature, the twin method can also be used in efforts to assess the degree of hereditary contribution. Such investigations are based on an examination of cases in which at least one member of the twin pair shows the trait. It was found in one study, for example, that in about 80 percent of all identical twin pairs in which one twin shows symptoms of the psychiatric disorder called schizophrenia, the other member of the pair also shows the symptoms (that is, the two are concordant for the schizophrenic trait). In the remaining 20 percent, the twins are discordant (that is, one lacks the trait). Since identical twins often have similar environments, this information by itself does not distinguish between the effects of heredity and environment. When pairs of like-sexed fraternal twins reared together are studied, however, the degree of concordance for schizophrenia is very much lower—only about 15 percent (Figure 17).

Schizophrenia thus clearly develops much more easily in some genotypes than among others; this indicates a strong hereditary predisposition to the development of the trait. Schizophrenia also serves as a good example of the influence of environmental factors since concordance for the condition does not appear in 100 percent of identical twins.

Studies of concordance and discordance between identical and fraternal twins have been carried out for many other human characteristics, a few of which are also summarized in Figure 17. It has, for example, been known for many years that tuberculosis is a bacterial infection of environmental origin. Yet identical twins raised in the same home show concordance for the disease far more often than do fraternal twins. This finding seems to be explained by the high degree of genetic similarity between the identical twins. While the tuberculosis germ is not inherited, heredity does seem to make one more (or less) susceptible to this particular infection. Thus, the genes of one individual may provide the chemical basis for susceptibility to a disease, while the genes of another may fail to do so.

Adapted from H.L. Carson, *Heredity and Human Life* (1963); Columbia University Press

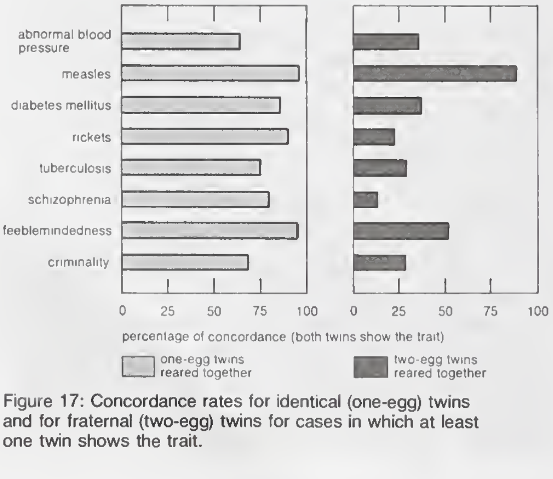

Figure 17: Concordance rates for identical (one-egg) twins and for fraternal (two-egg) twins for cases in which at least one twin shows the trait.

Indeed, there seem to be genetic differences between disease germs themselves that result in differences in their virulence. Thus, whether a genetically susceptible person actually develops a disease also depends in part on the heredity of the particular strain of bacteria or virus with which he or she must cope. Consequently, unless environmental factors such as these are adequately evaluated, the conclusions drawn from susceptibility studies can be unfortunately misleading.

The above discussion should help to make clear the limits of genetic determinism. The expression of the genotype can always be modified by the environment. It can be argued that all human illnesses have a genetic component and that the basis of all medical therapy is environmental modification. Specifically, this is the hope for the management of genetic diseases. The more that can be learned about the basic molecular and cellular dysfunctions associated with such diseases, the more amenable they will be to environmental manipulation. (H.L.C./Ar.R.)

Genetics and human disease

With the increasing ability to control infectious and nutritional diseases in developed countries, there has come the realization that genetic diseases are a major cause of disability, death, and human tragedy. Rare, indeed, is the family that is entirely free of any known genetic disorder. Many thousands of different genetic disorders with defined clinical symptoms have been identified. Of the 3 to 6 percent of newborns with a recognized birth defect, at least half involve a predominantly genetic contribution. Furthermore, genetic defects are the major known cause of pregnancy loss in developed nations, and almost half of all spontaneous abortions (miscarriages) involve a chromosomally abnormal fetus. About 30 percent of all postnatal infant mortality in developed countries is due to genetic disease; 30 percent of pediatric and 10 percent of adult hospital admissions can be traced to a predominantly genetic cause. Finally, medical investigators estimate that genetic defects—however minor—are present in at least 10 percent of all adults. Thus, these are not rare events.

A congenital defect is any biochemical, functional, or structural abnormality that originates prior to or shortly after birth. It must be emphasized that birth defects do not all have the same basis, and it is even possible for apparently identical defects in different individuals to reflect different underlying causes. Though the genetic and biochemical bases for most recognized defects are still uncertain, it is evident that many of these disorders result from a combination of genetic and environmental factors.

This article surveys the main categories of genetic disease, focusing on the types of genetic mutations that give rise to them, the risks associated with exposure to certain environmental agents, and the course of managing genetic disease through counseling, diagnosis, and treatment.

CLASSES OF GENETIC DISEASE

Most human genetic defects can be categorized as resulting from either chromosomal, single-gene Mendelian, single-gene non-Mendelian, or multifactorial causes. Each of these categories is discussed briefly below.

Diseases caused by chromosomal aberrations. About one out of 150 live newborns has a detectable chromosomal abnormality. Yet even this high incidence represents only a small fraction of chromosome mutations since the vast majority are lethal and result in prenatal death or stillbirth. Indeed, 50 percent of all first-trimester miscarriages and 20 percent of all second-trimester miscarriages are estimated to involve a chromosomally abnormal fetus.

Chromosome disorders can be grouped into three principal categories: (1) those that involve numerical abnormalities of the autosomes, (2) those that involve structural abnormalities of the autosomes, and (3) those that involve the sex chromosomes. Autosomes are the 22 sets of chromosomes found in all normal human cells. They are referred to numerically (*e.g.,* chromosome 1, chromosome 2) according to a traditional sort order based on size, shape, and other properties. Sex chromosomes make up the 23rd pair of chromosomes in all normal human cells and come in two forms, termed X and Y. In humans and many other animals, it is the constitution of sex chromosomes that determines the sex of the individual, such that XX results in a female, and XY results in a male.

Down syndrome

Numerical abnormalities. Numerical abnormalities, involving either the autosomes or sex chromosomes, are believed generally to result from meiotic nondisjunction—that is, the unequal division of chromosomes between daughter cells—that can occur during either maternal or paternal gamete formation. Meiotic nondisjunction leads to eggs or sperm with additional or missing chromosomes. Although the biochemical basis of numerical chromosome abnormalities remains unknown, maternal age clearly has an effect, such that older women are at significantly increased risk to conceive and give birth to a chromosomally abnormal child. The risk increases with age in an almost exponential manner, especially after age 35, so that a pregnant woman age 45 or older has between a 1 in 20 and 1 in 50 chance that her child will have trisomy 21 (Down syndrome), while the risk is only 1 in 400 for a 35-year-old woman and less than 1 in 1,000 for a woman under the age of 30. There is no clear effect of paternal age on numerical chromosome abnormalities.

Although Down syndrome is probably the best known and most commonly observed of the autosomal trisomies, being found in about 1 out of 800 live births, both trisomy 13 and trisomy 18 are also seen in the population, albeit at greatly reduced rates. The vast majority of conceptions involving trisomy for any of these three autosomes are nonetheless lost to miscarriage, as are all conceptions involving pure trisomy for any of the other autosomes. Similarly, monosomy for any of the autosomes is lethal in utero and therefore is not seen in the population. Because numerical chromosomal abnormalities generally result from independent meiotic events, parents who have one pregnancy with a numerical chromosomal abnormality are generally not at markedly increased risk above the general population to repeat the experience. Nonetheless, a small increased risk is generally cited for these couples to account for unusual situations, such as chromosomal translocations or gonadal mosaicism, described below.

Structural abnormalities. Structural abnormalities of the autosomes are even more common in the population than are numerical abnormalities and include translocations of large pieces of chromosomes, as well as smaller deletions, insertions, or rearrangements. Indeed, about 5 percent of all cases of Down syndrome result not from classic trisomy 21 but from the presence of excess chromosome 21 material attached to the end of another chromosome as the result of a translocation event. If balanced, structural chromosomal abnormalities may be compatible with a normal phenotype, although unbalanced chromosome structural abnormalities can be every bit as devastating as numerical abnormalities. Furthermore, because many structural defects are inherited from a parent who is a balanced carrier, couples who have one pregnancy with a structural chromosomal abnormality generally are at significantly increased risk above the general population to repeat the experience. Clearly, the likelihood of a recurrence would depend on whether a balanced form of the structural defect occurs in one of the parents.

Even a small deletion or addition of autosomal material—too small to be seen by normal karyotyping methods—can produce serious malformations and mental retardation. One example is *cri du chat* (French: "cry of the cat") syndrome, which is associated with the loss of a small segment of the short arm of chromosome 5. Newborns with this disorder have a "mewing" cry like that of a cat. Mental retardation is usually severe.

Turner's syndrome

Abnormalities of the sex chromosomes. About 1 in 400 male and 1 in 650 female live births demonstrate some form of sex chromosome abnormality, although the symptoms of these conditions are generally much less severe than are those associated with autosomal abnormalities. Turner's syndrome is a condition of females who, in the classic form, carry only a single X chromosome (45,X). Turner's syndrome is characterized by a collection of symptoms, including short stature, webbed neck, and incomplete or absent development of secondary sex characteristics, leading to infertility. Although Turner's syndrome is seen in about 1 in 2,500 to 1 in 5,000 female live births, the 45,X karyotype accounts for 10 to 20 percent of the chromosomal abnormalities seen in spontaneously aborted fetuses, demonstrating that almost all 45,X conceptions are lost to miscarriage. Indeed, the majority of live-born females with Turner's syndrome are diagnosed as mosaics, meaning that some proportion of their cells are 45,X while the rest are either 46,XX or 46,XY. The degree of clinical severity generally correlates inversely with the degree of mosaicism, so that females with a higher proportion of normal cells will tend to have a milder clinical outcome.

In contrast to Turner's syndrome, which results from the absence of a sex chromosome, three alternative conditions result from the presence of an extra sex chromosome: Klinefelter's syndrome, trisomy X, and 47,XYY syndrome. These conditions, each of which occurs in about 1 in 1,000 live births, are clinically mild, perhaps reflecting the fact that the Y chromosome carries relatively few genes, and, although the X chromosome is gene rich, most of these genes become transcriptionally silent in all but one X chromosome in each somatic cell (*i.e.*, all cells except eggs and sperm) via a process called X inactivation. The phenomenon of X inactivation prevents a female who carries two copies of the X chromosome in every cell from expressing twice the amount of gene products encoded exclusively on the X chromosome, in comparison with males, who carry a single X. In brief, at some point in early development, one X chromosome in each somatic cell of a female embryo undergoes chemical modification and is inactivated so that gene expression no longer occurs from that template. This process is apparently random in most embryonic tissues, so that roughly half of the cells in each somatic tissue will inactivate the maternal X, while the other half will inactivate the paternal X. Cells destined to give rise to eggs do not undergo X inactivation, and cells of the extra-embryonic tissues preferentially inactivate the paternal X, although the rationale for this preference is unclear. The inactivated X chromosome typically replicates later than other chromosomes, and it physically condenses to form a Barr body, a small structure found at the rim of the nucleus in female somatic cells between divisions (Figure 18). The discovery of X inactivation is generally attributed to British geneticist Mary Lyon, and it is therefore often called "lyonization." The result of X inactivation is that all normal females are mosaics with regard to this chromosome, meaning that they are composed of some cells that express genes only from the maternal X chromosome and others that express genes only from the paternal X chromosome. Although the process is apparently random, not every female has an exact 1 : 1 ratio of maternal to paternal X inactivation. Indeed, studies suggest that ratios of X inactivation can vary widely between different women. Finally, not all genes on the X chromosome are inactivated; a small number escape modification and remain actively expressed from both X chromosomes in the cell. Although this class of genes has not yet been fully characterized, aberrant expression of these genes has been

From the Cytogenetics Laboratory of Dr. Arthur Robinson, National Jewish Hospital and Research Center/National Asthma Center, Denver, Colorado

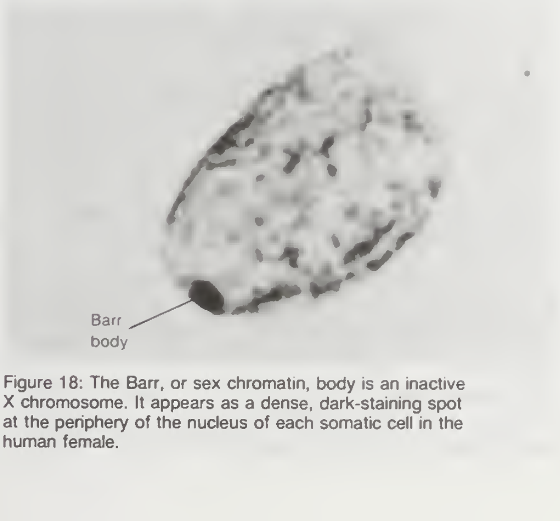

Figure 18: The Barr, or sex chromatin, body is an inactive X chromosome. It appears as a dense, dark-staining spot at the periphery of the nucleus of each somatic cell in the human female.

raised as one possible explanation for the phenotypic abnormalities experienced by individuals with too few or too many X chromosomes.

Klinefelter's syndrome

Klinefelter's syndrome (47,XXY) occurs in males and is associated with increased stature and infertility. Gynecomastia (*i.e.*, partial breast development in a male) is sometimes also seen. Males with Klinefelter's syndrome, like normal females, inactivate one of their two X chromosomes in each cell.

Trisomy X (47,XXX) is seen in females and is generally also considered clinically benign, although menstrual irregularities or sterility have been noted in some cases. Females with trisomy X inactivate two of the three X chromosomes in each of their cells.

Another condition, 47,XYY syndrome, also occurs in males and is associated with tall stature but few, if any, other clinical manifestations. There is some evidence of mild learning disability associated with each of the sex chromosome trisomies, although there is no evidence of mental retardation in these persons.

Finally, persons with karyotypes of 48,XXXY or 49,XXXXY have been reported but are extremely rare. These individuals show clinical outcomes similar to those seen in males with Klinefelter's syndrome but with slightly increased severity. In these persons the "$n - 1$ rule" for X inactivation still holds, so that all but one of the X chromosomes present in each somatic cell are inactivated.

Diseases associated with single-gene (Mendelian) inheritance. The term *Mendelian* is often used to denote patterns of genetic inheritance similar to those described for traits in the garden pea by Gregor Mendel in the 1860s. Disorders associated with single-gene Mendelian inheritance are typically categorized as autosomal dominant, autosomal recessive, or sex-linked. Each category is described briefly in this section.

Autosomal dominant inheritance. A disease trait that is inherited in an autosomal dominant manner can occur in either sex and can be transmitted by either parent. It manifests itself in the heterozygote (designated *Aa*), who receives a mutant gene (designated *A*) from one parent and a normal ("wild-type") gene (designated *a*) from the other. In such a case the pedigree (*i.e.*, a pictorial representation of family history) is vertical—that is, the disease passes from one generation to the next. Figure 19 illustrates the pedigree for a family with achondroplasia, an autosomal dominant disorder characterized by short-limbed dwarfism that results from a specific mutation in the fibroblast growth factor receptor 3 (*FGFR3*) gene. In pedigrees of this sort, circles refer to females and squares to males; two symbols directly joined at the midpoint represent a mating, and those suspended from a common overhead line represent siblings, with descending birth order from left to right. Solid symbols represent affected individuals, and open symbols represent unaffected individuals. The Roman numerals denote generations, whereas the Arabic numerals identify individuals within each generation. Each person listed in a pedigree may therefore be specified uniquely by a combination of one Roman and one Arabic numeral, such as II-1.

Achondroplasia

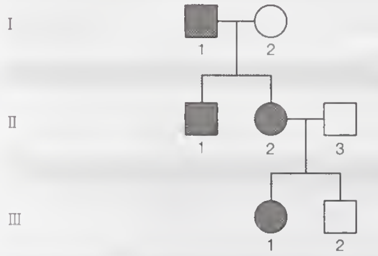

Figure 19: Pedigree of a family with a history of achondroplasia, an autosomal dominantly inherited disease (see text).

An individual who carries one copy of a dominant mutation (*Aa*) will producc two kinds of germ cells—eggs or sperm—typically in equal proportions; one half will bear the mutant gene (*A*), and the other will bear the normal gene (*a*). As a result, an affected heterozygote has a 50 percent chance of passing on the disease gene to each of his or her children. If an individual were to carry two copies of the dominant mutant gene (inherited from both parents), he or she would be homozygous (*AA*). The homozygote for a dominantly inherited abnormal gene may be equally affected with the heterozygote. Alternatively, he or she may be much more seriously affected; indeed, the homozygous condition may be lethal, sometimes even in utero or shortly after birth. Such is the case with achondroplasia, so that a couple with one affected partner and one unaffected partner will typically see half of their children affected, whereas a couple with both partners affected will see two-thirds of their surviving children affected and one-third unaffected, because 1 out of 4 conceptions will produce a homozygous fetus who will die before or shortly after birth.

Although autosomal dominant traits are typically evident in multiple generations of a family, they can also arise from new mutations, so that two unaffected parents, neither of whom carries the mutant gene in their somatic cells, can conceive an affected child. Indeed, for some disorders the new mutation rate is quite high; almost 7 out of 8 children with achondroplasia are born to two unaffected parents. Examples of autosomal dominant inheritance are common among human traits and diseases. More than 2,000 of these traits have been clearly identified; a sampling is given in Table 5.

Table 5: Human Conditions Attributable to a Single Dominant Gene

trait	conspicuous signs
Achondroplasia	dwarfism, large head, short extremities, short fingers and toes
Osteogenesis imperfecta	bone fragility, deafness
Huntington's disease	involuntary movement, emotional disturbance, dementia
Marfan's syndrome	long, thin extremities and fingers, eye and cardiovascular problems
Neurofibromatosis	pigmented spots (café au lait) on skin, skin tumours, occasional brain or other internal tumours

In many genetic diseases, including those that are autosomal dominant, specific mutations associated with the same disease present in different families may be uniform, such that every affected individual carries exactly the same molecular defect (allelic homogeneity), or they may be heterogeneous, such that tens or even hundreds of different mutations, all affecting the same gene, may be seen in the affected population (allelic heterogeneity). In some cases even mutations in different genes can lead to the same clinical disorder (genetic heterogeneity). Achondroplasia is characterized by allelic homogeneity, such that essentially all affected individuals carry exactly the same mutation.

With regard to the physical manifestations (*i.e.*, the phenotype) of some genetic disorders, a mutant gene may cause many different symptoms and may affect many different organ systems (pleiotropy). For example, along with the short-limbed dwarfism characteristic of achondroplasia, some individuals with this disorder also exhibit a long, narrow trunk, a large head with frontal bossing, and hyperextensibility of most joints, especially the knees. Similarly, for some genetic disorders, clinical severity may vary dramatically, even among affected members in the same family. These variations of phenotypic expression are called variable expressivity, and they are undoubtedly due to the modifying effects of either other genes or environmental factors. Finally, although for some disorders, such as achondroplasia, essentially all individuals carrying the mutant gene exhibit the disease phenotype, for other disorders some individuals who carry the mutant gene may express no apparent phenotypic abnormalities at all. Such unaffected individuals are called "non-penetrant," although they can pass on the mutant gene to their offspring, who could be affected.

Autosomal recessive inheritance. Nearly 2,000 traits have been related to single genes that are recessive; that is, their effects are masked by normal ("wild-type") dominant alleles and manifest themselves only in individuals homozygous for the mutant gene. A partial list of recessively inherited diseases is given in Table 6. For example, sickle cell anemia, a severe hemoglobin disorder, results only when a mutant gene (*a*) is inherited from both parents. Each of the latter is a carrier, a heterozygote with one normal gene and one mutant gene (*Aa*) who is phenotypically unaffected. The chance of such a couple producing a child with sickle cell anemia is one out of four for each pregnancy. For couples consisting of one carrier (*Aa*) and one affected individual (*aa*), the chance of their having an affected child is one out of two for each pregnancy.

Table 6: Human Characteristics Often Attributable to a Single Pair of Recessive Genes

trait	conspicuous signs
Albinism	lack of pigment in skin, hair, and eyes, with significant visual problems
Tay-Sachs disease	metabolic disorder that is lethal in childhood
Cystic fibrosis	chronic lung and intestinal symptoms
Phenylketonuria	enzyme disorder leading to mental retardation
Thalassemia	abnormal production of hemoglobin in red blood cells, leading to severe anemia

Phenylketonuria

Many autosomal recessive traits reflect mutations in key metabolic enzymes and result in a wide variety of disorders classified as inborn errors of metabolism. One of the best-known examples of this class of disorders is phenylketonuria (PKU), which results from mutations in the gene encoding the enzyme phenylalanine hydroxylase (PAH). PAH normally catalyzes the conversion of phenylalanine, an amino acid prevalent in dietary proteins and in the artificial sweetener aspartame, to another amino acid called tyrosine. In persons with PKU, dietary phenylalanine either accumulates in the body or some of it is converted to phenylpyruvic acid, a substance that normally is produced only in small quantities. Individuals with PKU tend to excrete large quantities of this acid, along with phenylalanine, in their urine. When infants accumulate high concentrations of phenylpyruvic acid and unconverted phenylalanine in their blood and other tissues, the consequence is mental retardation. Fortunately, with early detection, strict dietary restriction of phenylalanine, and supplementation of tyrosine, mental retardation can be prevented.

Since the recessive genes that cause inborn errors of metabolism are individually rare in the gene pool, it is not often that both parents are carriers; hence, the diseases are relatively uncommon. If the parents are related (consanguineous), however, they will be more likely to have inherited the same mutant gene from a common ancestor. For this reason, consanguinity is often more common in the parents of those with rare, recessive inherited diseases. The pedigree of a family in which PKU has occurred follows (see Figure 20). This pedigree demonstrates that the affected individuals for recessive diseases are usually siblings in one generation—the pedigree tends to be "horizontal" rather than "vertical" as in dominant inheritance.

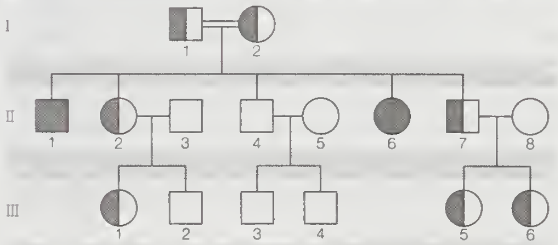

Figure 20: Pedigree of a family in which the gene for phenylketonuria is segregating. The half-solid symbols represent heterozygous carriers of the trait; the double line between the I-1 and I-2 signifies a consanguineous mating.

Sex-linked inheritance. In humans, there are hundreds of genes located on the X chromosome that have no counterpart on the Y chromosome. The traits governed by these genes thus show sex-linked inheritance. This type of inheritance has certain unique characteristics, which include the following: (1) There is no male-to-male (father-to-son) transmission, since sons will, by definition, inherit the Y rather than the X chromosome. (2) The carrier female (heterozygote) has a 50 percent chance of passing the mutant gene to each of her children; sons who inherit the mutant gene will be hemizygotes and will manifest the trait, while daughters who receive the mutant gene will be unaffected carriers. (3) Males with the trait will pass the gene on to all of their daughters, who will be carriers. (4) Most sex-linked traits are recessively inherited, so that heterozygous females generally do not display the trait. Table 7 lists some sex-linked conditions. Figure 21 shows a pedigree of a family in which a mutant gene for hemophilia A, a sex-linked recessive disease, is segregating. Hemophilia A gained notoriety in early studies of human genetics because it affected at least 10 males among the descendants of Queen Victoria, who was a carrier.

Hemophilia A

Table 7: Some Sex-Linked Recessively Inherited Conditions

trait	conspicuous signs
Hemophilia A	bleeding tendency with joint involvement
Duchenne's muscular dystrophy	progressive muscle weakness
Lesch-Nyhan syndrome	cerebral palsy, self-mutilation
Fragile-X syndrome	mental retardation, characteristic facies

Hemophilia A, the most widespread form of hemophilia, results from a mutation in the gene encoding clotting factor VIII. Because of this mutation, affected males cannot produce functional factor VIII, so that their blood fails to clot properly, leading to significant and potentially life-threatening loss of blood after even minor injuries. Bleeding into joints commonly occurs as well and may be crippling. Therapy consists of avoiding trauma and of administering injections of purified factor VIII, which was once isolated from outdated human blood donations but can now be made in large amounts through recombinant DNA technology.

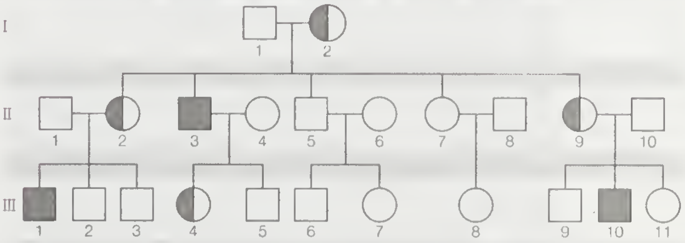

Figure 21: Pedigree of a family with a history of hemophilia A, a sex-linked recessively inherited disease.The half-solid circles represent female carriers (heterozygotes); the solid squares signify affected males (hemizygotes).

Although heterozygous female carriers of X-linked recessive mutations generally do not exhibit traits characteristic of the disorder, cases of mild or partial phenotypic expression in female carriers have been reported, resulting from non-random X inactivation.

Diseases associated with single-gene (non-Mendelian) inheritance. Although disorders resulting from single gene defects that demonstrate Mendelian inheritance are perhaps better understood, it is now clear that a significant number of single-gene diseases also exhibit distinctly non-Mendelian patterns of inheritance. Among these are such disorders that result from triplet repeat expansions within or near specific genes (*e.g.,* Huntington's disease and fragile-X syndrome); a collection of neurodegenerative disorders, such as Leber hereditary optic neuropathy (LHON), that result from inherited mutations in the mitochondrial

DNA; and diseases that result from mutations in imprinted genes (*e.g.,* Angelman's syndrome and Prader-Willi syndrome).

Triplet repeat expansions. At least a dozen different disorders are now known to result from triplet repeat expansions in the human genome, and these fall into two groups: (1) those that involve a polyglutamine tract within the encoded protein product that becomes longer upon expansion of a triplet repeat, an example of which is Huntington's disease; and (2) those that have unstable triplet repeats in non-coding portions of the gene that, upon expansion, interfere with appropriate expression of the gene product, an example of which is fragile-X syndrome (see Figure 22). Both groups of disorders exhibit a distinctive pattern of non-Mendelian inheritance termed anticipation, in which, following the initial appearance of the disorder in a given family, subsequent generations tend to show both increasing frequency and increasing severity of the disorder. This phenotypic anticipation is paralleled by increases in the relevant repeat length as it is passed from one generation to the next, with increasing size leading to increasing instability, until a "full expansion" mutation is achieved, generally several generations following the initial appearance of the disorder in the family. The full expansion mutation is then passed to subsequent generations in a standard Mendelian fashion—for example, autosomal dominant for Huntington's disease and sex-linked for fragile-X syndrome.

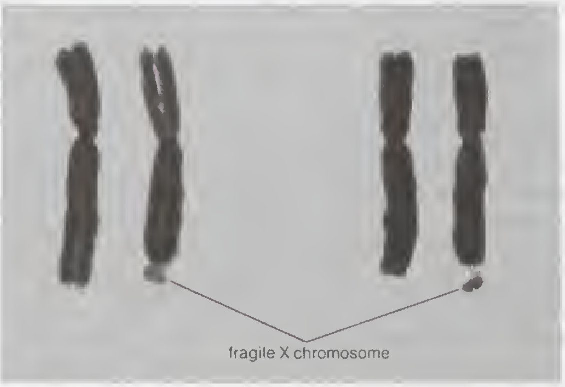

Figure 22: *The fragile X chromosome.*
The right-hand member in each of these two pairs of X chromosomes is a fragile X; the leader points to the fragile site at the tip of the long arm. Males hemizygous for this chromosome exhibit the fragile-X syndrome of mild to moderate mental retardation.

Mitochondrial DNA mutations. Disorders resulting from mutations in the mitochondrial genome demonstrate an alternative form of non-Mendelian inheritance, termed maternal inheritance, in which the mutation and disorder are passed from mothers—never from fathers—to all of their children. The mutations generally affect the function of the mitochondrion, compromising, among other processes, the production of cellular adenosine triphosphate (ATP). Severity and even penetrance can vary widely for disorders resulting from mutations in the mitochondrial DNA, generally believed to reflect the combined effects of heteroplasmy (*i.e.,* mixed populations of both normal and mutant mitochondrial DNA in a single cell) and other confounding genetic or environmental factors. There are close to 50 mitochondrial genetic diseases currently known.

Imprinted gene mutations. Finally, some genetic disorders are now known to result from mutations in imprinted genes. Genetic imprinting involves a sex-specific process of chemical modification to the imprinted genes, so that they are expressed unequally, depending on the sex of the parent of origin. So-called maternally imprinted genes are generally expressed only when inherited from the father, and so-called paternally imprinted genes are generally expressed only when inherited from the mother. The disease gene associated with Prader-Willi syndrome is maternally imprinted, so that although every child inherits two copies of the gene (one maternal, one paternal), only the paternal copy is expressed. If the paternally inherited copy carries a mutation, the child will be left with no functional copies of the gene expressed, and the clinical traits of Prader-Willi syndrome will result. Similarly, the disease gene associated with Angelman's syndrome is paternally imprinted, so that although every child inherits two copies of the gene, only the maternal copy is expressed. If the maternally inherited copy carries a mutation, the child again will be left with no functional copies of the gene expressed, and the clinical traits of Angelman's syndrome will result. Individuals who carry the mutation but received it from the "non-imprinting" parent can certainly pass it on to their children, although they will not exhibit clinical features of the disorder.

Upon rare occasion, persons are identified with an imprinted gene disorder who show no family history and who do not appear to carry any mutation in the expected gene. These cases are now known to result from uniparental disomy, a phenomenon whereby a child is conceived who carries the normal complement of chromosomes, but who has inherited both copies of a given chromosome from the same parent, rather than one from each parent, as is the normal fashion. If any key genes on that chromosome are imprinted in the parent of origin, the child may end up with no expressed copies, and a genetic disorder may result. Similarly, other genes may be overexpressed in cases of uniparental disomy, perhaps also leading to clinical complications. Finally, uniparental disomy can account for very rare instances whereby two parents, only one of whom is a carrier of an autosomal recessive mutation, can nonetheless have an affected child, in the circumstance that the child inherits two mutant copies from the carrier parent.

Diseases caused by multifactorial inheritance. Genetic disorders that are multifactorial in origin represent probably the single largest class of inherited disorders affecting the human population. By definition, these disorders involve the influence of multiple genes, generally acting in concert with environmental factors. Such common conditions as cancer, heart disease, and diabetes are now considered to be multifactorial disorders. Indeed, improvements in the tools used to study this class of disorders have enabled the assignment of specific contributing gene loci to a number of common traits and disorders. Identification and characterization of these contributing genetic factors may not only enable improved diagnostic and prognostic indicators but may also identify potential targets for future therapeutic intervention.

Table 8: Common Multifactorially Determined Diseases
Alcoholism
Alzheimer's disease
Cancer
Coronary heart disease
Diabetes
Epilepsy
Hypertension
Obesity
Schizophrenia

Table 8 lists some conditions associated with multifactorial inheritance. Because the genetic and environmental factors that underlie these conditions are often unknown, the risks of recurrence are usually arrived at empirically. In general, it can be said that risks of recurrence are not as great for multifactorial conditions as for single-gene diseases and that the risks vary with the number of relatives affected and the closeness of their relationship. Moreover, close relatives of more severely affected individuals (*e.g.,* those with bilateral cleft lip and cleft palate) are generally at greater risk than those related to persons with a less severe form of the same condition (*e.g.,* unilateral cleft lip).

GENETICS OF CANCER

Although at least 90 percent of all cancers are sporadic, meaning that they do not seem to run in families, nearly 10 percent of cancers are now recognized as familial, and some are actually inherited in an apparently autosomal dominant manner. Cancer may therefore be considered a multifactorial disease, resulting from the combined influence of many genetic factors acting in concert with environmental insults (*e.g.,* ultraviolet radiation, cigarette smoke, and viruses).

Cancers, both familial and sporadic, generally arise from alterations in one or more of three classes of genes: oncogenes, tumour suppressor genes, and genes whose products participate in genome surveillance—for example, in DNA damage repair. All of these functions are described in the article CANCER. For familial cancers, affected members inherit one mutant copy of a gene that falls into one of the latter two classes. That mutation alone is not sufficient to cause cancer, but it predisposes individuals to the disease because they are now either more sensitive to spontaneous somatic mutations, as in the case of altered tumour suppressor genes, or are more prone to experience mutations, as in the case of impaired DNA repair enzymes. Of course, sporadic cancers can also arise from mutations in these same classes of genes, but because all of the mutations must arise in the individual *de novo,* as opposed to being inherited, they generally appear only later in life, and they do not run in families.

Retinoblastoma

Retinoblastoma, an aggressive tumour of the eye that typically occurs in childhood, offers perhaps one of the clearest examples of the interplay between inherited and somatic mutations in the genesis of cancer. Current data suggest that 60 to 70 percent of all cases of retinoblastoma are sporadic, while the rest are inherited. The relevant gene, *RB,* encodes a protein that normally functions as a suppressor of cell cycle progression and is considered a classic tumour suppressor gene. Children who inherit one mutant copy of the *RB* gene are at nearly 100 percent risk to develop retinoblastoma because the probability that their one remaining functional *RB* gene will sustain a mutation in at least one retinal cell is nearly assured. In contrast, children who inherit two functional copies of the *RB* gene must experience two mutations at the *RB* locus in the same retinal cell in order to develop retinoblastoma; this is a very rare event. This "two-hit" hypothesis of retinoblastoma formation, originated by Alfred Knudson, Jr., has provided a foundation upon which most subsequent theories of the genetic origins of familial cancer have been built.

Recent studies of both breast and colon cancers have revealed that, like retinoblastoma, these cancers are predominantly sporadic, although a small proportion are clearly familial. Sporadic breast cancer generally appears late in life, while the familial forms can present much earlier, often before age 40. For familial breast cancer, inherited mutations in one of two specific genes, *BRCA1* and *BRCA2,* account for at least half of the cases observed. The *BRCA1* and *BRCA2* genes both encode protein products believed to function in the pathways responsible for sensing and responding to DNA damage in cells. While a woman in the general population has about a 10 percent lifetime risk of developing breast cancer, half of all women with *BRCA1* or *BRCA2* mutations will develop breast cancer by age 50, and close to 90 percent will develop the disease by age 80. Women with *BRCA1* mutations are also at increased risk to develop ovarian tumours. As with retinoblastoma, both men and women who carry *BRCA1* or *BRCA2* mutations, whether they are personally affected or not, can pass the mutated gene to their offspring, although carrier daughters are much more likely than carrier sons to develop breast cancer.

BRCA1 and *BRCA2* genes

Two forms of familial colon cancer, hereditary nonpolyposis colorectal cancer (HNPCC) and familial adenomatous polyposis (FAP), have also been linked to predisposing mutations in specific genes. Persons with familial HNPCC have inherited mutations in one or more of their DNA mismatch repair genes, predominantly *MSH2* or *MLH1.* Similarly, persons with FAP carry inherited mutations in their *APC* genes, the protein product of which normally functions as a tumour suppressor. For persons in both categories, the combination of inherited and somatic mutations results in a nearly 100 percent lifetime risk of developing colon cancer.

Although most cancer cases are not familial, all are undoubtedly diseases of the genetic material of somatic cells. Studies of large numbers of both familial and sporadic cancers have led to the conclusion that cancer is a disease of successive mutations, acting in concert to deregulate normal cell growth, provide appropriate blood supply to the growing tumour, and ultimately enable tumour cell movement beyond normal tissue boundaries to achieve metastasis (*i.e.,* the dissemination of cancer cells to other parts of the body).

Many of the agents that cause cancer (*e.g.,* X rays, certain chemicals) also cause mutations or chromosome abnormalities. For example, a large fraction of sporadic tumours have been found to carry oncogenes, altered forms of normal genes (proto-oncogenes) that have sustained a somatic "gain-of-function" mutation. An oncogene may be carried by a virus, or it can result from a chromosomal rearrangement, as is the case in chronic myelogenous leukemia, a cancer of the white blood cells characterized by the presence of the so-called Philadelphia chromosome in affected cells. The Philadelphia chromosome arises from a translocation in which one half of the long arm of chromosome 22 becomes attached to the end of the long arm of chromosome 9, creating the dominant oncogene *BCR/abl* at the junction point. The specific function of the *BCR/abl* fusion protein is not entirely clear. Another example is Burkitt's lymphoma, in which a rearrangement between chromosomes places the *myc* gene from chromosome 8 under the influence of regulatory sequences that normally control expression of immunoglobulin genes. This deregulation of *myc,* a protein involved in mediating cell cycle progression, is thought to be one of the major steps in the formation of Burkitt's lymphoma.

COGNITIVE AND BEHAVIORAL GENETICS

Mental activities, expressed in human behaviour, are intimately related to physical activities in the brain and nervous system. In 1929 British physician Sir Archibald Garrod emphasized this when he wrote: "Each one of us differs from his fellows, not only in bodily structure and the proteins which enter into his composite, but apart from, or rather in consequence of, such individualities, men differ in mental outlook, character and ability." Since that time, many investigators have sought to analyze the molecular and cellular components of behaviour in order to relate genes to such abstractions as intellect, temperament, and the emotions. Because the brain is ultimately responsible for behavioral development, neurobiologists have attempted to understand the unusual precision by which this organ's various regions are interconnected and the intricate chemical signals that, under genetic control, organize its complicated nerve fibre circuits.

"Nature" versus "nurture"

Some of the most powerful experiments to dissect the "nature"-versus-"nurture" aspects of human intelligence and behaviour have involved studies of twins, both monozygotic (identical) and dizygotic (fraternal). Cognitive or behavioral characteristics that are entirely under genetic control would be predicted to be the same, or concordant, in monozygotic twins, who share identical genes regardless of their upbringing. These same characteristics would be predicted to be less concordant in dizygotic twins, who share, on average, only half of their genes. Comparison of the concordance rates among monozygotic and dizygotic twins monitored for different traits allows an estimate of the heritability of those traits—that is, the proportion of population variation for a given trait that can be attributed to genes. A heritability value of 1.0 implies a purely genetic basis for a trait, and a value of 0.0 implies a purely environmental basis. Intelligence, measured as IQ, has a heritability value of 0.5, indicating that both genetics and the environment play major roles. In contrast, schizophrenia has a value of 0.7, and both autism and bipolar disorder have heritability values of 1.0. Clearly, genetics play a large role in determining not only how our bodies look and function but also how we think and feel.

GENETIC DAMAGE FROM ENVIRONMENTAL AGENTS

We are exposed to many agents, both natural and manmade, that can cause genetic damage. Among these agents are viruses; compounds produced by plants, fungi, and bacteria; industrial chemicals; products of combustion; alcohol; ultraviolet and ionizing radiation; and even the oxygen that we breathe. Many of these agents have long been unavoidable, and consequently human beings have evolved defenses to minimize the damage that they cause and ways to repair the damage that cannot be avoided.

Viruses. Viruses survive by injecting their genetic material into living cells with the consequence that the biochemical machinery of the host cell is subverted from serving its own needs to serving the needs of the virus. During this process the viral genome often integrates itself into the genome of the host cell. This integration, or insertion, can occur either in the intergenic regions that make up the vast majority of human genomes, or it can occur in the middle of an important regulatory sequence or even in the region coding for a protein, *i.e.,* a gene. In either of the latter two scenarios, the regulation or function of the interrupted gene is lost. If that gene encodes a protein that normally regulates cell division, the result may be unregulated cell growth and division. Alternatively, some viruses carry dominant oncogenes in their genomes, which can transform an infected cell and start it on the path toward cancer.

Finally, viruses can cause mutations leading to cancer by killing the infected cell. Indeed, one of the body's defenses against viral infection involves recognizing and killing infected cells. The death of cells necessitates their replacement by the division of uninfected cells, and the more cell division that occurs, the greater the likelihood of a mutation arising from the small but finite infidelity in DNA replication. Among the viruses that can cause cancer are: Epstein-Barr virus, papillomaviruses, hepatitis B and C viruses, retroviruses (*e.g.,* human immunodeficiency virus), and herpesviruses.

Plants, fungi, and bacteria. During the ongoing struggle for survival, organisms have evolved toxic compounds as protection against predators or simply to gain competitive advantage. At the same time, these organisms have evolved mechanisms that make themselves immune to the effects of the toxins that they produce. Plants in particular utilize this strategy since they are rooted in place and cannot escape from predators. One-third of the dry weight of some plants can be accounted for by the toxic compounds that are collectively referred to as alkaloids. *Aspergillus flavus,* a fungus that grows on stored grain and peanuts, produces a powerful carcinogen called aflatoxin that can cause liver cancer. Bacteria produce many proteins that are toxic to the infected host such as diphtheria toxin. They also produce proteins called bacteriocins that are toxic to other bacteria. Toxins can cause mutations indirectly by causing cell death, which necessitates replacement by cell division, thus enhancing the opportunity for mutation. Cyanobacteria that grow in illuminated surface water produce several carcinogens such as microcystin, saxitoxin, and cylindrospermopsin that can also cause liver cancer.

Industrial chemicals. Tens of thousands of different chemicals are routinely used in the production of plastics, fuels, food additives, and even medicines. Many of these chemicals are mutagens, and some have been found to be carcinogenic (cancer producing) in rats or mice. A relatively easy and inexpensive test for mutagenicity, the Ames test, utilizes mutant strains of the bacterium *Salmonella typhimurium* and can be completed in a few days. Testing for carcinogenesis, on the other hand, is very time consuming and expensive because the test substance must be administered to large numbers of laboratory animals, usually mice, for months before the tissues can be examined for cancers. For this reason, the number of known mutagens far exceeds the number of known carcinogens. Furthermore, animal tests for carcinogenesis are not completely predictive of the effects of the test chemical on humans for several reasons. First, the abilities of laboratory animals and humans to metabolize and excrete specific chemicals can differ greatly. In addition, in order to avoid the need to test each chemical at a range of doses, each chemical is usually administered at the maximum tolerated dose. At such high doses, toxicity and cell death occurs, necessitating cell replacement by growth and cell division; cell division, in turn, increases the opportunity for mutation and hence for cancer. Alternatively, unusually high doses of a chemical may actually mask the carcinogenic potential of a compound because damaged cells may die rather than survive in mutated form.

Combustion products. The burning of fossil fuels quite literally powers modern industrial societies. If the combustion of such fuels were complete, the products would be carbon dioxide and water. However, combustion is rarely complete, as is evidenced by the visible smoke issuing from chimneys and from the exhausts of diesel engines. Moreover, in addition to the particulates that we can see, incomplete combustion produces a witch's brew of volatile compounds that we do not see; and some of these, such as the dibenzodioxins, are intensely mutagenic and have been demonstrated to cause cancer in laboratory rodents. Epidemiological data indicates that dioxins are associated with increased risk of a variety of human cancers. The health consequences of combustion are further increased by impurities in fossil fuels and in the oxygen that supports their burning. For example, coal contains sulfur, mercury, lead, and other elements in addition to carbon. During combustion sulfur becomes sulfur dioxide, and that, in turn, gives rise to sulfurous and sulfuric acids. The mercury in the fuel is emitted as a vapour that is very toxic. Atmospheric nitrogen is oxidized at the high temperature of combustion.

Cigarette smoke

The smoke from a cigarette, drawn directly into the lungs, imparts a large number of particulates, as well as a host of volatile compounds, directly into the airways and alveoli. Some of the volatile compounds are toxic in their own right and others, such as hydroquinones, slowly oxidize, producing genotoxic free radicals. As macrophages in the lungs attempt to engulf and eliminate particulates, they cause the production of mutagenic substances. A large fraction of lung cancers are attributable to cigarette smoking, which is also a risk factor for atherosclerosis, high blood pressure, heart attacks, and strokes.

Alcohol. Moderate consumption of alcohol (ethanol) is well tolerated and may even increase life span. However, alcohol is a potentially toxic substance and one of its metabolites, acetaldehyde, is a mild mutagen. Hence, it is not surprising that the chronic consumption of alcohol leads to liver cirrhosis and other untoward effects. Consumption of alcohol during pregnancy can cause fetal alcohol syndrome, which is characterized by low birth weight, mental retardation, and congenital heart disease.

Skin cancer and the ozone layer

Ultraviolet radiation. Due to human activities that result in the release of volatile halocarbon compounds, such as the refrigerant freon and the solvent carbon tetrachloride, the chlorine content of the upper atmosphere is increasing. Chlorine catalyzes the decomposition of ozone, which shields the Earth from ultraviolet radiation that is emitted from the Sun. The Earth's ozone shield has been progressively depleted, most markedly over the polar regions but also measurably so over the densely populated regions of northern Europe, Australia, and New Zealand. One consequence has been an increase in a variety of skin cancers, including melanoma, in those areas. Steps have been taken to stop the release of halocarbons, but the depletion of the ozone layer will nonetheless persist and may worsen for at least several decades.

Ultraviolet light, when acting on DNA, can lead to covalent linking of adjacent pyrimidine bases. Such pyrimidine dimerization is mutagenic, but this damage can be repaired by an enzyme called photolyase, which utilizes the energy of longer wavelengths of light to cleave the dimers. However, people with a defect in the gene coding for photolyase develop xeroderma pigmentosum, a condition characterized by extreme sensitivity to sunlight. These individuals develop multiple skin cancers on all areas of exposed skin, such as the head, neck, and arms.

Ultraviolet light can also be damaging because of photosensitization, the facilitation of photochemical processes. One way that photosensitizers work is by absorbing a photon and then transferring the energy inherent in that photon to molecular oxygen, thus converting the less active ground-state molecular oxygen into a very reactive excited state, referred to as singlet oxygen, that can attack a variety of cellular compounds, including DNA. Diseases that have a photosensitizing component include lupus and porphyrias. In addition to photosensitizers that occur naturally in the human body, some foods and medicines (*e.g.*, tetracyclines and neuroleptics) also act in this way, producing painful inflammation and blistering of the skin following even modest exposure to the sun.

Ionizing radiation. X rays and gamma rays are sufficiently energetic to cleave water into hydrogen atoms and hydroxyl radicals and are consequently referred to as ionizing radiation. Ionizing radiation and the products of the cleavage of water are able to damage all biological macromolecules, including DNA, proteins, and polysaccharides, and they have long been recognized as being mutagenic, carcinogenic, and lethal. People are routinely exposed to natural sources of ionizing radiation, such as cosmic rays and radioisotopes such as carbon-14 and radon. They are also exposed to X rays and man-made radioisotopes used for diagnostic purposes, and some people have been exposed to radioactive fallout from nuclear weapon tests and reactor accidents. Such exposures would be much more damaging were it not for multiple mechanisms of DNA repair, which have evolved to deal with simple errors in replication as well as damage from naturally occurring sources of damage.

Molecular oxygen. Molecular oxygen (O_2), although essential for life, must be counted among the environmental toxins and mutagens. Because of its unusual electronic structure, O_2 is most easily reduced not by electron pairs but rather by single electrons added one at a time. As O_2 is converted into water, superoxide (O_2^-), hydrogen peroxide (H_2O_2), and a hydroxyl radical (HO) are produced as intermediates. O_2^- can initiate free radical oxidation of important metabolites, inactivate certain enzymes, and cause release of iron from specific enzymes. The second intermediate, H_2O_2, is a strong oxidant and can give rise to an even more potent oxidant, namely HO, when it reacts with ferrous iron. Thus, O_2^- and H_2O_2 can collaborate in the formation of the destructive HO and can subsequently lead to DNA damage, mutagenesis, and cell death. Breathing 100 percent oxygen causes damage to the alveoli, which leads to accumulation of fluid in the lungs. Thus, paradoxically, prolonged exposure to hyperoxia causes death due to lack of oxygen.

Humans have evolved multiple defense systems to counter the toxicity and mutagenicity of O_2. Thus, O_2 is rapidly converted into O_2 and H_2O_2 by a family of enzymes called superoxide dismutases. H_2O_2, in turn, is eliminated by other enzymes called catalases and peroxidases, which convert it into O_2 and water.

A few genetic diseases are known to be related to oxygen radicals or to the enzymes that defend against them. Chronic granulomatous disease (CGD) is caused by a defect in the ability of the phagocytic leukocytes to mount the respiratory burst, part of the body's defense against infection. Upon contacting microorganisms and engulfing them, phagocytes greatly increase their consumption of O_2 (the respiratory burst) while releasing O_2^-, H_2O_2, hypochlorite (HOCl), and other agents that kill the microbe. The reduction of O_2 to O_2^- is caused by a multicomponent enzyme called the NADPH oxidase. A defect in any of the components of this oxidase will lead to the absence of the respiratory burst, giving rise to the constant infections indicative of CGD. Before the discovery and clinical application of antibiotics, people born with CGD died from infection during early childhood.

Lou
Gehrig's
disease

Another such genetic disease is the familial form of amyotrophic lateral sclerosis (ALS), also known as Lou Gehrig's disease, which is characterized by late-onset progressive paralysis due to the loss of motor neurons. Approximately 20 percent of cases of ALS have been shown to result from mutations affecting the enzyme superoxide dismutase. The disease is genetically dominant, so that the mutant enzyme causes the disease even when half of the superoxide dismutase present in cells exists in the normal form. Interestingly, most of the mutant variants retain full catalytic activity.

MANAGEMENT OF GENETIC DISEASE

The management of genetic disease can be divided into counseling, diagnosis, and treatment. In brief, the fundamental purpose of genetic counseling is to help the individual or family understand their risks and options and to empower them to make informed decisions. Diagnosis of genetic disease is sometimes clinical, based on the presence of a given set of symptoms, and sometimes molecular, based on the presence of a recognized gene mutation, whether clinical symptoms are present or not. The cooperation of family members may be required to achieve diagnosis for a given individual, and, once accurate diagnosis of that individual has been determined, there may be implications for the diagnoses of other family members. Balancing privacy issues within a family with the ethical need to inform individuals who are at risk for a particular genetic disease can become extremely complex.

Finally, although effective treatments exist for some genetic diseases, for others there are none. It is perhaps this latter set of disorders that raises the most troubling questions with regard to presymptomatic testing, because phenotypically healthy individuals can be put in the position of hearing that they are going to become ill and potentially die and that there is nothing they or anyone else can do to stop it. Fortunately, with time and research, this set of disorders is slowly becoming smaller.

Genetic counseling. Genetic counseling represents the most direct medical application of the advances in understanding of basic genetic mechanisms. Its chief purpose is to help people make responsible and informed decisions concerning their own health or that of their children. Genetic counseling, at least in democratic societies, is non-directive; the counselor provides information, but decisions are left up to the individual or the family.

Calculating risks of known carriers. Most couples who present themselves for pre-conceptional counseling fall into one of two categories: those who have already had a child with genetically based problems, and those who have one or more relatives with a disease they think might be inherited. The counselor must confirm the diagnosis in the affected person with meticulous accuracy, so as to rule out the possibility of alternative explanations for the clinical symptoms observed. A careful family history permits construction of a pedigree that may illuminate the nature of the inheritance (if any), may affect the calculation of risk figures, and may bring to light other genetic influences. The counselor, a certified health-care professional with special training in medical genetics, must then decide whether the disease in question has a strong genetic component and, if so, whether the heredity is single-gene, chromosomal, or multifactorial.

In the case of single-gene Mendelian inheritance, the disease may be passed on as an autosomal recessive, autosomal dominant, or sex-linked recessive trait, as discussed in the section *Classes of genetic disease.* If the prospective parents already have a child with an autosomal recessive inherited disease, they both are considered by definition to be carriers, and there is a 25 percent risk that each future child will be affected. If one of the parents carries a mutation known to cause an autosomal dominant inherited disease, whether that parent is clinically affected or not, there is a 50 percent risk that each future child will inherit the mutation and therefore may be affected. If, however, the couple has borne a child with an autosomal dominant inherited disease though neither parent carries the mutation, then it will be presumed that a spontaneous mutation has occurred and that there is not a markedly increased risk for recurrence of the disease in future children. There is a caveat to this reasoning, however, because there is also the possibility that the new mutation might have occurred in a progenitor germ cell in one of the parents, so that some unknown proportion of that individual's eggs or sperm may carry the mutation, even though it is absent from the somatic cells—including blood, which is generally the tissue sampled for testing. This scenario is called germ-line mosaicism. With regard to X-linked disorders, if the pedigree or carrier testing suggests that the mother carries a gene for a sex-linked disease, there is a 50 percent chance that each son will be affected and that each daughter will be a carrier.

Counseling for chromosomal inheritance most frequently involves either an inquiring couple (consultands) who have had a child with a known chromosomal disorder, such as Down syndrome, or a couple who have experienced multiple miscarriages. To provide the most accurate recurrence risk values to such couples, both parents should be karyotyped to determine if one may be a balanced translocation carrier. Balanced translocations refer to genomic rearrangements in which there is an abnormal covalent arrangement of chromosome segments, although there is no net gain or loss of key genetic material. If both parents exhibit completely normal karyotypes, the recurrence risks cited are low and are strictly empirical.

Most of the common hereditary birth defects, however, are multifactorial. (See above *Diseases caused by multifactorial inheritance.*) If the consulting couple have had one affected child, the empirical risk for each future child will be about 3 percent. If they have borne two affected children, the chance of recurrence will rise to about 10 percent. Clearly these are population estimates, so that the risks within individual families may vary.

Estimating probability: Bayes's theorem. As described above, the calculation of risks is relatively straightforward when the consultands are known carriers of diseases due to single genes of major effect that show regular Mendelian inheritance. For a variety of reasons, however, the parental genotypes frequently are not clear and must be approximated from the available family data. Bayes's theorem, a statistical method first devised by the English clergyman-scientist Thomas Bayes in 1763, can be used to assess the relative probability of two or more alternative possibilities (*e.g.,* whether a consultand is or is not a carrier). The likelihood derived from the appropriate Mendelian law (prior probability) is combined with any additional information that has been obtained from the consultand's family history or from any tests performed (conditional probability). A joint probability is then determined for each alternative outcome by multiplying the prior probability by all conditional probabilities. By dividing the joint probability of each alternative by the sum of all joint probabilities, the posterior probability is arrived at. Posterior probability is the likelihood that the individual, whose genotype is uncertain, either carries the mutant gene or does not.

This method can be applied to, for example, the sex-linked recessive disease Duchenne's muscular dystrophy (DMD). In this example, the consultand wishes to know her risk of having a child with DMD. The family's pedigree is illustrated in Figure 23. It is known that the consultand's grandmother (I-2) is a carrier, since she had two affected sons (spontaneous mutations occurring in both brothers would be extremely unlikely). What is uncertain is whether the consultand's mother (II-4) is also a carrier. The Bayesian method for calculating the consultand's risk is as follows:

	likelihood that consultand's mother (II-4) is a carrier	likelihood that consultand's mother (II-4) is not a carrier
prior probability	1/2	1/2
conditional probability	1/4 (for each of her sons there was a 1/2 chance of being unaffected)	1
joint probability	$1/2 \times 1/4 = 1/8$	$1 \times 1/2 = 1/2$
posterior probability	$\frac{1/8}{1/8 + 1/2} = 1/5$	$\frac{1/2}{1/8 + 1/2} = 4/5$

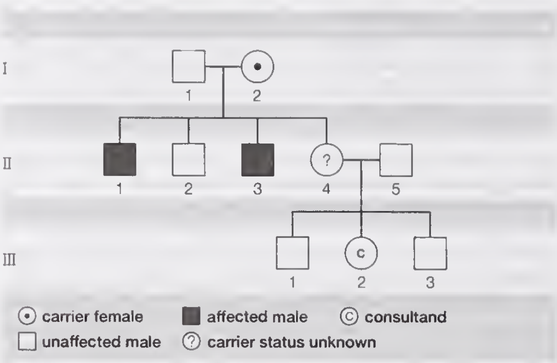

Figure 23: Pedigree of a family with a history of Duchenne's muscular dystrophy. The consultand (III-2) wishes to know her risk of having an affected child.

If II-4 is a carrier (risk = 1/5), then there is a 1/2 chance that the consultand is also a carrier, so her total empirical risk is 1/5 × 1/2 = 1/10. If she becomes pregnant, there is a 1/2 chance that her child will be male and a 1/2 chance that the child, regardless of sex, will inherit the familial mutation. Hence, the total empirical risk for the consultand (III-2) to have an affected child is 1/10 × 1/2 × 1/2 = 1/40. Of course, if the familial mutation is known, presumably from molecular testing of an affected family member, the carrier status of III-2 could be determined directly by molecular analysis, rather than estimated by Bayesian calculation. If the family is cooperative and an affected member is available for study, this is clearly the most informative route to follow, because the risk for the consultand to carry the familial mutation would be either 1 or 0, and not 1/10. If her risk is 1, then each of her sons will have a 1/2 chance of being affected. If her risk is 0, none of her children will be affected (unless a new mutation occurs, which is very rare).

Options available

After determining the nature of the heredity, the counselor discusses with the consultand the likely risks and the available options to minimize impact of those risks on the individual and the family. In the case of a couple in which one member has a family history of a genetic disorder—for example, cystic fibrosis—typical options might include any of the following choices: (1) Accept the risks and take a chance that any future children may be affected. (2) Seek molecular testing for known mutations for cystic fibrosis in relevant family members to determine with greater accuracy whether either or both prospective parents are carriers for this recessive disorder. (3) If both members of the couple are determined to be carriers, utilize donor sperm for artificial insemination. This option is a good genetic solution only if the husband carries a dominant mutation or if both parents are carriers of a recessive mutation. If the recessive trait is reasonably common, as are mutations for cystic fibrosis, however, it would be reasonable to ask that the sperm donor be checked for carrier status before pursuing this option. (4) Proceed with natural reproduction, but pursue prenatal diagnosis with the possibility of selective termination of an affected pregnancy, if desired by the parents. (5) Pursue in vitro fertilization with donor eggs, if the woman is the at-risk partner, or use both eggs and sperm from the couple but employ pre-implantation diagnostics to select only unaffected embryos for implantation (see below). (6) Decide against biological reproduction because the risks and available options are unacceptable; possibly pursue adoption.

Diagnosis. *Prenatal diagnosis.* Perhaps one of the most sensitive areas of medical genetics is prenatal diagnosis, the genetic testing of an unborn fetus, because of fears of eugenic misuse or because some couples may choose to terminate a pregnancy depending on the outcome of the test. Nonetheless, prenatal testing in one form or another is now almost ubiquitous in most industrialized nations, and recent advances both in testing technologies and in the set of "risk factor" genes to be screened promise to make prenatal diagnosis even more widespread. Indeed, parents may soon be able to ascertain not only information about the sex and health status of their unborn child but also about his or her complexion, personality, and intellect. Whether parents should have access to all of this information and how they may choose to use it is a matter of much debate.

Current forms of prenatal diagnosis can be divided into two classes, those that are apparently noninvasive and those that are more invasive. At present the noninvasive tests are generally offered to all pregnant women, while the more invasive tests are generally recommended only if some risk factors exist. The noninvasive tests include ultrasound imaging and maternal serum tests. Serum tests include one for alphafetoprotein (AFP) or one for alphafetoprotein, estriol, and human chorionic gonadotropin (triple screen). These tests serve as screens for structural fetal malformations and for neural tube closure defects. The triple screen also can detect some cases of Down syndrome, although there is a significant false positive and false negative rate.

Amniocentesis

More invasive tests include amniocentesis, chorionic villus sampling, percutaneous umbilical blood sampling, and, upon rare occasion, pre-implantation testing of either a polar body or a dissected embryonic cell. Amniocentesis is a procedure in which a long, thin needle is inserted through the abdomen and uterus into the amniotic sac, enabling the removal of a small amount of the amniotic fluid bathing the fetus. This procedure is generally performed under ultrasound guidance during the 15th to 17th week of pregnancy, and although it is generally regarded as safe, complications can occur, ranging from cramping to infection or loss of the fetus. The amniotic fluid obtained can be used in each of three ways: (1) living fetal cells recovered from this fluid can be induced to grow and can be analyzed to assess chromosome number, composition, or structure; (2) cells recovered from the fluid can be used for molecular studies; and (3) the amniotic fluid itself can be analyzed biochemically to determine the relative abundance of a variety of compounds associated with normal or abnormal fetal metabolism and development. Amniocentesis is typically offered to pregnant women over the age of 35 due to the significantly increased rate of chromosome disorders observed in the children of older mothers. A clear advantage of amniocentesis is the wealth of material obtained and the relative safety of the procedure. The disadvantage is timing: results may not be received until the pregnancy is already into the 19th week or beyond, at which point the possibility of termination may be much more physically and emotionally wrenching than if considered earlier.

Chorionic villus sampling (CVS) is a procedure in which either a needle is inserted through the abdomen or a thin tube is inserted into the vagina and cervix to obtain a small sample of placental tissue called chorionic villi. CVS has the advantage of being performed earlier in the pregnancy (generally 10–11 weeks), although the risk of complications is greater than that for amniocentesis. Risks associated with CVS include fetal loss and fetal limb reduction if the procedure is performed earlier than 10 weeks gestation. Another disadvantage of CVS reflects the tissue sampled: chorionic villi are not part of the embryo, and as such a sample may not accurately represent the embryonic genetic constitution. In contrast, amniotic cells are embryonic in origin, having been sloughed off into the fluid. Therefore, abnormalities, often chromosomal, may be seen in the chorionic villi but not in the fetus, or vice versa.

Both percutaneous umbilical blood sampling (PUBs) and pre-implantation testing are rare, relatively high-risk, and performed only in very unusual cases. Pre-implantation testing of embryos derived by in vitro fertilization is a particularly new technique and is currently used only in cases of couples at high risk for having a fetus affected with a given familial genetic disorder who find all other alternatives unacceptable. Pre-implantation testing involves obtaining eggs and sperm from the couple, combining them in the laboratory, and allowing the resultant embryos to grow until they reach the early blastocyst stage of development, at which point a single cell is removed from the rest and harvested for fluorescent in situ hybridization (FISH) or molecular analysis. The problem with this procedure is that one cell is scant material for diagnosis, so that a large array of tests cannot be performed. Similarly, if the test fails for any technical reason, it cannot be repeated. Finally, embryos determined to be normal and therefore selected for implantation into the mother are subject to other complications normally associated with in vitro fertilization—namely, that only a small fraction of the implanted embryos make it to term and that multiple, and therefore high-risk, pregnancies are common. Nonetheless, many at-risk couples find these complications easier to accept than an elective termination of the pregnancy.

Finally, it should be noted that researchers have identified fetal cells in the maternal circulation and that procedures are currently under development to enable their isolation and analysis, thereby providing a noninvasive alternative for molecular prenatal testing. Although these techniques are currently experimental and are not yet available for clinical application, they may well become the methods of choice in the future.

Genetic testing. In the case of genetic disease, options often exist for presymptomatic diagnosis—that is, diagnosis of individuals at risk for developing a given disorder, even though at the time of diagnosis they may be clinically healthy. Options may even exist for carrier testing, studies that determine whether an individual is at increased risk of having a child with a given disorder, even though he or she personally may never display symptoms. Accurate predictive information can enable early intervention, often preventing the clinical onset of symptoms rather than waiting for and then responding to them, in which case irreversible damage may have already occurred. In the case of carrier testing, accurate information can enable prospective parents to make more informed family planning decisions. Unfortunately, there can also be negative aspects of early detection, including such issues as privacy, individual responses to potentially negative information, discrimination in the workplace, or discrimination in access to or cost of health or life insurance. While some governments have outlawed the use of presymptomatic genetic testing information by insurance companies and employers, others have embraced it as a way to bring spiraling health care costs under control. Some communities have even considered instituting premarital carrier testing for common disorders in the populace.

Genetic testing procedures can be divided into two different groups: (1) testing of individuals considered at risk from phenotype or family history, and (2) screening of entire populations, regardless of phenotype or personal family history, for evidence of genetic disorders common in that population. Both forms are currently pursued in many societies. Indeed, with the explosion of information about the human genome and the increasing identification of potential "risk genes" for common disorders, such as cancer, heart disease, or diabetes, the role of predictive genetic screening in general medical practice is likely to increase.

At present, adults are generally tested for evidence of genetic disease only if personal or family history suggests they are at increased risk for a given disorder. A typical example would be a young man whose father, paternal aunt, and older brother have all been diagnosed with early onset colon cancer. Although this person may appear perfectly healthy, he is at significantly increased risk to carry mutations associated with familial colon cancer, and accurate genetic testing could enable heightened surveillance (*e.g.,* frequent colonoscopies) that might ultimately save his life.

Carrier testing for adults in most developed nations is generally offered only if family history or ethnic origins suggest an increased risk of having a particular disease. A typical example would be to offer carrier testing for cystic fibrosis to a couple including one member who has a sibling with the disorder. Another would be to offer carrier testing for Tay-Sachs disease to couples of Ashkenazic Jewish origin, a population known to carry an increased frequency of Tay-Sachs mutations. The same would be true for couples of African or Mediterranean descent with regard to sickle cell anemia or thalassemia, respectively. Typically, in each of these cases a genetic counselor would be involved to help the individuals or couples understand their options and make informed decisions.

Newborn screening

Screening of large unphenotyped populations for evidence of genetic disease is currently pursued in most industrialized nations only in the newborn population, although future developments in the identification of risk genes for common adult-onset disorders may change this policy. So-called mandated newborn screening was initiated in many societies in the latter quarter of the 20th century in an effort to prevent the drastic and often irreversible damage associated with a small number of relatively common genetic disorders whose sequelae can be either prevented or significantly relieved by early detection and intervention. The general practice is to collect a small sample of blood from each newborn, generally by pricking the infant's heel and collecting drops of blood on special filter paper, which is then analyzed. Perhaps the best-known disorder screened in this manner is phenylketonuria (PKU), an autosomal recessive inborn error of metabolism discussed in the section *Autosomal recessive inheritance.* With early diagnosis and dietary intervention that is maintained throughout life, children with PKU can escape mental retardation and grow into healthy adults who lead full and productive lives. Although many of the genetic disorders currently tested by mandated newborn screening are metabolic in nature, this trend is beginning to change. For example, in some communities newborns are screened for profound congenital hearing loss, which is now known to be frequently genetic in origin and for which effective intervention is now available (*e.g.,* through cochlear implants).

Genetic tests themselves can take many forms, and the choice of tests depends on a number of factors. For example, screening for evidence of sickle cell anemia, a hemoglobin disorder, is generally pursued at least initially by tests involving the hemoglobin proteins themselves, rather than DNA, because the relevant gene product (blood) is readily accessible and because the protein test is currently cheaper to perform than the DNA test. In contrast, screening for cystic fibrosis, a disorder that predominantly affects the lungs and pancreas, is generally pursued in the at-risk newborn at the level of DNA because there is no cheap and accurate alternative. Older persons suspected of having cystic fibrosis, however, can also be diagnosed with a "sweat test" that measures sweat electrolytes.

Tests involving analysis of DNA are particularly powerful because they can be performed using very tiny samples; also, the DNA tested can originate from almost any tissue type, regardless of whether the gene of interest happens to be expressed in that tissue. Current technologies applied for mutation detection include traditional karyotyping and Southern blotting, as well as a multitude of new tests, including FISH with specific probes or the polymerase chain reaction (PCR), which refers to an enzymatic process by which specific regions of the genome can be amplified for molecular study. Which tests are applied depends on whether the genetic abnormalities are likely to be chromosomal (in which case karyotyping or FISH is appropriate), large deletions or other rearrangements (best tested for by Southern blotting or PCR), or point mutations (best confirmed by PCR followed by oligonucleotide hybridization or restriction enzyme digestion). If a large number of different point mutations are sought, as is often the case, the most appropriate technology may be microarray hybridization analysis, which can test for tens to hundreds of thousands of different point mutations in the same sample simultaneously.

Options for treatment. Options for the treatment of genetic disease are both many and expanding. Although a significant number of genetic diseases still have no effective treatment, for many the treatments are quite good. Current approaches include dietary management, such as the restriction of phenylalanine in PKU; protein or enzyme replacement, such as that used in Gaucher's syndrome, hemophilia, and diabetes; and tissue replacement, such as blood transfusions or bone marrow transplantation in sickle cell anemia and thalassemia. Other treatments are strictly symptomatic, such as the use of splints in Ehlers-Danlos syndrome, administration of antibiotics in early cystic fibrosis, or female hormone replacement in Turner's syndrome. Many options involve surveillance and surgery, such as regular checks of aortic root diameter followed by surgery to prevent aortic dissection in Marfan's syndrome, or regular colonoscopy in persons at risk for familial colon cancer, followed by surgical removal of the colon at the first signs of disease.

Some genetic diseases may also be amenable to treatment by gene therapy, the introduction of normal genetic sequences to replace or augment the inherited gene whose mutation underlies the disease. Although some successes have been reported with gene therapy trials in humans—for example, with patients who have severe combined immunodeficiency (SCID) or hemophilia—significant technical challenges remain.

ETHICAL ISSUES

Our genetic constitution contributes to making us not only what we are—tall or short, male or female, healthy or sick—but also who we are—how we think and feel. Furthermore, although we generally like to think of our genomes as being uniquely ours, in fact we share significant aspects of them with our families, and information about our own genes is also information about our loved ones. Perhaps most important, in the biological sense, the genes we pass on to our children represent the closest we will ever come to immortality. For these reasons and others, human genetics is a topic fraught with ethical dilemma, with enormous power for good but also frightening possibilities for misuse. The challenge and responsibility are to harness available information and technologies to improve life and health for all people, without compromising privacy, autonomy, or diversity. Of vital importance in achieving these goals is an educated society that is aware of the advantages of new technologies yet is also concerned about their potential dangers.

(1999); RICKI LEWIS, *Human Genetics: Concepts and Applications,* 3rd ed. (1999); and DANIEL L. HARTL *Genetics: Analysis of Genes and Genomes,* 5th ed. (2001), are comprehensive tertiary-level genetics textbooks. VICTOR A. MCKUSICK, *Mendelian Inheritance in Man,* 12th ed., 3 vol. (1998), is a compendium of all the known inherited phenotypes with descriptions and references. GEORGE P. RÉDEI, *Genetics Manual: Current Theory, Concepts, Terms* (1998), provides a good up-to-date overview treatment for students.

JAMES D. WATSON *et al., Molecular Biology of the Gene,* 4th ed., 2 vol. (1987); and DAVID A. MICKLOS and GREG A. FREYER, *DNA Science: A First Course in Recombinant DNA Technology* (1990), provide an introduction to molecular biology; R.W. OLD and S.B. PRIMROSE, *Principles of Gene Manipulation: An Introduction to Genetic Engineering,* 5th ed. (1994), is one of the best texts dealing exclusively with genetic engineering. JAMES D. WATSON *et al., Recombinant DNA,* 2nd ed. (1992), provides a relatively short but extremely useful treatment of the methods and applications of recombinant DNA technology and other current methods in molecular genetics. PETER SUDBERY, *Human Molecular Genetics* (1998), describes some of the current technological approaches used in human genetics. HAROLD VARMUS and ROBERT A. WEINBERG, *Genes and the Biology of Cancer* (1998); and HARVEY LODISH *et al., Molecular Cell Biology,* 4th ed. (2000), are well-written books aimed at the general public. (Ar.R./A.J.F.G.)

Geneva

One of Europe's most cosmopolitan cities, Geneva (French Genève, German Genf, Italian Ginevra) has served as a model for republican government and owes its preeminence to the triumph of human, rather than geographic, factors. It developed its unique character from the 16th century, when, as the centre of the Calvinist Reformation, it became the "Protestant Rome." Situated in the far southwestern corner of Switzerland that juts into France, the canton of Geneva has a total area of 109 square miles (282 square kilometres), of which seven square miles constitute the city proper. Territorial isolation has been a basic feature of this region, which did not establish its definitive frontiers until 1815. Cut off politically and culturally after the Reformation from its natural geographic surroundings in Roman Catholic France and Savoy, Geneva was forced to establish an attenuated but powerful network of intellectual and economic relationships with the rest of Europe and with nations overseas.

A city-state transformed after many vicissitudes into a democratic Swiss canton, Geneva has functioned primarily as a centre of commerce, in contact with both Germanic and Mediterranean countries. Contemporary Geneva is, above all, a service metropolis, retaining its financial importance and housing the headquarters of many public and private international organizations.

This article is divided into the following sections:

Physical and human geography

THE LANDSCAPE

Site. Geneva is located at the southwestern end of Lake Geneva (Lac Léman) at its junction with the Rhône River. The city lies at an elevation of 1,230 feet (375 metres) in the centre of a natural basin encircled by mountains. This excellent site, besides commanding the important Swiss corridor between the Alps and the Jura Mountains, is also the focus of Alpine passes leading into Italy and, along the Saône–Rhône axis, of routes to the Mediterranean.

Climate. The local climate is tempered by the presence of the lake, while the Jura create a screen that diminishes rainfall. Average temperatures in Geneva are about 32° F (0° C) in January and about 64° F (18° C) in July. Geneva is thus neither disagreeably hot in summer nor cold in winter, but it must sometimes endure the harsh north wind known as the bise. Annual precipitation averages about 37 inches (930 millimetres).

Layout. Bisected by the lower lake basin and the river, Geneva exhibits the classic pattern of old European cities, with neighbourhoods lying in belts around the original nucleus. The Haute-ville, or upper city, centred on the city's original hill site at the Plateau des Tranchées and dominated by the Cathedral of St. Peter, is the historic heart of Geneva. The typical medieval and Renaissance houses are crowded together along narrow streets. This neighbourhood has undergone relative depopulation as housing has given way to government buildings and art, antiques, and interior furnishings businesses.

Residential areas

At the foot of the hill an area reclaimed from the lake and the Rhône forms a low-lying shopping district. On the site of the old fortifications—mostly to the south of the Rhône—lie suburbs dating from the 19th century. Beyond is an irregular belt of working-class residential areas, near the railway stations and industrial zones.

International agencies such as the Red Cross and the World Health Organization are found on the old patrician properties north of the Rhône. In this section, too, is the Palais des Nations, now the European home of the United Nations. At the lake's edge the Jet d'Eau—reputedly the world's tallest fountain, with a jet of water rising 476 feet (145 metres)—provides a familiar symbol of the city.

THE PEOPLE

It was not until after 1945 that the city's population began to register rapid growth, with the influx of other Swiss citizens and foreigners attracted by Geneva's international institutions and financial, chemical, and construction industries. By the late 1980s the population was approximately one-third foreign, one-third Swiss from other cantons, and only one-third native Genevese. Immigration to Geneva has consisted not only of the traditional contingents from Italy, France, and the Iberian Peninsula but also of a rising number from the Americas, Asia, and Africa. Although the large foreign presence is one of the constants of the city's demography, French remains the first language of Geneva.

Among the native population and in the professional classes, Protestants are in the majority, but within the population as a whole, Geneva is no longer the "Protestant Rome." Roman Catholics, in fact, make up slightly more than half the population.

THE ECONOMY

Industry. Manufacturing is handicapped by lack of space and raw materials, but Geneva, as one of the oldest banking centres in Europe, has profited from an early start in capital accumulation. It benefits from a skilled labour force and managers who are international in outlook. Certain older activities, such as cotton textile manufacture, have disappeared, but watchmaking has a continuing tradition of precision and quality. Industrial production is diversified and is, above all, designed for export. The largest industry is the manufacture of instruments and precision machinery. Principal specialties are equipment for hydraulic plants (turbines and alternators), electrical equipment, machine tools, and measuring devices.

The chemical industry is the second largest in Switzerland, after that of Basel. It supplies luxury items—such as fragrances and bases for perfume—as well as medicines. The food-processing industry is important, and Geneva also manufactures almost half of all Swiss-made cigarettes. Agriculture supplies such commodities as wheat, rapeseed, dairy products, and wine. Only about 1 percent of the canton's people are employed in farming.

Commerce and finance. Service industries employ more

Geneva in its lake setting, with the International Labour Office and the Parc Villa Barton in the foreground.

than two-thirds of the population. Wholesale and retail trade, banking, tourism, insurance, and the stock exchange are among the principal employers. Although nationally Geneva is second to Zürich in total volume of financial transactions, it has retained a position of worldwide significance. Geneva is one of the world's leading sanctuaries for capital, and it has been estimated that its banks hold more than half the total amount of foreign capital in Switzerland.

Financial role

Transportation. In the area of transport, success came late. It was said that Geneva lost to Lausanne the battle to become a leading railroad centre in the 19th century, but since World War II the city has acquired a large international airport at Cointrin. Multilane expressways have linked Geneva with Lausanne and with the rest of the Swiss highway system since 1964 and with the French system since 1970. In addition, the city contributed labour and financing for the construction of the highway tunnel beneath Mont Blanc and the Route-Blanche (White Way) to Italy. Since 1984 Geneva has enjoyed a high-speed railway system, the *trains à grande vitesse* (TGV), providing a three-hour connection with Paris. Local transportation is provided by an extensive bus, trolley, and streetcar system.

ADMINISTRATION

The canton of Geneva, which still calls itself La Republique du Genève, is governed by the Constitution of 1848 (as amended). Cantonal government is exercised by an executive power, the Council of State, consisting of seven members who are elected for four-year terms, and by a legislature, the Great Council, composed of 100 deputies who are also elected for four-year terms by proportional ballot.

The canton is divided into communes, each of which has its own assembly, administrative council, and mayor. Citizens have the rights of legislative initiative and referendum at both the communal and cantonal levels. To represent it in the federal government, the canton elects two deputies to the Council of States and a varying number of representatives to the National Council.

CULTURAL LIFE

Geneva has an ancient cultural tradition. A scholarly elite long cultivated theology, philosophy, literature, and, especially since the 17th century, the natural and applied sciences. Numerous scientific organizations are based in Geneva, including the European Organization for Nuclear Research (CERN), a leader in subnuclear physics research, and the World Meteorological Organization (WMO). The Geneva City Conservatory and Botanical Gardens is a major botanical research centre. In 1872 the Academy, in existence since the 16th century, became a university, and it has acquired an outstanding reputation. Other aspects of Geneva's active cultural life revolve around its museums, the Grand Théâtre (the city's opera house), and the proceedings of international meetings held there. The music conservatory and international performance competitions attract large numbers of musicians, and the Orchestre de la Suisse Romande is renowned worldwide. There are a number of distinguished small publishing houses in Geneva, and the city contributes substantially to the French-language services of the Swiss television and radio system. The *Journal de Geneve,* one of the world's premier newspapers, merged with *Le Nouveau Quotidien* to become *Le Temps* in 1998.

The lake provides many recreational opportunities for swimming, sailing, and fishing. Winter sports such as skiing and skating are popular, and rock climbing and mountaineering are pursued for both science and sport.

History

FOUNDATION AND MEDIEVAL GROWTH

The original site of the city was an easily defended hill dominating the outlet of the lake. Human occupation began in the Paleolithic Period and further developed in the Neolithic, which was marked by the growth of a vast lake-dwelling community with habitations built on piles. The original name of Genava (or Geneva) undoubtedly dates back to the pre-Celtic Ligurian peoples. In about 500 BC Geneva was a fortified settlement of the Allobrogian Celts, and as early as 58 BC it served as a departure point in the campaign of the Helvetians and the Romans for Gaul. By AD 379 Geneva was the seat of a bishop and was within the Roman Empire, but when it had been Christianized and when it became a Roman city are uncertain. After the Germanic invasions Geneva became

Capital of Burgundy

part of the Burgundian kingdom and served as its first capital from 443 to 534.

For a time Geneva belonged to Lotharingia and then again to Burgundy (888–1032). During the early feudal period the city formed the hub of the lands belonging to the Genevese counts. With the final extinction of their line in 1401, the bishop, who was a direct vassal of the Holy Roman emperor and invested with temporal power, vied for control with the neighbouring counts of Savoy.

THE 15TH TO 18TH CENTURY

In the 15th century the counts of Savoy rose to the status of dukes and made strenuous efforts to assert their sovereignty in Geneva at the expense of the bishops, who made correspondingly generous offers to the burghers to win their support against the dukes. But the burghers were slow to forsake the dukes, from whom they secured a contract recognizing their General Council—the public assembly to which every citizen belonged—as the central legislative body of the city.

Geneva and Savoy. The dukes of Savoy were ambitious and successful rulers who in time assumed a kingly title. They continued to assert their claims to Geneva, even when it lost to Lyon its preeminence as a centre of international trade fairs, with the result that its prosperity and population declined. The dukes used cunning as well as force to uphold their sovereignty, and from 1449 until 1522 they had members of their own family enthroned as bishop of Geneva.

Independence

The last ruling bishop, Pierre de La Baume, fled from Geneva in July 1533, and a year later the burghers declared the see vacant. Thus they rid themselves at once of their bishop and their allegiance to Savoy, and proclaimed themselves a state. When the Savoyards threatened invasion a year later, the Bernese offered to incorporate Geneva under their government. Having no wish to exchange the domination of Savoy for that of Bern, the Genevans refused. Because they desperately needed Bernese troops, however, they could not safely object to a rapprochement with Protestant Bern in the matter of religion; so in 1536 they declared themselves Protestant, a move that also served to justify the permanent exclusion of the bishop. As a result, they alienated the Roman Catholic Swiss cantons, so that Geneva's adhesion to the confederation was vetoed for generations to come.

John Calvin. Protestantism did not appeal immediately to everyone in Geneva. Some felt closer to French-speaking, Roman Catholic Fribourg than to relatively patrician, German-speaking Bern; and for many the theology of Martin Luther and Huldrych Zwingli was altogether foreign. This situation was resolved by John Calvin, a French theologian and practical visionary who transformed Geneva into a modern city-state and reconciled its people to the Reformed religion. Adapting traditional institutions to serve new purposes, Calvin was remarkably successful in presiding over Geneva's formative years as an autonomous state. He owed his success in part to the continuing presence of the Protestant Bernese troops. He was thus able to reorganize Geneva without hostile intervention by the Roman Catholic Savoyards, whose forces at other times stood on the frontiers of the city.

Calvin was also fortunate in that the persecution of Protestants in France brought into Geneva refugees sympathetic to his purposes. This enabled him to replenish with immigrants a citizen roll diminished by his own harsh policy of expelling all those who resisted conversion to the Reformed religion. The immigrants brought new trades, industries, and wealth, and Geneva became an industrial, financial, and commercial metropolis. Calvin's academies and seminaries attracted scholars from all over Europe.

A few such visitors found that they had only exchanged one form of persecution for another. The Spanish-born physician and theological writer Michael Servetus and Jacques Gruet, an apostate Protestant, were put to death for heresy. As Geneva grew and prospered, however, religious fanaticism died down.

The Savoyards made a final abortive attempt to recapture Geneva with a surprise attack led by the Duke on the night of Dec. 11–12, 1602, but they were driven out in a brief skirmish. This event, known as the Escalade, is still commemorated annually in Geneva.

Class conflicts. Between the mid-16th and early 18th centuries, the powers of the aristocratic Council of Twenty-five were systematically enlarged at the expense of the General Council, which eventually was summoned only to rubber-stamp the decisions of the magistrates.

Social changes added a further dimension to these developments. Among the French and Italian Protestants who found refuge in Geneva were several from noble families who brought with them not only their wealth but also their assumed right to lead and rule. These families grew to monopolize the Council of Twenty-five and to set up what was in fact the rule of a hereditary nobility, but one veiled by the ceremonies, styles, and language of republicanism.

Social changes

Social change of another kind was taking place as well. The number of residents of Geneva who were able to qualify as citizens became proportionately smaller as the population grew from about 13,000 to 25,000. In the 16th century the great majority of male residents were citizens; by 1700 the citizens constituted a minority—only about 1,500 of Geneva's 5,000 adult males. The other inhabitants were not only excluded from many civil rights and privileges but also were denied access to all the most lucrative trades and professions.

For reasons such as these, discontented factions multiplied behind the tranquil facade of Genevan life. There were citizens who opposed the domination of the patrician families, and there were unenfranchised residents who opposed the monopoly of rights and privileges by the citizens. Opposition to the ruling clique developed among the citizens at the end of the 17th century, asserting the rights of the General Council against the usurpations of the Council of Twenty-five.

Despite these currents of political opposition, Geneva in the 18th century was at the zenith of its prosperity. Material wealth stimulated a burst of culture and artistic creativity. As the birthplace of Rousseau and the sanctuary of Voltaire, Geneva attracted the elite of the Enlightenment and helped to foster the development of the new political science, derived from natural law.

In 1798, with the aid of local Jacobins, Geneva was annexed to France. The city was reduced to a subservient role and submitted, in 1802, to the protection of Napoleon Bonaparte. The Emperor distrusted Geneva, "that city where they know English too well" (it was indeed harbouring a secret liberal and Anglophile opposition), and the French period became an era of stagnation and recession.

THE 19TH AND 20TH CENTURIES

Swiss Geneva. As early as 1813 Geneva threw in its lot with France's enemies and was thus able to claim indemnities upon the fall of the empire. The aristocratic republic was restored and undertook negotiations to join the Swiss Confederation. On Sept. 12, 1814, the Genevan republic was admitted to the ranks of the Swiss cantons. Through the cession of 12 Savoyard communes by the Second Treaty of Paris (Nov. 20, 1815), it rounded out its territories into a single block.

Geneva's aristocrats were again in power, and gradually the bourgeoisie and the common people began once more to challenge openly the patrician regime. On Oct. 7, 1846, the working-class suburb of Saint-Gervais revolted, and the conservative government was overthrown. Opposition by the Swiss Diet to the Sonderbund (a league of seven Roman Catholic cantons) and the 1847 civil war between federal forces and the rebellious cantons permitted the radicals, led by James Fazy, to take the offensive. The radicals, who drew up the new Constitution of 1848, were thereafter masters of Geneva, and Fazy dominated the political scene until 1861. In many ways the founder of modern Geneva, he opened the canton to railway lines, created the Bank of Geneva, and, above all, made widespread urban expansion possible by demolishing the city's outer fortifications.

In 1860 the Savoyards voted to accept the sovereignty of France, and a free zone was created for Geneva by agreement with the French. The city regained, and until 1914 held, its role as a regional economic capital. It also continued to assert its international influence. The Red Cross was founded in Geneva in 1864; the Geneva conventions for the protection of prisoners of war were signed there; and the League of Nations was installed in the city in 1919.

The city since 1945. The history of Geneva since World War II has been marked by steady economic growth, halted only temporarily by the oil crisis of the early 1970s. The population of the canton increased from 187,000 in 1945 to more than 350,000 by the mid-1980s, and revenues rose from 660,000,000 Swiss francs to more than 9,000,000,000 during the same period. This prosperity was experienced almost entirely in the commercial and financial sectors; industry declined radically, affording employment to only 20 percent of the work force in 1980, as opposed to more than 36 percent in 1950. Building alone among Geneva's industries flourished after the war, as offices, houses, and shops—indeed whole new suburbs—had to be provided for the ever-increasing population.

In keeping with its cosmopolitan traditions, Geneva attracted international bodies seeking a location for their headquarters. The United Nations took over the old League of Nations buildings; the International Labour Organisation, the World Council of Churches, and other institutions resumed their operations in Geneva; and the city became a favoured neutral meeting place for diplomatic initiatives.

Postwar politics

In 1960 Geneva was one of the first Swiss cantons to extend the vote to women, but participation in elections and referendums remained unusually low. Genevese political parties were generally to the left of their counterparts in the Confederation, but they continued to maintain consensus politics and coalition government; this occurred despite the challenge of the communists, legalized as the Workers' Party (Parti du Travail) in 1944, and the right-wing nationalists, or Vigilantes, who had some success in the elections of 1965. In the federal government at Bern, representatives of Geneva failed to attain much prominence, and political life in Geneva tended to be centred more on the canton than on the nation. (P.G./M.C.)

For most of the post-World War II era, Geneva experienced continuous economic growth as international organizations and companies built headquarters in the city. However, during the late 1980s and early '90s the city began to stagnate as some international organizations left and the real-estate bubble, which had fueled a dramatic increase in property prices, burst. Throughout much of the 1990s the city's economy lagged behind the rest of Switzerland, and the unemployment rate, which hitherto had been negligible, was among the highest in the country. By the end of the 1990s, the economy had begun to recover.

Despite increasing competition from other cities, Geneva maintained its reputation as an international city throughout the last decades of the 20th century. In 1979 Geneva became the permanent headquarters for the international Disarmament Conference, involving more than 60 countries. A nuclear test ban treaty and an agreement to prohibit the production of antipersonnel mines were among the conference's breakthroughs. Geneva was also the site of the historic initial summit between U.S. President Ronald Reagan and Soviet leader Mikhail Gorbachev in 1985. Although the meeting did not produce any firm commitments, it was the first time the leaders had discussed nuclear arms reductions and paved the way for later agreements and the eventual end of the Cold War. Under the auspices of the United Nations Children's Fund, the International Convention on the Rights of Children was negotiated in Geneva in 1994. In 1995 the World Trade Organization was established with Geneva as its headquarters. The city is also the headquarters for the European Organization for Nuclear Research (CERN), which is commonly credited with developing the World Wide Web. By the beginning of the 21st century, international organizations based in Geneva had been selected as Nobel Prize winners more than 40 times. With Switzerland's neutral foreign policy, Geneva was expected to continue its central international role well into the 21st century. (Ed.)

BIBLIOGRAPHY. Good introductions to Geneva are provided by the collective volume, BENJAMIN LAEDERER (ed.), *Geneva: Crossroad of the Nations* (1964; originally published in French, 1963); and PAUL GUICHONNET, *Histoire de Genève* (1974). Urban evolution is the subject of LOUIS BLONDEL, *Le Développement urbain de Genève à travers les siècles* (1946); and ANDRÉ CORBOZ, *Invention de Carouge, 1772–1792* (1968). The historical literature is rich, although little is available in English translation. PAUL-F. GEISENDORF, *Bibliographie raisonnée de l'histoire de Genève des origines à 1798* (1966), is a well-researched bibliography. See also LOUIS BINZ, *Genève et les Suisses: du Moyen Age à la Restauration* (1964), a detailed survey, and *Brève histoire de Genève* (1981); RENÉ GUERDAN, *Histoire de Genève* (1981), especially useful for the modern period; PAUL-E. MARTIN (ed.), *Histoire de Genève,* 2 vol. (1951–56); and FRANÇOIS RUCHON, *Histoire politique de la République de Genève . . . ,* 2 vol. (1953). Genghis Khan

The Mongol Temüjin, known to history as Genghis Khan (Chinggis, or Jenghiz, Khan), was a warrior and ruler of genius who, starting from obscure and insignificant beginnings, brought all the nomadic tribes of Mongolia under the rule of himself and his family in a rigidly disciplined military state. He then turned his attention toward the settled peoples beyond the borders of his nomadic realm and began the series of campaigns of plunder and conquest that eventually carried the Mongol armies as far as the Adriatic Sea in one direction and the Pacific coast of China in the other, leading to the establishment of the great Mongol Empire.

Historical background. With the exception of the saga-like *Secret History of the Mongols* (1240?), only non-Mongol sources provide near-contemporary information about the life of Genghis Khan. Almost all writers, even those who were in the Mongol service, have dwelt on the enormous destruction wrought by the Mongol invasions. One Arab historian openly expressed his horror at the recollection of them. Beyond the reach of the Mongols and relying on second-hand information, the 13th-century chronicler Matthew Paris called them a "detestable nation of Satan that poured out like devils from Tartarus so that they are rightly called Tartars." He was making a play on words with the classical word Tartarus (Hell) and the ancient tribal name of Tatar borne by some of the nomads, but his account catches the terror that the Mongols evoked. As the founder of the Mongol nation, the organizer of the Mongol armies, and the genius behind their campaigns, Genghis Khan must share the reputation of his people, even though his generals were frequently operating on their own, far from direct supervision. Nevertheless, it would be mistaken to see the Mongol campaigns as haphazard incursions by bands of marauding savages. Nor is it true, as some have supposed, that these campaigns were somehow brought about by a progressive desiccation of Inner Asia that compelled the nomads to look for new pastures. Nor, again, were the Mongol invasions a unique event. Genghis Khan was neither the first nor the last nomadic conqueror to burst out of the steppe and terrorize the settled periphery of Eurasia. His campaigns were merely larger in scale, more successful, and more lasting in effect than those of other leaders. They impinged more violently upon those sedentary peoples who had the habit of recording events in writing, and they affected a greater part of the Eurasian continent and a variety of different societies.

Struggles between nomadic and sedentary societies

Two societies were in constant contact, two societies that were mutually hostile, if only because of their diametrically opposed ways of life, and yet these societies were interdependent. The nomads needed some of the staple products of the south and coveted its luxuries. These could be had by trade, by taxing transient caravans, or by armed raids. The settled peoples of China needed the products of the steppe to a lesser extent, but they could not ignore the presence of the nomadic barbarians and were forever preoccupied with resisting encroachment by one means or another. A strong dynasty, such as the 17th-century Manchu, could extend its military power directly over all Inner Asia. At other times the Chinese would have to play off one set of barbarians against another, transferring their support and juggling their alliances so as to prevent any one tribe from becoming too strong.

The cycle of dynastic strength and weakness in China was accompanied by another cycle, that of unity and fragmentation amongst the peoples of the steppe. At the peak of their power, a nomadic tribe under a determined leader could subjugate the other tribes to its will and, if the situation in China was one of weakness, might extend its power well beyond the steppe. In the end this extension of nomadic power over the incompatible, sedentary culture of the south brought its own nemesis. The nomads lost their traditional basis of superiority—that lightning mobility that required little in the way of supply and fodder—and were swallowed up by the Chinese they had conquered. The cycle would then be resumed; a powerful China would reemerge, and disarray and petty squabbling among ephemeral chieftains would be the new pattern of life among the nomads. The history of the Mongol conquests illustrates this analysis perfectly, and it is against this background of political contrasts and tensions that the life of Genghis Khan must be evaluated. His campaigns were not an inexplicable natural or even God-given catastrophe but the outcome of a set of circumstances manipulated by a soldier of ambition, determination, and genius. He found his tribal world ready for unification, at a time when China and other settled states were, for one reason or another, simultaneously in decline, and he exploited the situation.

Early struggles. Various dates are given for the birth of Temüjin (or Temuchin), as Genghis Khan was named—after a leader who was defeated by his father, Yesügei, when Temüjin was born. The chronology of Temüjin's early life is uncertain. He may have been born in 1155, in 1162 (the date favoured today in Mongolia), or in 1167. According to legend, his birth was auspicious, because he came into the world holding a clot of blood in his hand. He is also said to have been of divine origin, his first ancestor having been a gray wolf, "born with a destiny from heaven on high." Yet his early years were anything but promising. When he was nine, Yesügei, a member of the royal Borjigin clan of the Mongols, was poisoned by a band of Tatars, another nomadic people, in continuance of an old feud.

Cast out by his clan

With Yesügei dead, the remainder of the clan, led by the rival Taychiut family, abandoned his widow, Höelün, and her children, considering them too weak to exercise leadership and seizing the opportunity to usurp power. For a time the small family led a life of extreme poverty, eating roots and fish instead of the normal nomad diet of mutton and mare's milk. Two anecdotes illustrate both Temüjin's straitened circumstances and, more significantly, the power he already had of attracting supporters through sheer force of personality. Once he was captured by the Taychiut, who, rather than killing him, kept him around their camps, wearing a wooden collar. One night, when they were feasting, Temüjin, noticing that he was being ineptly guarded, knocked down the sentry with a blow from his wooden collar and fled. The Taychiut searched all night for him, and he was seen by one of their people, who, impressed by the fire in his eyes, did not denounce him but helped him escape at the risk of his own life. On another occasion horse thieves came and stole eight of the nine horses that the small family owned. Temüjin pursued them. On the way he stopped to ask a young stranger, called Bo'orchu, if he had seen the horses. Bo'orchu immediately left the milking he was engaged in, gave Temüjin a fresh horse, and set out with him to help recover the lost beasts. He refused any reward but, recognizing Temüjin's authority, attached himself irrevocably to him as a *nökör,* or free companion, abandoning his own family.

Temüjin and his family apparently preserved a considerable fund of prestige as members of the royal Borjigin clan, in spite of their rejection by it. Among other things, he was able to claim the wife to whom Yesügei had betrothed him just before his death. But the Merkit people, a tribe living in north Mongolia, bore Temüjin a grudge, because Yesügei had stolen his own wife, Höelün, from one of their men, and in their turn they ravished Temüjin's wife Börte. Temüjin felt able to appeal to Toghril, Khan of the Kereit tribe, with whom Yesügei had had the relationship of *anda,* or sworn brother, and at that time the most powerful Mongol prince, for help in recovering Börte. He had had the foresight to rekindle this friendship by presenting Toghril with a sable skin, which he himself had received as a bridal gift. He seems to have had nothing else to offer; yet, in exchange; Toghril promised to reunite Temüjin's scattered people, and he is said to have redeemed his promise by furnishing 20,000 men and persuading Jamuka, a boyhood friend of Temüjin's, to supply an army as well. The contrast between Temüjin's destitution and the huge army furnished by his allies is hard to explain, and no authority other than the narrative of the *Secret History* is available.

Rise to power. With powerful allies and a force of his own, Temüjin routed the Merkit, with the help of a strategy by which Temüjin was regularly to scotch the seeds of future rebellion. He tried never to leave an enemy in his rear; years later, before attacking China, he would first make sure that no nomad leader survived to stab him in the back. Not long after the destruction of the Merkit, he treated the nobility of the Jürkin clan in the same way. These princes, supposedly his allies, had profited by his absence on a raid against the Tatars to plunder his property. Temüjin exterminated the clan nobility and took the common people as his own soldiery and servants. When his power had grown sufficiently for him to risk a final showdown with the formidable Tatars, he first defeated them in battle and then slaughtered all those taller than the height of a cart axle. Presumably the children could be expected to grow up ignorant of their past identity and to become loyal followers of the Mongols. When the alliance with Toghril of the Kereit at last broke down and Temüjin had to dispose of this obstacle to supreme power, he dispersed the Kereit people among the Mongols as servants and troops. This ruthlessness was not mere wanton cruelty. Temüjin intended to leave alive none of the old, rival aristocrats, who might prove a focus of resistance; to provide himself with a fighting force; and, above all, to crush the sense of clan loyalties that favoured fragmentation and to unite all the nomads in personal obedience to his family. And when, in 1206, he was accepted as emperor of all the steppe people, he was to distribute thousands of families to the custody of his own relatives and companions, replacing the existing pattern of tribes and clans by something closer to a feudal structure.

Destruction of the Merkit

At least from the time of the defeat of the Merkits, Temüjin was aiming at supremacy in the steppes for himself. The renewed friendship with Jamuka lasted only a year and a half. Then, one day while the two friends were on the march, Jamuka uttered an enigmatic remark about the choice of camping site, which provoked Temüjin's wife Börte to advise him that it was high time for the two friends to go their separate ways. What lies behind this episode is difficult to see. The story in the *Secret History* is too puzzling in its brevity and its allusive language to permit a reliable explanation. It has been suggested that Jamuka was trying to provoke a crisis in the leadership. Equally, it may be that the language is deliberately obscure to gloss over the fact that Temüjin was about to desert his comrade. In any event, Temüjin took Börte's advice. Many of Jamuka's own men also abandoned him, probably seeing in Temüjin the man they thought more likely to win in the end. The *Secret History* justifies their action in epic terms. One of the men tells Temüjin of a vision that had appeared to him and that could only be interpreted as meaning that Heaven and Earth had agreed that Temüjin should be lord of the empire. Looking at the situation in a more down-to-earth way, the interplay of the vacillating loyalties of the steppe may be discerned. The clansmen knew what was afoot, and some of them hastened to move over to Temüjin's side, realizing that a strong leader was in the offing and that it would be prudent to declare for him early on.

The break with Jamuka brought about a polarization within the Mongol world that was to be resolved only with the disappearance of one or the other of the rivals. Jamuka has no advocate in history. The *Secret History* has much to tell about him, not always unsympathetically, but it is essentially the chronicle of Temüjin's family; and Jamuka appears as the enemy, albeit sometimes a reluctant one. He is an enigma, a man of sufficient force of personality to lead a rival coalition of princes and to get himself elected *gur-khān,* or supreme Khan, by them. Yet he was an intriguer, a man to take the short view, ready to desert his friends, even turn on them, for the sake of a quick profit. But for Temüjin, it might have been within Jamuka's power to dominate the Mongols, but Temüjin was incomparably the greater man; and the rivalry broke Jamuka.

Gathering of the clans around Temüjin and Jamuka

Clan leaders began to group themselves around Temüjin and Jamuka, and, a few years before the turn of the century, some of them proposed to make Temüjin Khan of the Mongols. The terms in which they did so, promising him loyalty in war and the hunt, suggest that all they were looking for was a reliable general, certainly not the overlord he was to become. Indeed, later on, some of them were to desert him. Even at this time, Temüjin was only a minor chieftain, as is shown by the next important event narrated by the *Secret History,* a brawl at a feast, provoked by his nominal allies the Jürkin princes, whom he later massacred. The Chin emperor in north China, too, looked on him as of no great consequence. In one of the reversals of policy characteristic of their manipulation of the nomads, the Chin attacked their onetime allies the Tatars. Together with Toghril, Temüjin seized the opportunity of continuing the clan feud and took the Tatars in the rear. The Chin emperor rewarded Toghril with the Chinese title of *wang,* or prince, and gave Temüjin an even less exalted one. And, indeed, for the next few years the Chin had nothing to fear from Temüjin. He was fully occupied in building up his power in the steppe and posed no obvious threat to China.

Temüjin now set about systematically eliminating all rivals. Successive coalitions formed by Jamuka were defeated. The Tatars were exterminated. Toghril allowed himself to be manoeuvred by Jamuka's intrigues and by his own son's ambitions and suspicions into outright war against Temüjin, and he and his Kereit people were destroyed. Finally, in the west, the Naiman ruler, fearful of the rising power of the Mongols, tried to form yet another coalition, with the participation of Jamuka, but was utterly defeated and lost his kingdom. Jamuka, inconstant as ever, deserted the Naiman Khan at the last moment. These campaigns took place in the few years before 1206 and left Temüjin master of the steppes. In that year a great assembly was held by the River Onon, and Temüjin was proclaimed Genghis Khan: the title probably meant Universal Ruler.

Unification of the Mongol nation. The year 1206 was a turning point in the history of the Mongols and in world history: the moment when the Mongols were first ready to move out beyond the steppe. Mongolia itself took on a new shape. The petty tribal quarrels and raids were a thing of the past. Either the familiar tribe and clan names had fallen out of use or those bearing them were to be found, subsequently, scattered all over the Mongol world, testifying to the wreck of the traditional clan and tribe system. A unified Mongol nation came into existence as the personal creation of Genghis Khan and, through many vicissitudes (feudal disintegration, incipient retribalization, colonial occupation), has survived to the present day. Mongol ambitions looked beyond the steppe. Genghis Khan was ready to start on his great adventure of world conquest. The new nation was organized, above all, for war. Genghis Khan's troops were divided up on the decimal system, were rigidly disciplined, and were well equipped and supplied. The generals were his own sons or picked men, absolutely loyal to him.

Beginning of the conquest of Asia

Genghis Khan's military genius could adapt itself to rapidly changing circumstances. Initially his troops were exclusively cavalry, riding the hardy, grass-fed Mongol pony that needed no fodder. With such an army, other nomads could be defeated, but cities could not be taken. Yet before long the Mongols were able to undertake the siege of large cities, using mangonels, catapults, ladders, burning oil, and so forth and even diverting rivers. It was only gradually, through contact with men from the more settled states, that Genghis Khan came to realize that there were more sophisticated ways of enjoying power than simply raiding, destroying, and plundering. It was a minister of the Khan of the Naiman, the last important Mongol tribe to resist Genghis Khan, who taught him the uses of literacy and helped reduce the Mongol language to writing. The *Secret History* reports it was only after the war against the Muslim empire of Khwārezm, in the region of the Amu Darya (Oxus) and Syr-darya (Jaxartes), probably in late 1222, that Genghis Khan learned from Muslim advisers the "meaning and importance of towns." And it was another adviser, formerly in the service of the Chin emperor, who explained to him the uses of peasants and craftsmen as producers of taxable goods. He had intended to turn the cultivated fields of north China into grazing land for his horses.

Subjugation of China

The great conquests of the Mongols, which would transform them into a world power, were still to come. China was the main goal. Genghis Khan first secured his western flank by a tough campaign against the Tangut kingdom of Hsi Hsia, a northwestern border state of China, and then fell upon the Chin empire of north China in 1211. In 1214 he allowed himself to be bought off, temporarily, with a huge amount of booty, but in 1215 operations werc resumed, and Peking was taken. Subsequently, the more systematic subjugation of north China was in the hands of his general Muqali. Genghis Khan himself was compelled to turn aside from China and carry out the conquest of Khwārezm. This war was provoked by the governor of the city of Otrar, who massacred a caravan of Muslim merchants who were under Genghis Khan's protection. The Khwārezm-Shāh refused satisfaction. War with Khwārezm would doubtless have come sooner or later, but now it could not be deferred. It was in this war that the Mongols earned their reputation for savagery and terror. City after city was stormed, the inhabitants massacred or forced to serve as advance troops for the Mongols against their own people. Fields and gardens were laid waste and irrigation works destroyed as Genghis Khan pursued his implacable vengeance against the royal house of Khwārezm. He finally withdrew in 1223 and did not lead his armies into war again until the final campaign against Hsi Hsia in 1226–27. He died on August 18, 1227.

Assessment. As far as can be judged from the disparate sources, Genghis Khan's personality was a complex one. He had great physical strength, tenacity of purpose, and an unbreakable will. He was not obstinate and would listen to advice from others, including his wives and mother. He was flexible. He could deceive but was not petty. He had a sense of the value of loyalty, unlike Toghril or Jamuka. Enemies guilty of treachery toward their lords could expect short shrift from him, but he would exploit their treachery at the same time. He was religiously minded, carried along by his sense of a divine mission, and in moments of crisis he would reverently worship the Eternal Blue Heaven, the supreme deity of the Mongols. So much is true of his early life. The picture becomes less harmonious as he moves out of his familiar sphere and comes into contact with the strange, settled world beyond the steppe. At first he could not see beyond the immediate gains to be got from massacre and rapine and, at times, was consumed by a passion for revenge. Yet all his life he could attract the loyalties of men willing to serve him, both fellow nomads and civilized men from the settled world. His fame could even persuade the aged Taoist sage Ch'ang-ch'un to journey the length of Asia to discourse upon religious matters. He was above all adaptable, a man who could learn.

Organization, discipline, mobility, and ruthlessness of purpose were the fundamental factors in his military successes. Massacres of defeated populations, with the resultant terror, were weapons he regularly used. His practice of summoning cities to surrender and of organizing the methodical slaughter of those who did not submit has been described as psychological warfare; but, although it was undoubtedly policy to sap resistance by fostering terror, massacre was used for its own sake. Mongol practice, especially in the war against Khwārezm, was to send agents to demoralize and divide the garrison and populace of an enemy city, mixing threats with promises. The Mongols' reputation for frightfulness often paralyzed their captives, who allowed themselves to be killed when resistance or flight was not impossible. Indeed, the Mongols were unaccountable. Resistance brought certain destruction, but at Balkh, now in Afghanistan, the population was slaughtered in spite of a prompt surrender, for tactical reasons.

The achievements of Genghis Khan were grandiose. He united all the nomadic tribes, and with numerically infcrior armies he defeated great empires, such as Khwārezm and the even more powerful Chin state. Yet he did not exhaust his people. He chose his successor, his son Ögödei, with great care, ensured that his other sons would obey Ögödei, and passed on to him an army and a state in full vigour. At the time of his death, Genghis Khan had conquered the land mass extending from Peking to the Caspian Sea, and his generals had raided Persia and Russia. His successors would extend their power over the whole of China, Persia, and most of Russia. Thcy did what he did not achieve and perhaps ncver really intendcd—that is, to wcld their conquests into a tightly organized empire. The dcstruction brought about by Genghis Khan survives in popular memory, but far more significant, thesc conquests were but the first stage of the Mongol Empire, the grcatcst continental empire of medieval and modern times. (C.R.B.)

BIBLIOGRAPHY. PAUL RATCHNEVSKY, *Genghis Khan: His Life and Legacy* (1991; originally published in German, 1983), is an important, scholarly biography. Other biographies include B.I. VLADIMIRTSOV, *The Life of Chingis-Khan* (1930, reissued 1969; originally published in Russian, 1922); R.P. LISTER, *Genghis Khan* (1969, reissued 1989), an account of his early life based on a Mongol chronicle written in 1240 and recovered in the 20th century; LEO DE HARTOG, *Genghis Khan, Conqueror of the World* (1989; originally published in Dutch, 1979); and MICHEL HOANG, *Genghis Khan* (1990; originally published in French, 1988), emphasizing the military strategy and foresight of the ruler.

Accessible versions of the only contemporary native Mongolian portrait of the early imperial period may be found in FRANCIS WOODMAN CLEAVES (trans. and ed.), *The Secret History of the Mongols,* trans. from Mongolian (1982); and *The History and the Life of Chinggis Khan: The Secret History of the Mongols,* trans. from Mongolian and annotated by URGUNGE ONON (1990). For general reading, LEONARDO OLSCHKI, *Marco Polo's Asia* (1960; originally published in Italian, 1957), is recommended. EUSTACE D. PHILLIPS, *The Mongols* (1969), is a brief general history of the early Mongols, concentrating on the period of expansion in the 13th century. A carefully researched history of Mongol conquests, illustrated with maps and tables, is offered in PETER BRENT, *Genghis Khan* (also published as *The Mongol Empire,* 1976). DAVID MORGAN, *The Mongols* (1986), situates the achievements of Genghis Khan within a general survey of imperial Mongolia. A well-documented account of Mongol successes in Europe with specific military detail is found in JAMES CHAMBERS, *The Devil's Horsemen,* rev. and extended ed. (1988). (C.R.B./Ed.)

Geochronology: The Interpretation and Dating of the Geologic Record

Geochronology is a field of scientific investigation concerned with determining the age and history of rocks and rock assemblages. Such time determinations are made and the record of past geologic events is deciphered by studying the distribution and succession of rock strata, as well as the character of the fossil organisms preserved within the strata.

The Earth's surface is a complex mosaic of exposures of different rock types that are assembled in an astonishing array of geometries and sequences. Individual rocks in the myriad of rock outcroppings (or in some instances shallow subsurface occurrences) contain certain materials or mineralogic information that can provide insight as to their "age."

For years investigators determined the relative ages of sedimentary rock strata on the basis of their positions in an outcrop and their fossil content. According to a long-standing principle of the geosciences, that of superposition, the oldest layer within a sequence of strata is at the base and the layers are progressively younger with ascending order. The relative ages of the rock strata deduced in this manner can be corroborated and at times refined by the examination of the fossil forms present. The tracing and matching of the fossil content of separate rock outcrops (*i.e.*, correlation) eventually enabled investigators to integrate rock sequences in many areas of the world and construct a relative geologic time scale.

Scientific knowledge of the Earth's geologic history has advanced significantly since the development of radiometric dating, a method of age determination based on the principle that radioactive atoms in geologic materials decay at constant, known rates to daughter atoms. Radiometric dating has provided not only a means of numerically quantifying geologic time but also a tool for determining the age of various rocks that predate the appearance of life-forms.

This article traces the notable developments that gave rise to geochronology and describes the principal methods of relative and absolute dating devised over the years. It also surveys the major intervals of Earth history, delineating the rock systems, environmental features, and life-forms associated with each.

For coverage of related topics in the *Macropædia* and *Micropædia*, see the *Propædia*, sections 241, 242, 243, 312, and 313, and the *Index*.

This article is divided into the following sections:

STUDY OF THE ROCK RECORD

Early views and discoveries

Some estimates suggest that as much as 70 percent of all rocks outcropping from the Earth's surface are sedimentary. Preserved in these rocks is the complex record of the many transgressions and regressions of the sea, as well as the fossil remains or other indications of now extinct organisms and the petrified sands and gravels of ancient beaches, sand dunes, and rivers.

Modern scientific understanding of the complicated story told by the rock record is rooted in the long history of observations and interpretations of natural phenomena extending back to the early Greek scholars. Xenophanes of Colophon (560?–478? BC), for one, saw no difficulty in describing the various seashells and images of life-forms embedded in rocks as the remains of long-deceased organisms. In the correct spirit but for the wrong reasons, Herodotus (5th century BC) felt that the small discoidal nummulitic petrifactions (actually the fossils of ancient lime-secreting marine protozoans) found in limestones outcropping at al-Jizah, Egypt, were the preserved remains of discarded lentils left behind by the builders of the pyramids.

These early observations and interpretations represent the unstated origins of what was later to become a basic principle of uniformitarianism, the root of any attempt at linking the past (as preserved in the rock record) to the present. Loosely stated, the principle says that the various natural phenomena observed today must also have existed in the past (see below *The emergence of modern geologic thought: Lyell's promulgation of uniformitarianism*).

Although quite varied opinions about the history and origins of life and of the Earth itself existed in the pre-Christian era, a divergence between Western and Eastern thought on the subject of natural history became more pronounced as a result of the extension of Christian dogma to the explanation of natural phenomena. Increasing constraints were placed upon the interpretation of nature in view of the teachings of the Bible. This required that the Earth be conceived of as a static, unchanging body, with a history that began in the not too distant past, perhaps as little as 6,000 years earlier, and an end, according to the scriptures, that was in the not too distant future. This biblical history of the Earth left little room for interpreting the Earth as a dynamic, changing system. Past catastrophes, particularly those that may have been responsible for altering the Earth's surface such as the great flood of Noah, were considered an artifact of the earliest formative history of the Earth. As such, they were considered unlikely to recur on what was thought to be an unchanging world.

With the exception of a few prescient individuals such as Roger Bacon (*c.* 1220–92) and Leonardo da Vinci (1452–1519), no one stepped forward to champion an enlightened view of the natural history of the Earth until the mid-17th century. Leonardo seems to have been among the first of the Renaissance scholars to "rediscover" the uniformitarian dogma through his observations of fossil marine organisms and sediments exposed in the hills of northern Italy. He recognized that the marine organisms now found as fossils in rocks exposed in the Tuscan Hills were simply ancient animals that lived in the region when it had been covered by the sea and were eventually buried by muds along the seafloor. He also recognized that the rivers of northern Italy, flowing south from the Alps and emptying into the sea, had done so for a very long time.

In spite of this deductive approach to interpreting natural events and the possibility that they might be preserved and later observed as part of a rock outcropping, little or no attention was given to the history—namely, the sequence of events in their natural progression—that might be preserved in these same rocks.

THE PRINCIPLE OF SUPERPOSITION OF ROCK STRATA

In 1669 the Danish-born natural scientist Nicolaus Steno (née Niels Steensen) published his noted treatise *De solido intra solidum naturaliter contento dissertationis prodromus* (Eng. trans. *The Prodromus of Nicolaus Steno's Dissertation Concerning a Solid Body Enclosed by Process of Nature Within a Solid*). This seminal work laid the essential framework for the science of geology by showing in very simple fashion that the layered rocks of Tuscany exhibit sequential change—that they contain a record of past events. Following from this observation, Steno concluded that the Tuscan rocks demonstrated superpositional relationships: rocks deposited first lie at the bottom of a sequence, while those deposited later are at the top. This is the crux of what is now known as the principle of superposition. Steno put forth still another idea—that layered rocks were likely to be deposited horizontally. Therefore, even though the strata of Tuscany were (and still are) displayed in anything but simple geometries, Steno's elucidation of these fundamental principles relating to the formation of stratified rock made it possible to work out not only superpositional relationships within rock sequences but also the relative age of each layer.

Steno's contributions

With the publication of the *Prodromus* and the ensuing widespread dissemination of Steno's ideas, other natural scientists of the latter part of the 17th and early 18th centuries applied them to their own work. The early English geologist John Strachey, for example, produced in 1725 what may well have been the first modern geologic maps of rock strata. He also described the succession of strata associated with coal-bearing sedimentary rocks in Somersetshire, the same region of England where he had mapped the rock exposures.

CLASSIFICATION OF STRATIFIED ROCKS

In 1756 Johann Gottlob Lehmann of Germany reported on the succession of rocks in the southern part of his country and the Alps, measuring and describing their compositional and spatial variation. While making use of Steno's principle of superposition, Lehmann recognized the existence of three distinct rock assemblages: (1) a successionally lowest category, the Primary (Urgebirge), composed mainly of crystalline rocks, (2) an intermediate category, or the Secondary (Flötzgebirge), composed of layered or stratified rocks containing fossils, and (3) a final or successionally youngest sequence of alluvial and related unconsolidated sediments (Angeschwemmtgebirge) thought to represent the most recent record of the Earth's history.

This threefold classification scheme was successfully applied with minor alterations to studies in other areas of Europe by three of Lehmann's contemporaries. In Italy, again in the Tuscan Hills in the vicinity of Florence, Giovanni Arduino, regarded by many as the father of Italian geology, proposed a four-component rock succession. His Primary and Secondary divisions are roughly similar to Lehmann's Primary and Secondary categories. In addition, Arduino proposed another category, the Tertiary division, to account for poorly consolidated though stratified fossil-bearing rocks that were superpositionally older than the (overlying) alluvium but distinct and separate from the hard (underlying) stratified rocks of the Secondary.

In two separate publications, one that appeared in 1762 and the second in 1773, Georg Christian Füchsel also applied Lehmann's earlier concepts of superposition to another sequence of stratified rocks in southern Germany. While using upwards of nine separate categories of sedimentary rocks, Füchsel essentially identified discrete rock bodies of unique composition, lateral extent, and position within a rock succession. (These rock bodies would constitute formations in modern terminology.)

Nearly 1,000 kilometres (620 miles) to the east, the German naturalist Peter Simon Pallas was studying rock sequences exposed in the southern Urals of eastern Russia. His report of 1777 differentiated a threefold division of rock, essentially reiterating Lehmann's work by extension.

Thus, by the latter part of the 18th century, the superpositional concept of rock strata had been firmly established through a number of independent investigations throughout Europe. Although Steno's principles were being widely applied, there remained to be answered a number of fundamental questions relating to the temporal and lateral relationships that seemed to exist among these disparate European sites. Were these various German, Italian, and Russian sites at which Lehmann's threefold rock succession was recognized contemporary? Did they record the same series of geologic events in the Earth's past? Were the various layers at each site similar to those of other sites? In short, was correlation among these various sites now possible?

The emergence of modern geologic thought

Inherent in many of the assumptions underlying the early attempts at interpreting natural phenomena in the latter part of the 18th century was the ongoing controversy between the biblical view of Earth processes and history and a more direct approach based on what could be observed and understood from various physical relationships demonstrable in nature. A substantial amount of information about the compositional character of many rock sequences was beginning to accumulate at this time. Abraham Gottlob Werner, a scholar of wide repute and following from the School of Mining in Freiberg, Ger., was very successful in reaching a compromise between what could be said to be scientific "observation" and biblical "fact." Werner's theory was that all rocks (including the sequences being identified in various parts of Europe at that time) and the Earth's topography were the direct result of either of two processes: (1) deposition in the primeval ocean, represented by the Noachian flood (his two "Universal," or Primary, rock series), or (2) sculpturing and deposition during the retreat of this ocean from the land (his two "Partial," or disintegrated, rock series). Werner's interpretation, which came to represent the so-called Neptunist conception of the Earth's beginnings, found widespread and nearly universal acceptance owing in large part to its theological appeal and to Werner's own personal charisma.

Werner's Neptunist theory

One result of Werner's approach to rock classification was that each unique lithology in a succession implied its own unique time of formation during the Noachian flood and a universal distribution. As more and more comparisons were made of diverse rock outcroppings, it began to become apparent that Werner's interpretation did not "universally" apply. Thus arose an increasingly vocal challenge to the Neptunist theory.

James Hutton's recognition of the geologic cycle

Attack on Neptunism and catastrophism

In the late 1780s the Scottish scientist James Hutton launched an attack on much of the geologic dogma that had its basis in either Werner's Neptunist approach or its corollary that the prevailing configuration of the Earth's surface is largely the result of past catastrophic events which have no modern counterparts. Perhaps the quintessential spokesman for the application of the scientific method in solving problems presented in the complex world of natural history, Hutton took issue with the catastrophist and Neptunist approach to interpreting rock histories and instead used deductive reasoning to explain what he saw. By Hutton's account, the Earth could not be viewed as a simple, static world not currently undergoing change. Ample evidence from Hutton's Scotland provided the key to unraveling the often thought but still rarely stated premise that events occurring today at the Earth's surface—namely erosion, transportation and deposition of sediments, and volcanism—seem to have their counterparts preserved in the rocks. The rocks of the Scottish coast and the area around Edinburgh proved the catalyst for his argument that the Earth is indeed a dynamic, ever-changing system, subject to a sequence of recurrent cycles of erosion and deposition and of subsidence and uplift. Hutton's formulation of the principle of uniformitarianism, which holds that Earth processes occurring today had their counterparts in the ancient past, while not the first time that this general concept was articulated, was probably the most important geologic concept developed out of rational scientific thought of the 18th century. The publication of Hutton's two-volume *Theory of the Earth* in 1795 firmly established him as one of the founders of modern geologic thought.

It was not easy for Hutton to popularize his ideas, however. The *Theory of the Earth* certainly did set the fundamental principles of geology on a firm basis, and several of Hutton's colleagues, notably John Playfair with his *Illustrations of the Huttonian Theory of the Earth* (1802), attempted to counter the entrenched Wernerian influence of the time. Nonetheless, another 30 years were to pass before Neptunist and catastrophist views of Earth history were finally replaced by those grounded in a uniformitarian approach.

This gradual unseating of the Neptunist theory resulted from the accumulated evidence that increasingly called into question the applicability of Werner's Universal and Partial formations in describing various rock successions. Clearly, not all assignable rock types would fit into Werner's categories, either superpositionally in some local succession or as a unique occurrence at a given site. Also, it was becoming increasingly difficult to accept certain assertions of Werner that some rock types (*e.g.,* basalt) are chemical precipitates from the primordial ocean. It was this latter observation that finally rendered the Neptunist theory unsustainable. Hutton observed that basaltic rocks exposed in the Salisbury Craigs, just on the outskirts of Edinburgh, seemed to have baked adjacent enclosing sediments lying both below and above the basalt. This simple observation indicated that the basalt was emplaced within the sedimentary succession while it was still sufficiently hot to have altered the sedimentary material. Clearly, basalt could not form in this way as a precipitate from the primordial ocean as Werner had claimed. Furthermore, the observations at Edinburgh indicated that the basalt intruded the sediments from below—in short, it came from the Earth's interior, a process in clear conflict with Neptunist theory.

While explaining that basalt may be intrusive, the Salisbury Craigs observations did not fully satisfy the argument that some basalts are not intrusive. Perhaps the Neptunist approach had some validity? The resolution of this latter problem occurred at an area of recent volcanism in the Auvergne area of central France. Here, numerous cinder cones and fresh lava flows composed of basalt provided ample evidence that this rock type is the solidified remnant of material ejected from the Earth's interior, not a precipitate from the primordial ocean.

Lyell's promulgation of uniformitarianism

Hutton's words were not lost on the entire scientific community. Charles Lyell, another Scottish geologist, was a principal proponent of Hutton's approach, emphasizing gradual change by means of known geologic processes. In his own observations on rock and faunal successions, Lyell was able to demonstrate the validity of Hutton's doctrine of uniformitarianism and its importance as one of the fundamental philosophies of the geologic sciences. Lyell, however, imposed some conditions on uniformitarianism that perhaps had not been intended by Hutton: he took a literal approach to interpreting the principle of uniformity in nature by assuming that all past events must have conformed to controls exerted by processes that behaved in the same manner as those processes behave today. No accommodation was made for past conditions that do not have modern counterparts. In short, volcanic eruptions, earthquakes, and other violent geologic events may indeed have occurred earlier in Earth history but no more frequently nor with greater intensity than today; accordingly, the surface features of the Earth are altered very gradually by a series of small changes rather than by occasional cataclysmic phenomena.

Uniformity of causes and uniformity of intensity

Lyell's contribution enabled the doctrine of uniformitarianism to finally hold sway, even though it did impose for the time being a somewhat limiting condition on the uniformity principle. This, along with the increased recognition of the utility of fossils in interpreting rock successions, made it possible to begin addressing the question of the meaning of time in Earth history.

Determining the relationships of fossils with rock strata

The hypothesis of fossil succession in the work of Georges Cuvier. During this period of confrontation between the proponents of Neptunism and uniformitarianism, there emerged evidence resulting from a lengthy and detailed study of the fossiliferous strata of the Paris Basin that rock successions were not necessarily complete records of past geologic events. In fact, significant breaks frequently occur in the superpositional record. These breaks affect not only the lithologic character of the succession but also the character of the fossils found in the various strata.

An 1812 study by the French zoologist Georges Cuvier was prescient in its recognition that fossils do in fact record events in Earth history and serve as more than just "follies" of nature. Cuvier's thesis, based on his analysis of the marine invertebrate and terrestrial vertebrate fauna of the Paris Basin, showed conclusively that many fossils, particularly those of terrestrial vertebrates, had no living counterparts. Indeed, they seemed to represent extinct forms, which, when viewed in the context of the succession of strata with which they were associated, constituted part of a record of biological succession punctuated by numerous extinctions. These, in turn, were followed by a seeming renewal of more advanced but related forms and were separated from each other by breaks in the associated rock record. Many of these breaks were characterized by coarser, even conglomeratic strata following a break, suggesting "catastrophic" events that may have contributed to the extinction of the biota. Whatever the actual cause, Cuvier felt that the evidence provided by the record of faunal succession in the Paris Basin could be interpreted by invoking recurring catastrophic geologic events, which in turn contributed to recurring massive faunal extinction, followed at a later time by biological renewal.

William Smith's work with faunal sequence. As Cuvier's theory of faunal succession was being considered, William Smith, a civil engineer from the south of England, was also coming to realize that certain fossils can be found consistently associated with certain strata. In the course of evaluating various natural rock outcroppings, quarries, canals, and mines during the early 1790s, Smith increasingly utilized the fossil content as well as the lithologic character of various rock strata to identify the successional position of different rocks, and he made use of this information to effect a correlation among various localities he had studied. The consistency of the relationships that Smith observed eventually led him to conclude that there is indeed faunal succession and that there appears to be a consistent progression of forms from more primitive to more advanced. As a result of this observation, Smith was able to begin what was to amount to a monumental effort at synthesizing all that was then known of the rock successions outcropping throughout parts of Great Britain. This effort culminated in the publication of his "Geologic Map of England, Wales and Part of Scotland" (1815), a rigorous treatment of diverse geologic information resulting from a thorough understanding of geologic principles, including those of original horizontality, superposition (lithologic, or rock, succession), and faunal succession. With this, it now became possible to assume within a reasonable degree of certainty that correlation could be made between and among widely separated areas. It also became apparent that many sites that had previously been classified according to the then-traditional views of Arduino, Füchsel, and Lehmann did not conform to the new successional concepts of Smith.

Foundations of stratigraphic correlation

EARLY ATTEMPTS AT MAPPING AND CORRELATION

The seminal work of Smith at clarifying various relationships in the interpretation of rock successions and their correlations elsewhere resulted in an intensive look at what the rock record and, in particular, what the fossil record had to say about past events in the long history of the Earth. A testimony to Smith's efforts in producing one of the first large-scale geologic maps of a region is its essential accuracy in portraying what is now known to be the geologic succession for the particular area of Britain covered.

The application of the ideas of Lyell, Smith, Hutton, and others led to the recognition of lithologic and paleontologic successions of similar character from widely scattered areas. It also gave rise to the realization that many of these similar sequences could be correlated.

The French biologist Jean-Baptiste de Monet, Chevalier de Lamarck, in particular, was able to demonstrate the similarity of fauna from a number of Cuvier's and Alexandre Brongniart's collections of fossils from the Paris Basin with fossil fauna from the sub-Apennines of Italy and the London Basin. While based mainly on the collections of Cuvier and Brongniart, Lamarck's observations provided much more insight into the real significance of using fossils strictly for correlation purposes. Lamarck disagreed with Cuvier's interpretation of the meaning of faunal extinction and regeneration in stratigraphic successions. Not convinced that catastrophes caused massive and widespread disruption of the biota, Lamarck preferred to think of organisms and their distribution in time and space as responding to the distribution of favourable habitats. If confronted with the need to adapt to abrupt changes in local habitat—Cuvier's catastrophes—faunas must be able to change in order to survive. If not, they became extinct. Lamarck's approach, much like that of Hutton, stressed the continuity of processes and the continuum of the stratigraphic record. Moreover, his view that organisms respond to the conditions of their environment had important implications for the uniformitarian approach to interpreting Earth history.

The impact of Lamarck's work

Once it was recognized that many of the rocks of the Paris Basin, London Basin, and parts of the Apennines apparently belonged to the same sequence by virtue of the similarity of their fossil content, Arduino's term Tertiary (proposed as part of his fourfold division of rock succession in the Tuscan Hills of Italy) began to be applied to all of these diverse locations. Further work by Lyell and Gérard-Paul Deshayes resulted in the term Tertiary being accepted as one of the fundamental divisions of geologic time.

THE CONCEPTS OF FACIES, STAGES, AND ZONES

Facies. During the latter half of the 18th and early 19th centuries, most of the research on the distribution of rock strata and their fossil content treated lithologic boundaries as events in time representing limits to strata that contain unique lithology and perhaps a unique fossil fauna, all of which are the result of unique geologic processes acting over a relatively brief period of time. Hutton recognized early on, however, that some variations occur in the sediments and fossils of a given stratigraphic unit and that such variations might be related to differences in depositional environments. He noted that processes such as erosion in the mountains of Scotland, transportation of sand and gravels in streams flowing from these mountains, and the deposition of these sediments could all be observed to be occurring concurrently. At a given time then, these diverse processes were all taking place at separate locations. As a consequence, different environments produce different sedimentary products and may harbour different organisms. This aspect of differing lithologic type or environmental or biological condition came to be known as facies. (It was Steno who had, in 1669, first used the term facies in reference to the condition or character of the Earth's surface at a particular time.)

The significance of the facies concept for the analysis of geologic history became fully apparent with the findings of the Swiss geologist Amanz Gressly. While conducting survey work in the Jura Mountains in 1838, Gressly observed that rocks from a given position in a local stratigraphic succession frequently changed character as he traced them laterally. He attributed this lateral variation to lateral changes in the depositional environments responsible for producing the strata in question. Having no term to apply to the observed changes, he adopted the word facies. While Gressly employed the term specifically in the context of lithologic character, it is applied more broadly today. As now used, the facies concept has come to encompass other types of variation that may be encountered as one moves laterally (*e.g.,* along outcroppings of rock strata exposed in stream valleys or mountain ridges) in a given rock succession. Lithologic facies, biological facies, and even environmental facies can be used to describe sequences of rocks of the same or different age having a particularly unique character.

Modern usage of the facies concept

Stages and zones. The extensive review of the marine invertebrate fauna of the Paris Basin by Deshayes and Lyell not only made possible the formalization of the term Tertiary but also had a more far-reaching effect. The thousands of marine invertebrate fossils studied by Deshayes enabled Lyell to develop a number of subdivisions of the Tertiary of the Paris Basin based on the quantification of molluskan species count and duration. Lyell noted that of the various assemblages of marine mollusks found, those from rocks at the top of the succession contained a large number of species that were still extant in modern environments. Progressively older strata yielded fewer and fewer forms that had living counterparts, until at the base of the succession, a very small number of the total species present could be recognized as having modern counterparts. This fact allowed Lyell to consider subdividing the Tertiary of the Paris Basin into smaller increments, each of which could be defined according to some relative percentage of living species present in the strata. The subdivision resulted in the delineation of the Eocene, Miocene, and Pliocene epochs in 1833. Later this scheme was refined to further divide the Pliocene into an Early and a Late Pliocene.

Lyell's biostratigraphically defined concept of sequence, firmly rooted in concepts of faunal succession and superposition, was developed on mixed but stratigraphically controlled collections of fossils. It worked, but it did not address the faunal composition of the various Paris Basin strata other than in gross intervals—intervals that were as much lithologically as paleontologically defined. Alcide d'Orbigny, a French geologist, demonstrated correlational and superpositional uniqueness by utilizing paleontologically distinct intervals of strata defined solely on the basis of their fossil assemblages in his study of the French Jurassic *Terrains Jurassiques* (1842). This departure from a lithologically based concept of paleontologic succession enabled d'Orbigny to define paleontologically unique stages. Each stage represented a unique period in time and formed the basis of later work that resulted in the further subdivision of d'Orbigny's original stages into 10 distinct stage assemblages. In spite of the work of Smith and to a lesser extent Lyell and others, d'Orbigny's approach was essentially that of a catastrophist. Stage boundaries were construed to represent unusual extrinsic geologic events, with significant implications for faunal continuity. The applicability of d'Orbigny's stages to areas outside of France had only limited success. At this point in the development of paleontology as a science, little was understood about the geologic time range of various fauna. Even less was known about the habitats—the environmental limits—of ancient fauna. Could certain groups of organisms have sufficiently widespread distribution in the rock record to enable correlations to be made with certainty? The Jurassic of western Europe consisted mostly of shallow marine sediments widely deposited throughout the area. It is now known that some of the mollusks with which d'Orbigny worked were undergoing very rapid evolutionary change; they were thus relatively short-lived as distinct forms in the geologic record and had a wide-ranging environmental tolerance. The result was that some forms, notably of the group of mollusks called ammonite cephalopods, were distributed extensively within a variety of sedimentary facies. The correlating of strata based on the faunal stage approach was widely accepted. Interestingly, most of d'Orbigny's Jurassic stages, with refinements, are still in use today.

Paleontologically distinct intervals of strata

Only a short time after d'Orbigny's original analysis of Jurassic strata, the German mineralogist and paleontologist Friedrich A. Quenstedt challenged (in 1856–58) the validity of using stages to effect correlations in cases where the actual geologic ranges and bed-by-bed distribution of individual component fossils of an assemblage were unknown. In retrospect, this seems blatantly obvious, but at the time the systematic stratigraphic documentation of fossil occurrence was not always carried out. Much critical biostratigraphic data necessary for the proper characterization of faunal assemblages was simply not collected. As argued, individual fossil ranges and their distributions could have profound influence on the concept of faunal succession and evolutionary dynamics.

Oppel's refinement of biostratigraphic concepts

Several of Quenstedt's students at the University of Tübingen followed up on this latter concern. One in particular, Carl Albert Oppel, essentially refined his mentor's concepts by paying particular attention to the character of the range of individual species in a succession of fauna. These intervals of unique biological character, which he called zones, were essentially subdivisions of the stages proposed by Quenstedt. Oppel's recognition of the earliest occurrence of a fossil species (or its first appearance), its range through a succession of strata, and its eventual loss from the local record (or its last appearance) led him to compare such biostratigraphic data from many species. By making use of such data on species that overlap in some or all of their stratigraphic ranges and from widely separated areas, Oppel was able to erect a biochronology based on a diverse record of first appearances, last appearances, and individual and overlapping range zones. This fine-scale refinement of a biologically defined sense of succession found wide applicability and enabled not only biochronological (or temporal) but also biofacies (spatial) understanding of the succession in question.

Figure 1 illustrates six of the Jurassic zones and some of the fossil species on which they are based. The zone of *Arietites bucklandi* is based on the joint occurrences of two species with differing ranges in time, here called "species J" and "G," of the *Arnioceras semicostatum* zone by overlap in the range of "species G" and "Q," and so on. The zonal fossils are characteristic but are not necessarily confined in their occurrence to the zone. (V.S.M./G.D.J.)

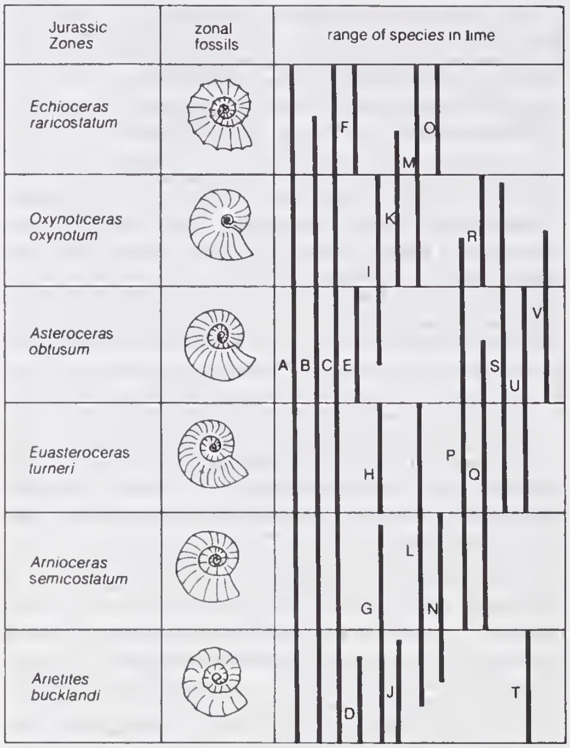

Figure 1: *Jurassic fossil zones and zonal fossils.*
These six ammonite species never overlap in stratigraphic distribution and therefore provide a guide for correlation wherever they occur. The ranges of hypothetical species (indicated by letters) within the Jurassic are also shown.

Completion of the Phanerozoic time scale

With the development of the basic principles of faunal succession and correlation and the recognition of facies variability, it was a relatively short step before large areas of Europe began to be placed in the context of a global geologic succession. This was not, however, accomplished in a systematic manner. Whereas the historical ideas of Lehmann and Arduino were generally accepted, it became increasingly clear that many diverse locally defined rock successions existed, each with its own unique fauna and apparent position within some sort of "universal" succession.

As discussed above, Arduino's Tertiary was recognized in certain areas and was in fairly common use after 1760, but only rudimentary knowledge of other rock successions existed by the later part of the 18th century. The German naturalist Alexander von Humboldt had recognized the widespread occurrence of fossil-bearing limestones throughout Europe. Particular to these limestones, which formed large tracts of the Jura Mountains of Switzerland, were certain fossils that closely resembled those known from the Lias and Oolite formations of England, which were then being described by William Smith. Subsequently, Humboldt's "Jura Kalkstein" succession, as he described it in 1795, came to be recognized throughout Europe and England. By 1839, when the geologist Leopold Buch recognized this rock sequence in southern Germany, the conceptual development of the Jurassic System was complete.

The coal-bearing strata of England, known as the Coal Measures, had been exploited for centuries, and their distribution and vertical and lateral variability were the subject of numerous local studies throughout the 17th and early 18th centuries, including those of Smith. In 1808 the geologist Jean-Baptiste-Julien d'Omalius d'Halloy described a coal-bearing sequence in Belgium as belonging to the Ter-

Refinement of systems

rain Bituminifère. Although the name did not remain in common usage for long, the Terrain Bituminifère found analogous application in the work of two English geologists, William D. Conybeare and William Phillips, in their synthesis of the geology of England and Wales in 1822. Conybeare and Phillips coined the term Carboniferous (or coal-bearing) to apply to the succession of rocks from north-central England that contained the Coal Measures. The unit also included several underlying rock formations extending down into what investigators now consider part of the underlying Devonian System. At the time, however, the approach by Conybeare and Phillips was to encompass in their definition of the Carboniferous all of the associated strata that could be reasonably included in the Coal Measures succession.

D'Omalius mapped and described a local succession in western France. While doing so, he began to recognize a common sequence of soft limestones, greensands (glauconite-bearing sandstones), and related marls in what is today known to be a widespread distribution along coastal regions bordering the North Sea and certain regions of the Baltic. The dominant lithology of this sequence is frequently the soft limestones or chalk beds so well known from the Dover region of southeast England and Calais in nearby France. D'Omalius called this marl, greensand, and chalk-bearing interval the Terrain Crétacé. Along with their adoption of the term Carboniferous in 1822, Conybeare and Phillips referred to the French Terrain Crétacé as the Cretaceous System.

Clearly, surficial deposits and related unconsolidated material, variously relegated to the categories of classification proposed by Arduino, Lehmann, Werner, and others as "alluvium" or related formations, deserved a place in any formalized system of rock succession. In 1829 Jules Desnoyers of France, studying sediments in the Seine valley, proposed using the term Quaternary to encompass all of these various post-Tertiary formations. At nearly the same time, the important work of Lyell on the faunal succession of the Paris Basin permitted finer-scaled discrimination of this classic Tertiary sequence. In 1833 Lyell, using various biostratigraphic evidence, proposed several divisions of the Tertiary System that included the Eocene, Miocene, and Pliocene epochs. By 1839 he proposed using the term Pleistocene instead of dividing his Pliocene Epoch into older and newer phases. The temporal subdivision of the Tertiary was completed by two German scientists, Heinrich Ernst Beyrich and Wilhelm Philipp Schimper. Beyrich introduced the Oligocene in 1854 after having investigated outcrops in Belgium and Germany, while Schimper proposed adding the Paleocene in 1874 based on his studies of Paris Basin flora.

Werner's quadripartite division of rocks in southern Germany was applied well into the second decade of the 19th century. During this time, rock sequences from the lower part of his third temporal subdivision, the Flötzgebirge, were subsequently subdivided into three formations, each having fairly widespread exposure and distribution. Based on his earlier work, Friedrich August von Alberti identified in 1834 these three distinct lithostratigraphic units, the Bunter Sandstone, the Muschelkalk Limestone, and the Keuper Marls and Clays, as constituting the Trias or Triassic System.

The Sedgwick–Murchison dispute

Perhaps one of the most intriguing episodes in the development of the geologic time scale concerns the efforts of two British geologists and in large measure their attempts at unraveling the complex geologic history of Wales. Adam Sedgwick and Roderick Impey Murchison began working, in 1831, on the sequence of rocks lying beneath the Old Red Sandstone (which had been included in the basal sequence of the Carboniferous, as defined by Conybeare and Phillips, earlier in 1822). What started as an earnest collaborative attempt at deciphering the structurally and stratigraphically complicated rock succession in Wales ended in 1835 with a presentation outlining two distinct subdivisions of the pre-Carboniferous succession. Working up from the base of the post-Primary rock succession of poorly fossiliferous clastic rocks in northern Wales, Sedgwick identified a sequence of rock units defined primarily by their various lithologies. He designated this succession the Cambrian, after Cambria, the Roman name for Wales. Murchison worked downward in the considerably more fossiliferous pre-Old Red Sandstone rock sequence in southern Wales and was able to identify a succession of strata containing a well-preserved fossil fauna. These sequences defined from southern Wales were eventually brought into the context of Sedgwick's Cambrian. Murchison named his rock succession the Silurian, after the Roman name for an early Welsh tribe. In a relatively short time, Murchison's Silurian was expanding both laterally and temporally as more and more localities containing the characteristic Silurian fauna were recognized throughout Europe. The major problem created by this conceptual "expansion" of the Silurian was that it came to be recognized in northern Wales as coincident with much of the strata in the upper portion of Sedgwick's Cambrian. With Sedgwick's Cambrian based mainly on lithologic criteria, the presence of Silurian fauna created correlational difficulties. As it turned out, Sedgwick's Cambrian was of little value outside of its area of original definition. With it being superseded by the paleontologically based concept of the Silurian, some sort of compromise had to be worked out.

This compromise came about primarily as a result of the work of Charles Lapworth, the English geologist who in 1879 proposed the designation Ordovician System for that sequence of rocks representing the upper part of Sedgwick's Cambrian succession and the lower (and generally overlapping) portion of Murchison's Silurian succession. The term Ordovician is derived from yet another Roman-named tribe of ancient Wales, the Ordovices. A large part of Lapworth's rationale for this division was based on the earlier work of the French-born geologist Joachim Barrande, who investigated the apparent Silurian fauna of central Bohemia. Barrande's 1851 treatise on this area of Czechoslovakia demonstrated a distinct succession from a "second" Silurian fauna to a "third" Silurian fauna. This divisible Silurian, as well as separate lines of evidence gathered by Lapworth in Scotland and Wales, finally enabled the individual character of the Cambrian, Ordovician, and Silurian systems to be resolved.

While involved in their work on Welsh stratigraphic successions, Sedgwick and Murchison had the opportunity to compare some rock outcroppings in Devonshire, in southwest England, with similar rocks in Wales. The Devon rocks were originally thought to belong to part of Sedgwick's Cambrian System, but they contained plant fossils very similar to basal Carboniferous (Old Red Sandstone) plant fossils found elsewhere. Eventually recognizing that these fossil-bearing sequences represented lateral equivalents in time and perhaps temporally unique strata as well, Sedgwick and Murchison in 1839 proposed the Devonian System.

During the early 1840s, Murchison traveled with the French paleontologist Edouard de Verneuil and the Latvian-born geologist Alexandr Keyserling to study the rock succession of the eastern Russian platform, the area of Russia west of the Ural Mountains. Near the town of Perm, Murchison and Verneuil identified fossiliferous strata containing both Carboniferous and a younger fauna at that time not recognized elsewhere in Europe or in the British Isles. Whereas the Carboniferous fossils were similar to those they had seen elsewhere (mainly from the Coal Measures), the stratigraphically higher fauna appeared somewhat transitional to the Triassic succession of Germany as then understood. Murchison coined the term Permian (after the town of Perm) to represent this intermediate succession.

The Carboniferous System and its North American equivalents

With continued refinement of the definition of the Carboniferous in Europe, particularly in England, what at one time comprised the Old Red Sandstone, Lower Coal Measures (Mountain Limestone and Millstone Grit), and Upper Coal Measures now stood as just the Lower and Upper Coal Measures. It was beginning to be recognized that certain rock sequences in the Catskill Mountains of eastern New York state in North America resembled the Old Red Sandstone of western England. Furthermore, coal-bearing strata exposed in Pennsylvania greatly resembled the similar coal-bearing strata of the Upper Coal

Measures. Lying beneath these coal-bearing rocks of Pennsylvania was a sequence of limestones that could be traced over thousands of square kilometres and that occurred in numerous outcrops along various tributary streams to the Ohio and Mississippi rivers in Indiana, Kentucky, Missouri, Illinois, and Iowa. This "subcarboniferous" strata, identified by the American geologist David Dale Owen in 1839, was subsequently termed Mississippian in 1870 as a result of work conducted by another American geologist, Alexander Winchell, in the upper Mississippi valley area. Eventually the overlying strata, the coal-bearing rocks originally described from Pennsylvania, were formalized as Pennsylvanian in 1891 by the paleontologist and stratigrapher Henry Shaler Williams.

The North American-defined Mississippian and Pennsylvanian systems were later correlated with presumed European and British successions. Although approximately similar in successional relationship, the Mississippian–Pennsylvanian boundary in North America is now considered slightly younger than the Lower–Upper Carboniferous boundary in Europe.

By the 1850s, with the development of the geologic time scale nearly complete, investigators were beginning to recognize that a number of major paleontologically defined boundaries were common and recurrent regardless of where a succession was studied. By this time rock successions were being defined according to fauna they contained, and the relative time scale, which was being erected, was based on the principle of faunal succession; consequently, any major hiatus or change in faunal character was bound to be interpreted as important. In 1838 Sedgwick proposed that all pre-Old Red Sandstone sediments be included in the rock succession designated the Paleozoic Series (or Era) that contained generally primitive fossil fauna. John Phillips, another English geologist, went on to describe the Mesozoic Era to accommodate what then was the Cretaceous, Jurassic, Triassic, and partially Permian strata, and the Kainozoic (Cainozoic, or Cenozoic) era to include Lyell's Eocene, Miocene, and Pliocene. This subdivision of the generally fossiliferous strata that lay superpositionally above the so-called Primary rocks of many of the early workers resulted in the recognition of three distinct eras. Subsequent subdivision of these eras into specific geologic periods finally provided the hierarchy for describing the relative dating of geologic events.

Development of radioactive dating methods and their application

As has been seen, the geologic time scale is based on stratified rock assemblages that contain a fossil record. For the most part, these fossils allow various forms of information from the rock succession to be viewed in terms of their relative position in the sequence. Approximately the first 87 percent of Earth history occurred before the evolutionary development of shell-bearing organisms. The result of this mineralogic control on the preservability of organic remains in the rock record is that the geologic time scale—essentially a measure of biologic changes through time—takes in only the last 13 percent of Earth history. Although the span of time preceding the Cambrian period—the Precambrian—is nearly devoid of characteristic fossil remains and coincides with some of the primary rocks of certain early workers, it must, nevertheless, be evaluated in its temporal context.

EARLY ATTEMPTS AT CALCULATING THE AGE OF THE EARTH

Difficulties of dating Precambrian events

Historically, the subdivision of Precambrian rock sequences (and, therefore, Precambrian time) had been accomplished on the basis of structural or lithologic grounds. With only minor indications of fossil occurrence (mainly in the form of algal stromatolites), no effective method of quantifying this loosely constructed chronology existed until the discovery of radioactivity enabled dating procedures to be applied directly to the rocks in question.

The quantification of geologic time remained an elusive matter for most human enquiry into the age of the Earth and its complex physical and biological history. Although Hindu teachings accept a very ancient origin for the Earth, medieval Western concepts of Earth history were based for the most part on a literal interpretation of Old Testament references. Biblical scholars of Renaissance Europe and later considered paternity as a viable method by which the age of the Earth since its creation could be determined. A number of attempts at using the "begat" method of determining the antiquity of an event—essentially counting backward in time through each documented human generation—led to the age of the Earth being calculated at several thousand years. One such attempt was made by Archbishop James Ussher of Ireland, who in 1650 determined that the Creation had occurred during the evening of Oct. 22, 4004 BC. By his analysis of biblical genealogies, the Earth was not even 6,000 years old!

From the time of Hutton's refinement of uniformitarianism, the principle found wide application in various attempts to calculate the age of the Earth. As previously noted, fundamental to the principle was the premise that various Earth processes of the past operated in much the same way as those processes operate today. The corollary to this was that the rates of the various ancient processes could be considered the same as those of the present day. Therefore, it should be possible to calculate the age of the Earth on the basis of the accumulated record of some process that has occurred at this determinable rate since the Creation.

Many independent estimates of the age of the Earth have been proposed, each made using a different method of analysis. Some such estimates were based on assumptions concerning the rate at which dissolved salts or sediments are carried by rivers, supplied to the world's oceans, and allowed to accumulate over time. These chemical and physical arguments (or a combination of both) were all flawed to varying degrees because of an incomplete understanding of the processes involved. The notion that all of the salts dissolved in the oceans were the products of leaching from the land was first proposed by the English astronomer and mathematician Edmond Halley in 1691 and restated by the Irish geologist John Joly in 1899. It was assumed that the ocean was a closed system and that the salinity of the oceans was an ever-changing and ever-increasing condition. Based on these calculations, Joly proposed that the Earth had consolidated and that the oceans had been created between 80 and 90 million years ago. The subsequent recognition that the ocean is not closed and that a continual loss of salts occurs due to sedimentation in certain environments severely limited this novel approach.

Equally novel but similarly flawed was the assumption that, if a cumulative measure of all rock successions were compiled and known rates of sediment accumulation were considered, the amount of time elapsed could be calculated. While representing a reasonable approach to the problem, this procedure did not or could not take into account different accumulation rates associated with different environments or the fact that there are many breaks in the stratigraphic record. Even observations made on faunal succession proved that gaps in the record do occur. How long were these gaps? Do they represent periods of nondeposition or periods of deposition followed by periods of erosion? Clearly sufficient variability in a given stratigraphic record exists such that it may be virtually impossible to even come to an approximate estimate of the Earth's age based on this technique. Nevertheless, many attempts using this approach were made (see Table 1).

William Thomson (later Lord Kelvin) applied his thermodynamic principles to the problems of heat flow, and this had implications for predicting the age of a cooling Sun and of a cooling Earth. From an initial estimate of 100 million years for the development of a solid crust around a molten core proposed in 1862, Thomson subsequently revised his estimate of the age of the Earth downward. Using the same criteria, he concluded in 1899 that the Earth was between 20 and 40 million years old.

Thomson's calculation was based on the assumption that the substance of the Earth is inert and thus incapable of producing new heat. His estimate came into question after the discovery of naturally occurring radioactivity by the

Table 1: Estimates of the Age of the Earth

date	author	maximum thickness (feet)	rate of deposit (years for 1 foot)	age* (millions of years)
1860	Phillips	72,000	1,332	96
1869	Huxley	100,000	1,000	100
1871	Haughton	177,200	8,616	1,526
1878	Haughton	177,200	?	200
1883	Winchell	—	—	3

French physicist Henri Becquerel in 1896 and the subsequent recognition by his colleagues, Marie and Pierre Curie, that compounds of radium (which occur in uranium minerals) produce heat. As a result of this and other findings, notably that of Ernest Rutherford (see below), it became apparent that naturally occurring radioactive elements in minerals common in the Earth's crust are sufficient to account for all observed heat flow. Within a short time another leading British physicist, John William Strutt, concluded that the production of heat in the Earth's interior was a dynamic process, one in which heat was continuously provided by such materials as uranium. The Earth was, in effect, not cooling.

AN ABSOLUTE AGE FRAMEWORK FOR THE STRATIGRAPHIC TIME SCALE

Disintegration theory

In his book *Radio-activity* (1904), Rutherford explained that radioactivity results from the spontaneous disintegration of an unstable element into a lighter element, which may decay further until a stable element is finally created. This process of radioactive decay involves the emission of positively charged particles (later to be recognized as helium nuclei) and negatively charged ones (electrons) and in most cases gamma rays (a form of electromagnetic radiation) as well. This interpretation, the so-called disintegration theory, came to provide the basis for the numerical quantification of geologic time. (For additional information on radioactive decay and the principles of radiometric dating, see *Absolute dating* below.)

In 1905 Strutt succeeded in analyzing the helium content of a radium-containing rock and determined its age to be 2 billion years. This was the first successful application of a radiometric technique to the study of Earth materials, and it set the stage for a more complete analysis of geologic time. Although faced with problems of helium loss and therefore not quite accurate results, a major scientific breakthrough had been accomplished. Also in 1905 the American chemist Bertram B. Boltwood, working with the more stable uranium–lead system, calculated the numerical ages of 43 minerals. His results, with a range of 400 million to 2.2 billion years, were an order of magnitude greater than those of the other "quantitative" techniques of the day that made use of heat flow or sedimentation rates to estimate time.

Acceptance of these new ages was slow in coming. Perhaps much to their relief, paleontologists now had sufficient time in which to accommodate faunal change. Researchers in other fields, however, were still conservatively sticking with ages on the order of several hundred million, but were revising their assumed sedimentation rates downward in order to make room for expanded time concepts.

In a brilliant contribution to resolving the controversy over the age of the Earth, Arthur Holmes, a student of Strutt, compared the relative (paleontologically determined) stratigraphic ages of certain specimens with their numerical ages as determined in the laboratory. This 1911 analysis provided for the first time the numerical ages for rocks from several Paleozoic geologic periods as well as from the Precambrian. Carboniferous-aged material was determined to be 340 million years, Devonian-aged material 370 million years, Ordovician (or Silurian) material 430 million years, and Precambrian specimens from 1.025 to 1.64 billion years. As a result of this work, the relative geologic time scale, which had taken nearly 200 years to evolve, could be numerically quantified. No longer did it have merely superpositional significance, it now had absolute temporal significance as well. (G.D.J.)

Nonradiometric dating

In addition to radioactive decay, many other processes have been investigated for their potential usefulness in absolute dating. Unfortunately, they all occur at rates that lack the universal consistency of radioactive decay. Sometimes human observation can be maintained long enough to measure present rates of change, but it is not at all certain on a priori grounds whether such rates are representative of the past. This is where radioactive methods frequently supply information that may serve to calibrate nonradioactive processes so that they become useful chronometers. Nonradioactive absolute chronometers may conveniently be classified in terms of the broad areas in which changes occur—namely, geologic and biological processes, which will be treated here.

GEOLOGIC PROCESSES AS ABSOLUTE CHRONOMETERS

Weathering processes. During the first third of the 20th century, several presently obsolete weathering chronometers were explored. Most famous was the attempt to estimate the duration of Pleistocene interglacial intervals through depths of soil development. In the American Midwest, thicknesses of gumbotil and carbonate-leached zones were measured in the glacial deposits (tills) laid down during each of the four glacial stages. Based on a direct proportion between thickness and time, the three interglacial intervals were determined to be longer than postglacial time by factors of 3, 6, and 8. To convert these relative factors into absolute ages required an estimate in years of the length of postglacial time. When certain evidence suggested 25,000 years to be an appropriate figure, factors became years—namely, 75,000, 150,000, and 200,000 years. And, if glacial time and nonglacial time are assumed approximately equal, the Pleistocene Epoch lasted about 1,000,000 years.

Obsidian hydration

Only one weathering chronometer is employed widely at the present time. Its record of time is the thin hydration layer at the surface of obsidian artifacts. Although no hydration layer appears on artifacts of the more common flint and chalcedony, obsidian is sufficiently widespread that the method has broad application.

In a specific environment the process of obsidian hydration is theoretically described by the equation $D = Kt^{1/2}$, in which D is thickness of the hydration rim, K is a constant characteristic of the environment, and t is the time since the surface examined was freshly exposed. This relationship is confirmed both by laboratory experiments at 100° C (212° F) and by rim measurements on obsidian artifacts found in carbon-14 dated sequences (see below *Carbon-14 dating and other cosmogenic methods*). Practical experience indicates that the constant K is almost totally dependent on temperature and that humidity is apparently of no significance. Whether in a dry Egyptian tomb or buried in wet tropical soil, a piece of obsidian seemingly has a surface that is saturated with a molecular film of water. Consequently, the key to absolute dating of obsidian is to evaluate K for different temperatures. Ages follow from the above equation provided there is accurate knowledge of a sample's temperature history. Even without such knowledge, hydration rims are useful for relative dating within a region of uniform climate.

Like most absolute chronometers, obsidian dating has its problems and limitations. Specimens that have been exposed to fire or to severe abrasion must be avoided. Furthermore, artifacts reused repeatedly do not give ages corresponding to the culture layer in which they were found but instead to an earlier time, when they were fashioned. Finally, there is the problem that layers may flake off beyond 40 micrometres (0.004 centimetre, or 0.002 inch) of thickness—*i.e.,* more than 50,000 years in age. Measuring several slices from the same specimen is wise in this regard, and such a procedure is recommended regardless of age.

Accumulational processes. Sediment in former or present water bodies, salt dissolved in the ocean, and fluorine in bones are three kinds of natural accumulations and possible time indicators. To serve as geochronometers, the records must be complete and the accumulation rates known.

The fossiliferous part of the geologic column includes perhaps 122,000 metres of sedimentary rock if maximum thicknesses are selected from throughout the world. During the late 1800s, attempts were made to estimate the time over which it formed by assuming an average rate of sedimentation. Because there was great diversity among the rates assumed, the range of estimates was also large—from a high of 2.4 billion years to a low of 3 million years. In spite of this tremendous spread, most geologists felt that time in the hundreds of millions of years was necessary to explain the sedimentary record.

Varve dating

If the geologic column (see below) were made up entirely of annual layers, its duration would be easy to determine. Limited sedimentary deposits did accumulate in this way, and they are said to be varved; one year's worth of sediment is called a varve, and, in general, it includes two laminae per year.

Varves arise in response to seasonal changes. New Mexico's Castile Formation, for example, consists of alternating layers of gypsum and calcite that may reflect an annual temperature cycle in the hypersaline water from which the minerals precipitated. In moist, temperate climates, lake sediments collecting in the summer are richer in organic matter than those that settle during winter. This feature is beautifully seen in the seasonal progression of plant microfossils found in shales at Oensingen, Switz. In the thick oil shales of Wyoming and Colorado in the United States, the flora is not so well defined, but layers alternating in organic richness seem to communicate the same seasonal cycle. These so-called Green River Shales also contain abundant freshwater-fish fossils that confirm deposition in a lake. At their thickest, they span 792 vertical metres. Because the average thickness of a varve is about 0.015 centimetre (0.006 inch), the lake is thought to have existed for more than 5 million years.

Each of the examples cited above is of a floating chronology—*i.e.,* a decipherable record of time that was terminated long ago. In Sweden, by contrast, it has been possible to tie a glacial varve chronology to present time, and so create a truly absolute dating technique. Where comparisons with radiocarbon dating are possible, there is general agreement.

Fluorine dating

As early as 1844, an English chemist named Middleton claimed that fossil bones contain fluorine in proportion to their antiquity. This idea is sound in principle, provided that all the other natural variables remain constant. Soil permeability, rainfall, temperature, and the concentration of fluorine in groundwater all vary with time and location, however. Fluorine dating is therefore not the simple procedure that Middleton envisioned.

Still, the idea that hydroxyapatite in buried bone undergoes gradual change to fluorapatite is a correct one. In a restricted locality where there is uniformity of climate and soil, the extent of fluorine addition is at least a measure of relative age and has been so used with notable success in dating certain hominid remains. Both the Piltdown hoax, for example, and the intrusive burial of the Galley Hill skeleton were exposed in part by fluorine measurements. Supplementing them were analyses of uranium, which resembles fluorine in its increase with time, and nitrogen, which decreases as bone protein decays away.

Fluorine changes could conceivably be calibrated if bone samples were found in a radiometrically dated sequence. Conditions governing fluorine uptake, however, are so variable even over short distances that it is risky to use fluorine content as an absolute chronometer much beyond the calibration site itself. In short, fluorine dating is not now and probably never will be an absolute chronometer. Even when used in relative dating, many fluorine analyses on diverse samples are needed, and these must be supplemented by uranium and nitrogen measurements to establish confidence in the chronological conclusions.

Geomagnetic variations. Based on three centuries of direct measurement, the Earth's magnetic field is known to be varying slowly in both its intensity and direction. In fact, change seems to have been the rule throughout all of the Earth's past. Magnetic minerals in rocks (and in articles of fired clay) provide the record of ancient change, for they took on the magnetic field existing at the time of their creation or emplacement.

Polar reversals were originally discovered in lava rocks and since have been noted in deep-sea cores. In both cases the time dimension is added through radiometric methods applied to the same materials that show the reversals. Potassium–argon is the commonest chronometer used (see below *Potassium–argon methods*). A magnetic-polarity (or paleomagnetic) time scale has been proposed along the line of the geologic time scale; time divisions are called intervals, or epochs.

BIOLOGICAL PROCESSES AS ABSOLUTE CHRONOMETERS

Tree-ring growth. In the early 1900s an American astronomer named Andrew E. Douglass went looking for terrestrial records of past sunspot cycles and not only found what he sought but also discovered a useful dating method in the process. The focus of his attention was the growth rings in trees—living trees, dead trees, beams in ancient structures, and even large lumps of charcoal.

Dendrochronology

The key documents for tree-ring dating, or dendrochronology, are those trees that grow or grew where roots receive water in direct proportion to precipitation. Under such a situation, the annual tree rings vary in width as a direct reflection of the moisture supplied. What is important in tree-ring dating is the sequence in which rings vary. Suppose, for example, that a 100-year-old tree is cut down and its ring widths are measured. The results can be expressed graphically, and, if a similar graph were made from a small stump found near the 100-year-old tree, the two graphs could be compared until a match of the curves was obtained. The time when the small stump was made would thereby be determined from the position of its outer ring alongside the 100-year record.

Not every tree species nor even every specimen of a suitable species can be used. In the American Southwest, success has been achieved with yellow pine, Douglas fir, and even sagebrush. Unfortunately, the giant sequoia of California does not live in a sufficiently sensitive environment to provide a useful record. The even older bristlecone pine in California's White Mountains does have a climate-sensitive record, but its area of growth is so limited and so inaccessible that no bristlecone specimens have so far appeared in archaeological sites. This shortcoming notwithstanding, dead bristlecone pine trees are presently providing rings as old as 8,200 years for dating by carbon-14. The purpose is to check the carbon-14 method (see below *Carbon-14 dating and other cosmogenic methods*).

Coral growth. Certain fossil corals have long been used to date rocks relatively, but only recently has it been shown that corals may also serve as absolute geochronometers. They may do so by preserving a record of how many days there were in a year at the time they were growing. The number of days per year has decreased through time because the rate of rotation of the Earth has decreased; geophysical evidence suggests that days are currently lengthening at the rate of 20 seconds per million years. If this were typical of the slowdown during the past, a year consisted of 423 days about 600 million years ago.

Readings from horn corals

It is thought that horn corals indicate the number of days per year by means of their exceedingly fine external ridges of calcium carbonate, each of which is believed to represent a day's growth. Several hundred of the fine ridges also seem to cluster as a unit that presumably corresponds to one year. In certain modern West Indian corals the number of fine ridges in a presumed annual increment is approximately 360, suggesting that coral patterns are being properly interpreted.

Not many fossil corals are in a state of preservation that permits the counting of ridges, but those that are seem to lend themselves well to this procedure. Several Middle Devonian corals indicate between 385 and 410 ridges, with an average of about 400. It remains to be seen whether this method of dating, so elegant in concept and so simple in application, will blossom or wither away in the years to come. (E.A.O./Ed.)

RELATIVE AND ABSOLUTE DATING

General considerations

DISTINCTIONS BETWEEN RELATIVE-AGE AND ABSOLUTE-AGE MEASUREMENTS

Relative age

Local relationships on a single outcrop or archaeological site can often be interpreted to deduce the sequence in which the materials were assembled. This then can be used to deduce the sequence of events and processes that took place or the history of that brief period of time as recorded in the rocks or soil. For example, the presence of recycled bricks at an archaeological site indicates the sequence in which the structures were built. Similarly, in geology, if distinctive granitic pebbles can be found in the sediment beside a similar granitic body, it can be inferred that the granite, after cooling, had been uplifted and eroded and therefore was not injected into the adjacent rock sequence. Although with clever detective work many complex time sequences or relative ages can be deduced, the ability to show that objects at two separated sites were formed at the same time requires additional information. A coin, vessel, or other common artifact could link two archaeological sites, but the possibility of recycling would have to be considered. It should be emphasized that linking sites together is essential if the nature of an ancient society is to be understood, as the information at a single location may be relatively insignificant by itself. Similarly, in geologic studies, vast quantities of information from widely spaced outcrops have to be integrated. Some method of correlating rock units must be found. In the ideal case, the geologist will discover a single rock unit with a unique collection of easily observed attributes called a marker horizon that can be found at widely spaced localities. Any feature, including colour variations, textures, fossil content, mineralogy, or any unusual combinations of these can be used. It is only by correlations that the conditions on different parts of the Earth at any particular stage in its history can be deduced. In addition, because sediment deposition is not continuous and much rock material has been removed by erosion, the fossil record from many localities has to be integrated before a complete picture of the evolution of life on Earth can be assembled. Using this established record, geologists have been able to piece together events over the past 600 million years, or about one-eighth of Earth history, during which time useful fossils have been abundant. The need to correlate over the rest of geologic time, to correlate nonfossiliferous units, and to calibrate the fossil time scale has led to the development of a specialized field that makes use of natural radioactive isotopes in order to calculate absolute ages.

Absolute age

The precise measure of geologic time has proven to be the essential tool for correlating the global tectonic processes (see below) that have taken place in the past. Precise isotopic ages are called absolute ages, since they date the timing of events not relative to each other but as the time elapsed between a rock-forming event and the present. Absolute dating by means of uranium and lead isotopes has been improved to the point that for rocks 3 billion years old geologically meaningful errors of ± 1 or 2 million years can be obtained. The same margin of error applies for younger fossiliferous rocks, making absolute dating comparable in precision to that attained using fossils. To achieve this precision, geochronologists have had to develop the ability to isolate certain high-quality minerals that can be shown to have remained closed to migration of the radioactive parent atoms they contain and the daughter atoms formed by radioactive decay over billions of years of geologic time. In addition, they have had to develop special techniques with which to dissolve these highly refractory minerals without contaminating the small amount (about one-billionth of a gram) of contained lead and uranium on which the age must be calculated. Since parent uranium atoms change into daughter atoms with time at a known rate, their relative abundance leads directly to the absolute age of the host mineral. Just as the use of the fossil record has allowed a precise definition of geologic processes in approximately the past 600 million years, absolute ages allow correlations back to the Earth's oldest known rocks formed almost 4 billion years ago. In fact, even in younger rocks, absolute dating is the only way that the fossil record can be calibrated. Without absolute ages, investigators could only determine which fossil organisms lived at the same time and the relative order of their appearance in the correlated sedimentary rock record.

Unlike ages derived from fossils, which occur only in sedimentary rocks, absolute ages are obtained from minerals that grow as liquid rock bodies cool at or below the surface. When rocks are subjected to high temperatures and pressures in mountain roots formed where continents collide, certain datable minerals grow and even regrow to record the timing of such geologic events. When these regions are later exposed in uptilted portions of ancient continents, a history of terrestrial rock-forming events can be deduced. Episodes of global volcanic activity, rifting of continents, folding, and metamorphism are defined by absolute ages. The results suggest that the present-day global tectonic scheme was operative in the distant past as well.

THE GLOBAL TECTONIC ROCK CYCLE

Theory of plate tectonics

Bringing together virtually all geologic aspects of the Earth's outer rock shell (the lithosphere) into a unifying theory called plate tectonics has had a profound impact on the scientific understanding of our dynamic planet. Continents move, carried on huge slabs, or plates, of dense rock about 100 kilometres thick over a low-friction, partially melted zone (the asthenosphere) below. In the oceans, new seafloor, created at the globe-circling oceanic ridges, moves away, cools, and sinks back into the mantle in what are known as subduction zones (*i.e.,* long, narrow belts at which one plate descends beneath another). Where this occurs at the edge of a continent, as along the west coast of North and South America, large mountain chains develop with abundant volcanoes and their subvolcanic equivalents. These units, called igneous rock, or magma in their molten form, constitute major crustal additions. By contrast, crustal destruction occurs at the margins of two colliding continents, as, for example, where the subcontinent of India is moving north over Asia. Great uplift, accompanied by rapid erosion, is taking place and large sediment fans are being deposited in the Indian Ocean to the south. With time, water-soluble "cement" will cause the sandy units to become sandstone. Rocks of this kind in the ancient record may very well have resulted from rapid uplift and continent collision.

When continental plates collide, the edge of one plate is thrust onto that of the other. The rocks in the lower slab undergo changes in their mineral content in response to heat and pressure and will probably become exposed at the surface again some time later. Rocks converted to new mineral assemblages because of changing temperatures and pressures are called metamorphic. Virtually any rock now seen forming at the surface can be found in exposed deep crustal sections in a form that reveals through its mineral content the temperature and pressure of burial.

Such regions of the crust may even undergo melting and subsequent extrusion of melt magma, which may appear at the surface as volcanic rocks or may solidify as it rises to form granites at high crustal levels. Magmas produced in this way are regarded as recycled crust, whereas others extracted by partial melting of the mantle below are considered primary. (For additional information on the tectonic rock cycle, see EARTH, THE: *The surface of the Earth as a mosaic of plates: Activity along plate boundaries.*)

Even the oceans and atmosphere are involved in this great cycle because minerals formed at high temperatures are unstable at surface conditions and eventually break down or weather, in many cases taking up water and carbon dioxide to make new minerals. If such minerals were deposited on a downgoing (*i.e.,* subducted) oceanic slab, they would eventually be heated and changed back into high-temperature minerals, with their volatile components being released. These components would then rise and be fixed in the upper crust or perhaps reemerge at the surface. Such hot circulating fluids can dissolve metals and eventually deposit them as economic mineral deposits on their way to the surface.

Geochronological studies have provided documentary evidence that these rock-forming and rock-re-forming processes were active in the past. Seafloor spreading has been traced, by dating minerals found in a unique grouping of rock units thought to have been formed at the oceanic ridges, to 500 million years ago, with rare occurrences as early as 2 billion years ago. Volcanic units resembling those formed over oceanic subduction zones can be dated worldwide to show that the Earth's most prolific volcanic event occurred about 2.7 billion years ago. Other ancient volcanic units document various cycles of mountain building. The source of ancient sediment packages like those presently forming off India can be identified by dating single detrital grains of zircon found in sandstone. Magmas produced by the melting of older crust can be identified because their zircons commonly contain inherited older cores. Episodes of continental collision can be dated by isolating new zircons formed as the buried rocks underwent local melting. Periods of deformation associated with major collisions cannot be directly dated if no new minerals have formed. The time of deformation can be bracketed, however, if datable units, which both predate and postdate it, can be identified. The timing of cycles involving the expulsion of fluids from deep within the crust can be ascertained by dating new minerals formed at high pressures in exposed deep crustal sections. In some cases, it is possible to prove that gold deposits may have come from specific fluids if the deposition time of the deposits can be determined and the time of fluid expulsion is known.

Dating of volcanic units

Where the crust is under tension, as in Iceland, great fissures develop. These fissures serve as conduits that allow black lava, called basalt, to reach the surface. The portion that remains in a fissure below the surface usually forms a vertical black tubular body known as a dike (or dyke). Precise dating of such dikes can reveal times of crustal rifting in the past. Dikes and lava, now exposed on either side of Baffin Bay, have been dated to determine the time when Greenland separated from North America—namely, about 60 million years ago.

Combining knowledge of the Earth processes observed today with absolute ages of ancient geologic analogues seems to indicate that the oceans and atmosphere were present by at least 3.5 billion years ago and that they were probably released by early heating of the planet (see below *Geologic history of the Earth: Development of the atmosphere and oceans*). The continents were produced over time; the earliest portions were formed nearly 4 billion years ago, and the process still continues today. Absolute dating allows rock units formed at the same time to be identified and reassembled into ancient mountain belts, which in many cases have been disassociated by subsequent tectonic processes. The most obvious of these is the Appalachian chain that occupies the east coast of North America and extends to parts of Newfoundland as well as parts of Ireland, England, and Norway. Relic oceanic crust, formed between 480 and 500 million years ago, was identified on both sides of the Atlantic in this chain, as were numerous correlative volcanic and sedimentary units. Evidence based on geologic description, fossil content, and absolute and relative ages leave no doubt that these rocks were all part of a single mountain belt before the Atlantic Ocean opened in stages from about 200 million years ago.

DETERMINATION OF SEQUENCE

Relative geologic ages can be deduced in rock sequences consisting of sedimentary, metamorphic, or igneous rock units. In fact, they constitute an essential part in any precise isotopic, or absolute, dating program. Such is the case because most rocks simply cannot be isotopically dated. Therefore, a geologist must first determine relative ages and then locate the most favourable units for absolute dating. It is also important to note that relative ages are inherently more precise, since two or more units deposited minutes or years apart would have identical absolute ages but precisely defined relative ages. While absolute ages require expensive, complex analytical equipment, relative ages can be deduced from simple visual observations.

Inherent preciseness of relative ages

Most methods for determining relative geologic ages are well illustrated in sedimentary rocks. These rocks cover roughly 75 percent of the surface area of the continents, and unconsolidated sediments blanket most of the ocean floor. They provide evidence of former surface conditions and the life-forms that existed under those conditions. The sequence of a layered sedimentary series is easily defined because deposition always proceeds from the bottom to the top. This principle would seem self-evident, but its first enunciation more than 300 years ago by Nicolaus Steno represented an enormous advance in understanding. Known as the principle of superposition, it holds that in a series of sedimentary layers or superposed lava flows the oldest layer is at the bottom, and layers from there upward become progressively younger (see above *Study of the rock record: Early views and discoveries: The principle of superposition of rock strata*). On occasion, however, deformation may have caused the rocks of the crust to tilt, perhaps to the point of overturning them. Moreover, if erosion has blurred the record by removing substantial portions of the deformed sedimentary rock, it may not be at all clear which edge of a given layer is the original top and which is the original bottom.

Identifying top and bottom is clearly important in sequence determination, so important in fact that a considerable literature has been devoted to this question alone. Many of the criteria of top–bottom determination are based on asymmetry in depositional features. Oscillation ripple marks, for example, are produced in sediments by water sloshing back and forth. When such marks are preserved in sedimentary rocks, they define the original top and bottom by their asymmetric pattern. Certain fossils also accumulate in a distinctive pattern or position that serves to define the top side.

In wind-blown or water-lain sandstone, a form of erosion during deposition of shifting sand removes the tops of mounds to produce what are called cross-beds. The truncated layers provide an easily determined depositional top direction. The direction of the opening of mud cracks or rain prints can indicate the uppermost surface of mudstones formed in tidal areas. When a section of rock is uplifted and eroded, as during mountain-building episodes, great volumes of rock are removed, exposing a variety of differently folded and deformed rock units. The new erosion surface must postdate all units, dikes, veins, and deformation features that it crosses. Even the shapes formed on the erosional or depositional surfaces of the ancient seafloor can be used to tell which way was up. A fragment broken from one bed can only be located in a younger unit, and a pebble or animal track can only deform a preexisting unit—*i.e.,* one below. In fact, the number of ways in which one can determine the tops of well-preserved sediments is limited only by the imagination, and visual criteria can be deduced by amateurs and professionals alike.

One factor that can upset the law of superposition in major sediment packages in mountain belts is the presence of thrust faults. Such faults, which are common in compression zones along continental edges, may follow bedding planes and then cross the strata at a steep angle, placing older units on top of younger ones. In certain places, the fault planes are only a few centimetres thick and are almost impossible to detect.

Deducing relative ages in metamorphic rocks

Relative ages also can be deduced in metamorphic rocks as new minerals form at the expense of older ones in response to changing temperatures and pressures. In deep mountain roots, rocks can even flow like toothpaste in their red-hot state. Local melting may occur, and certain minerals suitable for precise isotopic dating may form both in the melt and in the host rock. In the latter case, refractory grains in particular may record the original age of the rock in their cores and the time of melting in their newly grown tips. Analytical methods are now available to date both growth stages, even though each part may weigh only a few millionths of a gram (see below *Correlation*). Rocks that flow in a plastic state record their deformation in the alignment of their constituent minerals. Such rocks then predate the deformation. If other rocks that are clearly not deformed can be found at the same site, the time of deformation can be inferred to lie between the absolute isotopic ages of the two units.

Igneous rocks provide perhaps the most striking examples of relative ages. Magma, formed by melting deep within the Earth, cuts across and hence postdates all units as it rises through the crust, perhaps even to emerge at the surface as lava. Black lava, or basalt, the most common volcanic rock on Earth, provides a simple means for determining the depositional tops of rock sequences as well as proof of the antiquity of the oceans. Pillow shapes are formed as basaltic lava is extruded (*i.e.,* erupted) under water; these are convex upward with a lower tip that projects down between two convex tops below. The shapes of pillows in ancient basalts provide both a direct indication of depositional top and proof of underwater eruption. They are widespread in rocks as old as 3.5 billion years, implying that the oceans were already present.

Basaltic lava rocks that are common where ancient continents have been rifted apart are fed from below by near vertical fractures penetrating the crust. Material that solidifies in such cracks remains behind as dikes. Here the dikes must be younger than all other units. A more interesting case develops when a cooled older crust is fractured, invaded by a swarm of dikes, and subsequently subjected to a major episode of heating with deformation and intrusion of new magma. In this instance, even though the resulting outcrop pattern is extremely complex, all of the predike units can be distinguished by the relic dikes present. The dikes also record in their newly formed minerals components that can be analyzed to give both the absolute age and the temperature and pressure of the second event. Because dike swarms are commonly widespread, the conditions determined can often be extrapolated over a broad region. Dikes do not always continue upward in a simple fashion. In some cases, they spread between the layers of near-horizontal sedimentary or volcanic units to form bodies called sills. In this situation, fragments of the host rock must be found within the intrusive body to establish its relatively younger age.

Applying the principle of crosscutting relationships

Once most or all of the relative ages of various strata have been determined in a region, it may be possible to deduce that certain units have been offset by movement along fractures or faults while others have not. Dikes that cross fault boundaries may even be found. Application of the simple principle of crosscutting relationships can allow the relative ages of all units to be deduced. A number of criteria for establishing relative ages are illustrated in the diagram shown in Figure 2.

The principles for relative age dating described above require no special equipment and can be applied by anyone on a local or regional scale. They are based on visual observations and simple logical deductions and rely on a correlation and integration of data that occurs in fragmentary form at many outcrop locations.

CORRELATION

Principles and techniques. Correlation is, as mentioned earlier, the technique of piecing together the informational content of separated outcrops. When information derived from two outcrops is integrated, the time interval they represent is probably greater than that of each alone. Presumably if all the world's outcrops were integrated, sediments representing all of geologic time would be available for examination. This optimistic hope, however, must be tempered by the realization that much of the Precambrian record—older than 570 million years—is missing. Correlating two separated outcrops means establishing that they share certain characteristics indicative of contemporary formation. The most useful indication of time equivalence is similar fossil content, provided of course that such remains are present. The basis for assuming that like fossils indicate contemporary formation is faunal succession. However, as previously noted, times of volcanism and metamorphism, which are both critical parts of global processes, cannot be correlated by fossil content. Furthermore, useful fossils are either rare or totally absent in rocks from Precambrian time, which constitutes more than 87 percent of Earth history. Precambrian rocks must therefore be correlated by means of precise isotopic dating.

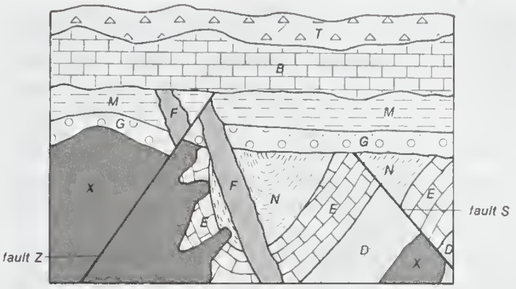

Figure 2: Hypothetical outcrop to which sequence-determining techniques can be applied. The correct sequence, from oldest to youngest, is *D,E,N,X,S,G,M,F,Z,B,T.*

From *Journal of Geological Education* (December 1967)

Unlike the principles of superposition and crosscutting, faunal succession is a secondary principle. That is to say, it depends on other sequence-determining principles for establishing its validity. Suppose there exist a number of fossil-bearing outcrops each composed of sedimentary layers that can be arranged in relative order, primarily based on superposition. Suppose, too, that all the layers contain a good representation of the animal life existing at the time of deposition. From an examination of such outcrops with special focus on the sequence of animal forms comes the empirical generalization that the faunas of the past have followed a specific order of succession, and so the relative age of a fossiliferous rock is indicated by the types of fossils it contains.

As was mentioned at the outset of this article, William Smith first noticed around 1800 that the different rock layers he encountered in his work were characterized by different fossil assemblages. Using fossils simply for identification purposes, Smith constructed a map of the various surface rocks outcropping throughout England, Wales, and southern Scotland. Smith's geologic map was extremely crude, but in its effect on Earth study it was a milestone.

Following Smith's pioneering work, generations of geologists have confirmed that similar and even more extensive fossil sequences exist elsewhere. To this day, fossils are useful as correlation tools to geologists specializing in stratigraphy. In dating the past, the primary value of fossils lies within the principle of faunal succession: each interval of geologic history had a unique fauna that associates a given fossiliferous rock with that particular interval.

Index fossils

The basic conceptual tool for correlation by fossils is the index, or guide, fossil. Ideally, an index fossil should be such as to guarantee that its presence in two separated rocks indicates their synchroneity. This requires that the lifespan of the fossil species be but a moment of time relative to the immensity of geologic history. In other words, the fossil species must have had a short temporal range. On the practical side, an index fossil should be distinctive in appearance so as to prevent misidentification, and it should be cosmopolitan both as to geography and as to rock type. In addition, its fossilized population should be sufficiently abundant for discovery to be highly probable. Such an array of attributes represents an ideal, and much stratigraphic geology is rendered difficult because of departure of the natural fossil assemblage from this ideal. Nevertheless, there is no greater testimony to the validity of fossil-based stratigraphic geology than the absolute dates made possible through radioactive measurements. Almost without exception, the relative order of strata defined by fossils has been confirmed by radiometric ages.

Correlation based on the physical features of the rock record also has been used with some success, but it is restricted to small areas that generally extend no more than several hundred kilometres. The first step is determining whether similar beds in separated outcrops can actually be traced laterally until they are seen to be part of the same original layer. Failing that, the repetition of a certain layered sequence (*e.g.,* a black shale sandwiched between a red sandstone and a white limestone) lends confidence to physical correlation. Finally, the measurement of a host of rock properties may well be the ultimate key to correlation of separated outcrops. The more ways in which two rocks are physically alike, the more likely it is that the two formed at the same time.

Only a partial listing of physical characteristics is necessary to indicate the breadth of approach in this area. Such features as colour, ripple marks, mud cracks, raindrop imprints, and slump structures are directly observable in the field. Properties derived from laboratory study include (1) size, shape, surface appearance, and degree of sorting of mineral grains, (2) specific mineral types present and their abundances, (3) elemental composition of the rock as a whole and of individual mineral components, (4) type and abundance of cementing agent, and (5) density, radioactivity, and electrical-magnetic-optical properties of the rock as a whole.

Well logging

With the development of miniaturized analytical equipment, evaluation of rock properties down a small drill hole has become possible. The technique, called well logging, involves lowering a small instrument down a drill hole on the end of a wire and making measurements continuously as the wire is played out in measured lengths. By this technique it is possible to detect depth variations in electrical resistivity, self-potential, and gamma-ray emission rate and to interpret such data in terms of continuity of the layering between holes. Subsurface structures can thus be defined by the correlation of such properties.

Field geologists always prize a layer that is so distinctive in appearance that a series of tests need not be made to establish its identity. Such a layer is called a key bed. In a large number of cases, key beds originated as volcanic ash. Besides being distinctive, a volcanic-ash layer has four other advantages for purposes of correlation: it was laid down in an instant of geologic time; it settles out over tremendous areas; it permits physical correlation between contrasting sedimentary environments; and unaltered mineral crystals that permit radiometric measurements of absolute age often are present.

Correlation may be difficult or erroneous if several different ash eruptions occurred, and a layer deposited in one is correlated with that from another. Even then, the correlation may be justified if the two ash deposits represent the same volcanic episode. Much work has been undertaken to characterize ash layers both physically and chemically and so avoid incorrect correlations. Moreover, single or multigrain zircon fractions from the volcanic source are now being analyzed to provide precise absolute ages for the volcanic ash and the fossils in the adjacent units.

Geologic column and its associated time scale. The end product of correlation is a mental abstraction called the geologic column. It is the result of integrating all the world's individual rock sequences into a single sequence. In order to communicate the fine structure of this so-called column, it has been subdivided into smaller units. Lines are drawn on the basis of either significant changes in fossil forms or discontinuities in the rock record (*i.e.,* unconformities, or large gaps in the sedimentary sequence); the basic subdivisions of rock are called systems, and the corresponding time intervals are termed periods. In the upper part of the geologic column, where fossils abound, these rock systems and geologic periods are the basic units of rock and time. Lumping of periods results in eras, and splitting gives rise to epochs. In both cases, a threefold division into early–middle–late is often used, although those specific words are not always applied. Similarly, many periods are split into three epochs. Names assigned to individual epochs follow no single worldwide standard except for the seven epochs making up the last two periods (see below Table 4).

Over the interval from the Paleozoic to the present, about 35 epochs are recognized in North America. This interval is represented by approximately 250 formations, discrete layers thick enough and distinctive enough in lithology to merit delineation as units of the geologic column. Also employed in subdivision is the zone concept, in which it is the fossils in the rocks rather than the lithologic character that defines minor stratigraphic boundaries. The basis of zone definition varies among geologists, some considering a zone to be all rocks containing a certain species (usually an invertebrate), whereas others focus on special fossil assemblages.

The lower part of the geologic column, where fossils are very scarce, was at one time viewed in the context of two eras of time, but subsequent mapping has shown the provincial bias in such a scheme. Consequently, the entire lower column is now considered a single unit, the Precambrian. The results of isotopic dating are now providing finer Precambrian subdivisions that have worldwide applicability. For a detailed discussion of this subject, see below *Precambrian era.*

The geologic column and the relative geologic time scale are sufficiently defined to fulfill the use originally envisioned for them—providing a framework within which to tell the story of Earth history. Just as human history has its interweaving plots of warfare, cultural development, and technological advance, so the Earth's rocks tell another story of intertwined sequences of events. Mountains have been built and eroded away, seas have advanced and retreated, a myriad of life-forms has inhabited land and sea. In all these happenings the geologic column and its associated time scale spell the difference between an unordered series of isolated events and the unfolding story of a changing Earth.

Absolute dating

Although relative ages can generally be established on a local scale, the events recorded in rocks from different locations can be integrated into a picture of regional or global scale only if their sequence in time is firmly established. The time that has elapsed since certain minerals formed can now be determined because of the presence of a small amount of natural radioactive atoms in their structures. Whereas studies using fossil dating began almost 300 years ago, radioactivity itself was not discovered until roughly a century ago, and it has only been from about 1950 that extensive efforts to date geologic materials have become common. Methods of isotopic measurement continue to be refined today, and absolute dating has become an essential component of virtually all field-oriented geologic investigations. In the process of refining isotopic measurements, methods for low-contamination chemistry had to be developed, and it is significant that many such methods now in worldwide use resulted directly from work in geochronology.

It has already been explained how different Earth processes create different rocks as part of what can be considered a giant rock-forming and -reforming cycle. Attention has been called wherever possible to those rocks that contain minerals suitable for precise isotopic dating. It is important to remember that precise ages cannot be obtained for just any rock unit but that any unit can be dated relative to a datable unit. The following discussion will show why this is so, treating in some detail the analytic and geologic problems that have to be overcome if precise ages are to be determined. It will become apparent, for example, that isotopic ages can be reset by high temperatures; however, this seeming disadvantage can be turned to one's favour in determining the cooling history of a rock. As various dating methods are discussed, the great interdependence of the geologic and analytic components essential to geochronology should become evident.

Significance of isotope geology

The field of isotope geology complements geochronology. Workers in isotope geology follow the migration of isotopes produced by radioactive decay through large- and small-scale geologic processes. Isotopic tracers of this kind can be thought of as an invisible dye injected by nature into Earth systems that can be observed only with sophisticated instruments. Studying the movement or distribution of these isotopes can provide insights into the nature of geologic processes.

PRINCIPLES OF ISOTOPIC DATING

All absolute isotopic ages are based on radioactive decay, a process whereby a specific atom or isotope is converted into another specific atom or isotope at a constant and known rate. Most elements exist in different atomic forms that are identical in their chemical properties but differ in the number of neutral particles—*i.e.*, neutrons—in the nucleus. For a single element, these atoms are called isotopes. Because isotopes differ in mass, their relative abundance can be determined if the masses are separated in a mass spectrometer (see below *Use of mass spectrometers*).

Observing the radioactive decay process in the laboratory

Radioactive decay can be observed in the laboratory by either of two means: (1) a radiation counter (*e.g.*, a Geiger counter), which detects the number of high-energy particles emitted by the disintegration of radioactive atoms in a sample of geologic material, or (2) a mass spectrometer, which permits the identification of daughter atoms formed by the decay process in a sample containing radioactive parent atoms. The particles given off during the decay process are part of a profound fundamental change in the nucleus. To compensate for the loss of mass (and energy), the radioactive atom undergoes internal transformation and in most cases simply becomes an atom of a different chemical element. In terms of the numbers of atoms present, it is as if apples changed spontaneously into oranges at a fixed and known rate. In this analogy, the apples would represent radioactive, or parent, atoms, while the oranges would represent the atoms formed, the so-called daughters. Pursuing this analogy further, one would expect that a new basket of apples would have no oranges but that an older one would have many. In fact, one would expect that the ratio of oranges to apples would change in a very specific way over the time elapsed, since the process continues until all the apples are converted. In geochronology the situation is identical. A particular rock or mineral that contains a radioactive isotope (or radioisotope) is analyzed to determine the number of parent and daughter isotopes present, whereby the time since that mineral or rock formed is calculated. Of course, one must select geologic materials that contain elements with long half-lives—*i.e.*, those for which some parent atoms would remain.

Given below is the simple mathematical relationship that allows the time elapsed to be calculated from the measured parent/daughter ratio. The age calculated is only as good as the existing knowledge of the decay rate and is valid only if this rate is constant over the time that elapsed.

Radioactive decay as an immutable process

Fortunately for geochronology the study of radioactivity has been the subject of extensive theoretical and laboratory investigation by physicists for almost a century. The results show that there is no known process that can alter the rate of radioactive decay. By way of explanation it can be noted that since the cause of the process lies deep within the atomic nucleus, external forces such as extreme heat and pressure have no effect. The same is true regarding gravitational, magnetic, and electric fields, as well as the chemical state in which the atom resides. In short, the process of radioactive decay is immutable under all known conditions. Although it is impossible to predict when a particular atom will change, given a sufficient number of atoms, the rate of their decay is found to be constant. The situation is analogous to the death rate among human populations insured by an insurance company. Even though it is impossible to predict when a given policyholder will die, the company can count on paying off a certain number of beneficiaries every month. The recognition that the rate of decay of any radioactive parent atom is proportional to the number of atoms (N) of the parent remaining at any time gives rise to the following expression:

$$\begin{array}{ccc} R & \propto & N \\ \text{rate of} & \text{is propor-} & \text{number of parent} \\ \text{disintegration} & \text{tional to} & \text{atoms present.} \end{array} \qquad (1)$$

Decay constant

Converting this proportion to an equation incorporates the additional observation that different radioisotopes have different disintegration rates even when the same number of atoms are observed undergoing decay. In other words, each radioisotope has its own decay constant, abbreviated λ, which provides a measure of its intrinsic rapidity of decay. Proportion 1 becomes:

$$R = \lambda N. \qquad (2)$$

Stated in words, this equation says that the rate at which a certain radioisotope disintegrates depends not only on how many atoms of that isotope are present but also on an intrinsic property of that isotope represented by λ, the so-called decay constant. Values of λ vary widely—from 10^{20} reciprocal seconds (*i.e.*, the unit of 1 second) for a rapidly disintegrating isotope such as helium-5 to less than 10^{-25} reciprocal seconds for slowly decaying cerium-142.

In the calculus, the rate of decay R in equation 2 is written as the derivative dN/dt, in which dN represents the small number of atoms that decay in an infinitesimally short time interval dt. Replacing R by its equivalent dN/dt results in the differential equation

$$\frac{dN}{dt} = -\lambda N. \qquad (3)$$

Solution of this equation by techniques of the calculus yields one form of the fundamental equation for radiometric age determination,

$$\frac{N}{N_0} = e^{-\lambda t}, \qquad (4)$$

in which N_0 is the number of radioactive atoms present in a sample at time zero, N is the number of radioactive atoms present in the sample today, e is the base of natural logarithms (equal to about 2.72), λ is the decay constant of the radioisotope being considered, and t is the time elapsed since time zero.

Definition of half-life

Two alterations are generally made to equation 4 in order to obtain the form most useful for radiometric dating. In the first place, since the unknown term in radiometric dating is obviously t, it is desirable to rearrange equation 4 so that it is explicitly solved for t. Second, the more common way to express the intrinsic decay rate of a radioisotope is through its half-life (abbreviated $t_{1/2}$) rather than through the decay constant λ. Half-life is defined as the time period that must elapse in order to halve the initial number of radioactive atoms. The half-life and the decay constant are inversely proportional because rapidly decaying radioisotopes have a high decay constant but a short half-life. With t made explicit and half-life introduced, equation 4 is converted to the following form, in which the symbols have the same meaning:

$$t = \frac{t_{1/2}}{0.693} \times \log_e\left(\frac{N_0}{N}\right). \qquad (5)$$

Alternatively, because the number of daughter atoms is directly observed rather than N, which is the initial number of parent atoms present, another formulation may be more convenient. Since the initial number of parent atoms present at time zero N_0 must be the sum of the parent atoms remaining N and the daughter atoms present D, one can write:

$$D = N_0 - N. \qquad (6)$$

From equation 4 above, it follows that $N_0 = N(e^{\lambda t})$. Substituting this in equation 6 gives

$$D = Ne^{\lambda t} - N,$$

or

$$D = N(e^{\lambda t} - 1),$$

or $$\frac{D}{N} = (e^{\lambda t} - 1).$$

If one chooses to use P to designate the parent atom, the expression assumes its familiar form:

$$\frac{D}{P} = (e^{\lambda t} - 1) \tag{7}$$

and $$t = \frac{1}{\lambda} \ln \left(\frac{D}{P} + 1 \right). \tag{8}$$

This pair of equations states rigorously what might be assumed from intuition, that minerals formed at successively longer times in the past would have progressively higher daughter-to-parent ratios. This follows because, as each parent atom loses its identity with time, it reappears as a daughter atom. The increase in D/P with time is evident in equation (7) because larger values of time will increase the value of $e^{\lambda t}$, where λ is constant. Equation (8) documents the simplicity of direct isotopic dating. The time of decay is proportional to the natural logarithm (represented by ln) of the ratio of D to P. In short, one need only measure the ratio of the number of radioactive parent and daughter atoms present, and the time elapsed since the mineral or rock formed can be calculated, provided of course that the decay rate is known. Likewise, the conditions that must be met to make the calculated age precise and meaningful are in themselves simple:

Conditions for precise age calculations

1. The rock or mineral must have remained closed to the addition or escape of parent and daughter atoms since the time that the rock or mineral (system) formed.
2. It must be possible to correct for other atoms identical to daughter atoms already present when the rock or mineral formed.
3. The decay constant must be known.
4. The measurement of the daughter-to-parent ratio must be accurate because uncertainty in this ratio contributes directly to uncertainty in the age.

Different schemes have been developed to deal with the critical assumptions stated above. In uranium–lead dating, minerals virtually free of initial lead can be isolated and corrections made for the trivial amounts present. In whole rock isochron methods that make use of the rubidium–strontium or samarium–neodymium decay schemes (see below), a series of rocks or minerals are chosen that can be assumed to have the same age and identical abundances of their initial isotopic ratios. The results are then tested for the internal consistency that can validate the assumptions. In all cases, it is the obligation of the investigator making the determinations to include enough tests to indicate that the absolute age quoted is valid within the limits stated. In other words, it is the obligation of geochronologists to try to prove themselves wrong by including a series of cross-checks in their measurements before they publish a result. Such checks include dating a series of ancient units with closely spaced but known relative ages, as shown in Figure 3, and replicate analysis of different parts of the same rock body with samples collected at widely spaced localities.

The importance of internal checks as well as interlaboratory comparisons becomes all the more apparent when one realizes that geochronology laboratories are limited in number. Because of the expensive equipment necessary and the combination of geologic, chemical, and laboratory skills required, geochronology is usually carried out by teams of experts. Most geologists must rely on geochronologists for their results. In turn, the geochronologist relies on the geologist for relative ages. (E.A.O./T.E.Kr.)

Figure 3: *Absolute versus relative age, Keweenawan Lava.*
Precise absolute uranium–lead zircon ages are compared to relative ages for a series of basaltic and andesite lava flows in the Keweenawan Peninsula in Michigan. Although determined only at one location, the ages have regional significance as they bracket a widely correlated time during which the Earth's magnetic field had a reversed polarity. In addition, the ages establish the time of transition between lava eruption and conglomerate deposition (see text).

EVALUATION AND PRESENTATION SCHEMES IN DATING

Origin of radioactive elements used. In order for a radioactive parent–daughter pair to be useful for dating, many criteria must be met. This section examines these criteria and explores the ways in which the reliability of the ages measured can be assessed. Because geologic materials are diverse in their origin and chemical content and datable elements are unequally distributed, each method has its strengths and weaknesses.

When the elements in the Earth were first created, many radioactive isotopes were present. Of these, only the radioisotopes with extremely long half-lives remain. Table 2 lists a number of such isotopes and their respective daughter products that are used in various forms of rock dating. It should be mentioned in passing that some of the radioisotopes present early in the history of the solar system and now completely extinct have been recorded in meteorites in the form of the elevated abundances of their daughter isotopes. Analysis of such meteorites makes it possible to estimate the time that elapsed between element creation and meteorite formation. Natural elements that are still radioactive today produce daughter products at a very slow rate; hence, it is easy to date very old minerals but difficult to obtain the age of those formed in the recent geologic past. This follows from the fact that the amount of daughter isotopes present is so small that it is difficult to measure. The difficulty can be overcome to some degree by achieving lower background contamination, by improving instrument sensitivity, and by finding minerals with abundant parent isotopes. Geologic events of the not-too-distant past are more easily dated by using recently formed radioisotopes with short half-lives that produce more daughter products per unit time. Two sources of such isotopes exist. In one case, intermediate isotopes in the uranium or thorium decay chain can become isolated in certain minerals due to differences in chemical properties and, once fixed, can decay to new isotopes, providing a measure of the time elapsed since they were isolated. To understand this, one needs to know that though uranium-238 (^{238}U) does indeed decay to lead-206 (^{206}Pb), as indicated in Table 2, it is not a one-step process. In fact, this is a multistep process involving the expulsion of eight alpha particles and six beta particles, along with a considerable amount of energy. There exists a series of different elements, each of them in a steady state where they form at the same rate as they disintegrate. The number present is proportional to their decay rate, with long-lived members being more abundant. Because all of these isotopes have relatively short half-lives, none remains since the creation of the elements, but instead they are continuously pro-

Radioisotopes suitable for dating recent geologic events

Table 2: Major Decay Schemes for Isotopic Dating

parent isotope	daughter isotope	half-life in years	applicable materials
^{238}U	^{206}Pb	4.468 × 10^9	igneous and metamorphic rocks with zircon, baddeleyite, perovskite, monazite, titanite, rutile, xenotime, pitchblende, thorite, and thorianite; whole rock carbonates; single-mineral grains from sediments
^{235}U	^{207}Pb	0.7038 × 10^9	
^{232}Th	^{208}Pb	14.01 × 10^9	
^{40}K	^{40}Ar	1.25 × 10^9	potassium-bearing minerals (*e.g.*, mica); hornblende; meteorite impact glass; authigenic minerals

^{87}Rb	^{87}Sr	4.88 × 10^{10}	potassium-bearing minerals; authigenic minerals in sediments; felsic whole rocks
^{187}Re	^{187}Os	4.56 × 10^{10}	trace minerals from mineral deposits; molybdenite; others under investigation

vided by the decay of the long-lived parent. This type of dating, known as disequilibrium dating, will be explored below in the section *Uranium-series disequilibrium dating.*

Another special type of dating employs recently formed radioisotopes produced by cosmic-ray bombardment of target atoms at the Earth's surface or in the atmosphere. The amounts produced, although small, provide insight into many near-surface processes in the geologic past. This aspect of geology is becoming increasingly important as researchers try to read the global changes that took place during the Earth's recent past in an effort to understand or predict the future. The most widely used radioactive cosmogenic isotope is carbon of mass 14 (^{14}C), which provides a method of dating events that have occurred over roughly the past 50,000 years. This time spans much of the historic and prehistoric record of mankind. Cosmogenic isotopes and those used for disequilibrium dating are listed in Table 3.

The isochron method. Many radioactive dating methods are based on minute additions of daughter products to a rock or mineral in which a considerable amount of daughter-type isotopes already exists. These isotopes did not come from radioactive decay in the system but rather formed during the original creation of the elements. In this case, it is a big advantage to present the data in a form in which the abundance of both the parent and daughter isotopes are given with respect to the abundance of the initial background daughter. The incremental additions of the daughter type can then be viewed in proportion to the abundance of parent atoms. In mathematical terms this is achieved as follows. It has already been shown—equation 7—that the number of daughter atoms present from radioactive decay D^* can be related to the number of parent atoms remaining P by the simple expression:

$$D^* = P(e^{\lambda t} - 1). \qquad (9)$$

Table 3: Principal Cosmogenic and Uranium–Thorium Series Radioisotopes

radioisotope	half-life in years	principal uses
Cosmogenic isotope		
^{10}Be	1.5 × 10^6	dating marine sediment, manganese nodules, glacial ice, quartz in rock exposures, terrestrial age of meteorites, and petrogenesis of island-arc volcanics
^{14}C	5,730 ± 40	dating of biogenic carbon, calcium carbonate, terrestrial age of meteorites
^{26}Al	0.716 × 10^6	dating marine sediment, manganese nodules, glacial ice, quartz in rock exposures, terrestrial age of meteorites
^{32}Si	276 ± 32	dating biogenic silica, glacial ice
^{36}Cl	0.308 × 10^6	dating glacial ice, exposures of volcanic rocks, groundwater, terrestrial age of meteorites
^{39}Ar	269	dating glacial ice, groundwater
^{53}Mn	3.7 × 10^6	terrestrial age of meteorites, abundance of extraterrestrial dust in ice and sediment
^{59}Ni	8 × 10^4	terrestrial age of meteorites, abundance of extraterrestrial dust in ice and sediment
^{81}Kr	0.213 × 10^6	dating glacial ice, cosmic-ray exposure age of meteorites

When some daughter atoms are initially present (designated D_0), the total number D is the sum of radiogenic and initial atoms, so that

$$D = D_0 + P(e^{\lambda t} - 1). \qquad (10)$$

To establish the condition that both parent and daughter abundances should be relative to the initial background, a stable isotope S of the daughter element can be chosen and divided into all portions of this equation; thus,

$$\frac{D}{S} = \left(\frac{D}{S}\right)_0 + \frac{P}{S}(e^{\lambda t} - 1).$$

This equation has the form; $y = b + xm$, which is that of a straight line on x–y coordinates. The slope m is equal to $(e^{\lambda t} - 1)$ and the intercept is equal to $(D/S)_0$. This term, shown in Figure 4, is called the initial ratio. The slope is proportional to the geologic age of the system.

Advantages of the isochron method

In practice, the isochron approach has many inherent advantages. When a single body of liquid rock crystallizes, parent and daughter elements may separate so that, once solid, the isotopic data would define a series of points, such as those shown as open circles designated R$_1$, R$_2$, R$_3$ in Figure 4. They plot along a horizontal line reflecting a common value for the initial daughter isotope ratio $(D/S)_0$. With time each would then develop additional daughter abundances in proportion to the amount of parent present. If a number of samples are analyzed and the results are shown to define a straight line within error, then a precise age is defined because this is only possible if each is a closed system and each has the same initial ratio and age. The uncertainty in determining the slope is reduced because it is defined by many points. A second advantage of the method relates to the fact that under high-temperature conditions the daughter isotopes may escape from the host minerals. In this case, a valid age can still be obtained, provided that they remain within the rock. Should a point plot below the line, it could indicate that a particular sample was open to migration of the dating elements or that the sample was contaminated and lay below the isochron when the rock solidified.

Rubidium–strontium (Rb–Sr) dating was the first technique in which the whole rock isochron method was extensively employed. Certain rocks that cooled quickly at the surface were found to give precisely defined linear isochrons, but many others did not. Some studies have shown that rubidium is very mobile both in fluids that migrate through the rock as it cools and in fluids that are present as the rock undergoes chemical weathering. Similar studies have shown that the samarium–neodymium (Sm–Nd) parent–daughter pair is more resistant to secondary migration but that, in this instance, sufficient initial spread in the abundance of the parent isotope is difficult to achieve.

Analysis of separated minerals. When an igneous rock crystallizes, a wide variety of major and trace minerals may form, each concentrating certain elements and radioactive trace elements within the rock. By careful selection, certain minerals that contain little or no daughter element but abundant parent element can be analyzed. In this case, the slope of the line in Figure 4 is computed from an assumed value for the initial ratio, and it is usually possible to show that uncertainties related to this assumption are negligible. This is possible in potassium–argon (K–Ar) dating, for example, because most minerals do not take argon into their structures initially. In rubidium–strontium dating, micas exclude strontium when they form, but accept much rubidium. In uranium–lead (U–Pb) dating of zircon, the zircon is found to exclude initial lead almost completely. Minerals, too, are predictable chemical compounds that can be shown to form at specific temperatures and remain closed up to certain temperatures if a rock has been reheated or altered. A rock, on the other hand, may contain minerals formed at more than one time under a variety of conditions. Under such circumstances the isolation and analysis of certain minerals can indicate at what time these conditions prevailed. If a simple mineral is widespread in the geologic record, it is more valuable for dating as more units can be measured for age and compared by the same method. However, if a single parent–daughter pair that is amenable to precise analysis can be measured in a variety of minerals, the ages of a wide variety of rock types can be determined by a single method without the need for intercalibration. In some cases the discovery of a rare trace mineral results in a major breakthrough as it allows precise ages to be determined in formerly undatable units. For example, the mineral baddeleyite, an oxide of zirconium (ZrO_2), has been shown to be widespread in small amounts in mafic igneous rocks (*i.e.,* those composed primarily of one or more ferromagnesian, dark-coloured minerals). Here, a single uranium–lead isotopic analysis can provide an age that is more precise than can be obtained by the whole rock isochron method involving many analyses. When single minerals are analyzed, each grain can be studied under a microscope under intense side light so that alterations or imperfections can be revealed and excluded. If minerals are used for dating, the necessary checks on the ages are achieved by analyzing samples from more than one location and by analyzing different grain sizes or mineral types that respond differently to disturbing events. In summary, it can be said that minerals provide a high degree of sample integrity that can be predicted on the basis of experience gained through numerous investigations under a variety of geologic conditions. An ideal mineral is one that has sufficient parent and daughter isotopes to measure precisely, is chemically inert, contains little or no significant initial daughter isotopes, and retains daughter products at the highest possible temperatures. A specific datable mineral like rutile, which can be linked to a specific event such as the formation of a mineral deposit, is especially important.

Figure 4: *Isochron diagram.*
The isochron diagram allows radiogenic additions to be viewed in proportion to the abundance of radioactive parent atoms, all relative to a common background. In this case, the value of the initial parent-to-stable ratio in R_2 has been chosen to be twice that in R_1, and R_3 is set at twice that of R_2. Under these conditions, the amount of daughter isotope added over geologic time is proportional, so that the length of lines *a*, *b*, c are in the ratio of 1 to 2 to 4. Because each parent atom that disintegrates becomes a daughter atom, the point moves over and up on a −45° slope as drawn. With time, the line called an isochron rotates, and data plot at the positions shown by closed circles. These would be the values measured today, and the slope of the line would indicate the time elapsed.

Model ages. Since the Earth was formed, the abundance of daughter product isotopes, such as those listed in Table 2, has increased through time. For example, the ratio of lead of mass 206 relative to that of mass 204 has changed from an initial value of about 10 present when the Earth was formed to an average value of about 19 in rocks at the terrestrial surface today. This is true because uranium is continuously creating more lead. A lead-rich mineral formed and isolated early in Earth history would have a low lead-206 to lead-204 ratio because it did not receive subsequent additions by the radioactive decay of uranium. If the Earth's interior were a simple and homogeneous reservoir with respect to the ratio of uranium to lead, a single sample extracted by a volcano would provide the time of extraction. This would be called a model age. No parent–daughter value for a closed system is involved, rather just a single isotopic measurement of lead viewed with respect to the expected evolution of lead in the Earth. Unfortunately the simplifying assumption in this case is not true, and lead model ages are approximate at best. Other model ages can be calculated using neodymium isotopes by extrapolating present values back to a proposed mantle-evolution line. In both cases, approximate ages that have a degree of validity with respect to one another result, but they are progressively less reliable as the assumptions on which the model is calculated are violated.

The progressive increase in the abundance of daughter isotopes over time gains a special significance where the parent element is preferentially enriched in either the mantle or the crust. For example, rubidium is concentrated in the crust, and as a result the present-day continents, subjected to weathering, have an elevated radiogenic to stable isotope ratio ($^{87}Sr/^{86}Sr$) of 0.720. In contrast, modern volcanic rocks in the oceans imply that much of the mantle has a value between about 0.703 and 0.705. Should crustal material be recycled, the strontium isotopic signature of the melt would be diagnostic.

Multiple ages for a single rock; the thermal effect. Fossils record the initial, or primary, age of a rock unit. Isotopic systems, on the other hand, can yield either the primary age or the time of a later event, because crystalline materials are very specific in the types of atoms they incorporate, in terms of both the atomic size and charge. An element formed by radioactive decay is quite different from its parent atom and thus is out of place with respect to the host mineral. All it takes for such an element to be purged from the mineral is sufficient heat to allow solid diffusion to occur. Each mineral has a temperature at which rapid diffusion sets in, so that, as a region is slowly heated, first one mineral and then another loses its daughter isotopes. When this happens, the isotopic "clock" is reset to zero, where it remains until the mineral cools below the blocking temperature. (This is the temperature below which a mineral becomes a closed chemical system for a specific radioactive decay series. Accordingly, the parent–daughter isotope ratio indicates the time elapsed since that critical threshold was reached.) In this case, the host mineral could have an absolute age very much older than is recorded in the isotopic record. The isotopic age then is called a cooling age. It is even possible by using a series of minerals with different blocking temperatures to establish a cooling history of a rock body—*i.e.,* the times since the rock body cooled below successively lower temperatures. Such attempts can be complicated by the fact that a mineral may "grow" below the blocking temperature rather than simply become closed to isotopic migration. When this happens, the age has little to do with the cooling time. Another problem arises if a region undergoes a second reheating event. Certain minerals may record the first event, whereas others may record the second, and any suggestion of progressive cooling between the two is invalid. This complication does not arise when rapid cooling has occurred. Identical ages for a variety of minerals with widely different blocking temperatures is unequivocal proof of rapid cooling.

Blocking temperature

Fortunately for geologists the rock itself records in its texture and mineral content the conditions of its formation. A rock formed at the surface with no indication of deep burial or new mineral growth can be expected to give a valid primary age by virtue of minerals with low blocking temperatures. On the other hand, low-blocking-point minerals from a rock containing minerals indicative of high temperatures and pressures cannot give a valid primary age. Such minerals would be expected to remain open until deep-level rocks of this sort were uplifted and cooled.

Given these complicating factors, one can readily understand why geochronologists spend a great deal of their time and effort trying to see through thermal events that occurred after a rock formed. The importance of identifying and analyzing minerals with high blocking temperatures also cannot be overstated. Minerals with high blocking temperatures that form only at high temperatures are especially valuable. Once formed, these minerals can resist daughter loss and record the primary age even though they remained hot (say, 700° C) for a long time. The mineral zircon datable by the uranium–lead method is one such mineral. The mica mineral biotite dated by either the potassium–argon or the rubidium–strontium method occupies the opposite end of the spectrum and does not retain daughter products until cooled below about 300° C. Successively higher blocking temperatures are recorded for another mica type known as muscovite and for amphibole, but the ages of both of these minerals can be completely reset at temperatures that have little or no effect on zircon.

Taken in perspective, it is evident that many parts of the Earth's crust have experienced reheating temperatures above 300° C—*i.e.*, reset mica ages are very common in rocks formed at deep crustal levels. Vast areas within the Precambrian shield, which have identical ages reflecting a common cooling history, have been identified (see below *Precambrian rocks*). These are called geologic provinces. By contrast, rocks that have approached their melting point, say, 750° C, which can cause new zircon growth during a second thermal event, are rare, and those that have done this more than once are almost nonexistent.

INSTRUMENTS AND PROCEDURES

Use of mass spectrometers. The age of a geologic sample is measured on as little as a billionth of a gram of daughter isotopes. Moreover, all the isotopes of a given chemical element are nearly identical except for a very small difference in mass. Such conditions necessitate instrumentation of high precision and sensitivity. Both these requirements are met by the modern mass spectrometer. A high-resolution mass spectrometer of the type used today was first described by the American physicist Alfred O. Nier in 1940, but it was not until about 1950 that such instruments became available for geochronological research.

For isotopic dating with a mass spectrometer, a beam of charged atoms, or ions, of a single element from the sample is produced. This beam is passed through a strong magnetic field in a vacuum, where it is separated into a number of beams, each containing atoms of only the same mass. Because of the unit electric charge on every atom, the number of atoms in each beam can be evaluated by collecting individual beams sequentially in a device called a Faraday cup. Once in this collector, the current carried by the atoms is measured as it leaks across a resistor to ground. Currents measured are small, only from 10^{-11} to 10^{-15} ampere, so that shielding and preamplification are required as close to the Faraday cup as possible. It is not possible simply to count the atoms, because all atoms loaded into the source do not form ions and some ions are lost in transmission down the flight tube. Precise and accurate information as to the number of atoms in the sample can, however, be obtained by measuring the ratio of the number of atoms in the various separated beams. By adding a special artificially enriched isotope during sample dissolution and by measuring the ratio of natural to enriched isotopes in adjacent beams, the number of daughter isotopes can be readily determined. The artificially enriched isotope is called a "spike." It is usually a highly purified form of a low-abundance natural isotope, but an even better spike is an isotope with a mass not found in nature at all. Lead-205 produced in a type of particle accelerator called a cyclotron constitutes such an ideal spike.

Adding a spike

As the sample is heated and vaporizes under the vacuum in the source area of the mass spectrometer, it is commonly observed that the lighter isotopes come off first, causing a bias in the measured values that changes during the analysis. In most cases this bias, or fractionation, can be corrected if the precise ratio of two of the stable isotopes present is known. Today's state-of-the-art instruments produce values for strontium and neodymium isotopic abundances that are reproducible at a level of about 1 in 20,000. Such precision is often essential in the isochron method (see above) because of the small changes in relative daughter abundance that occur over geologic time.

Isotope dilution

Technical advances. The ability to add a single artificial mass to the spectrum in a known amount and to determine the abundances of other isotopes with respect to this provides a powerful analytical tool. By means of this process known as isotope dilution, invisibly small amounts of material can be analyzed, and because only ratios are involved, a loss of part of the sample during preparation has no effect on the result. Spike solutions can be calibrated simply by obtaining a highly purified form of the element being calibrated. After carefully removing surface contamination, a precisely weighted portion of the element is dissolved in highly purified acid and diluted to the desired level in a weighed quantity of water. What is required is dilution of one cubic centimetre to a litre from which a second cubic centimetre is again diluted to a litre to approach the range of parts per million or parts per billion typically encountered in samples. In this way, a known number of natural isotopes can be mixed with a known amount of spike and the concentration in the spike solution determined from the ratio of the masses. Once the calibration has been completed, the process is reversed and a weighed amount of spike is mixed with the parent and daughter elements from a mineral or rock. The ratio of the masses then gives the number of naturally produced atoms in the sample. The use of calibrated enriched isotopic tracers facilitates checks for contamination, even though the process is time-consuming. A small but known amount of tracer added to a beaker of water can be evaporated under clean-room conditions. Once loaded in a mass spectrometer, the contamination from the beaker and the water is easily assessed with respect to the amount of spike added. Contamination as small as 10^{-12} gram can be detected by this method.

The materials analyzed during isotopic investigations vary from microgram quantities of highly purified mineral grains to gram-sized quantities of rock powders. In all cases, the material must be dissolved without significant contamination. The spike should be added before dissolution. Most of the minerals in rocks can be dissolved in a day or so at a temperature near 100° C. Certain minerals that are highly refractory both in nature and in the laboratory (*e.g.*, zircon) may require five days or more at temperatures near 220° C. In this case, the sample is confined in a solid Teflon (trade name for a synthetic resin composed of polytetrafluoroethylene), metal-clad pressure vessel, introduced by the Canadian geochronologist Thomas E. Krogh in 1973.

The method just described proved to be a major technical breakthrough as it resulted in a reduction in lead-background contamination by a factor of between 10,000 and nearly 1,000,000. This means that a single grain can now be analyzed with a lower contamination level (or background correction) than was possible before with 100,000 similar grains. Advances in high-sensitivity mass spectrometry of course were essential to this development.

Ion-exchange chromatography

Once dissolved, the sample is ready for the chemical separation of the dating elements. This is generally achieved by using the methods of ion-exchange chromatography. In this process, ions are variously adsorbed from solution onto materials with ionic charges on their surface and separated from the rest of the sample. After the dating elements have been isolated, they are loaded into a mass spectrometer and their relative isotopic abundances determined.

The abundance of certain isotopes used for dating is determined by counting the number of disintegrations per minute (*i.e.*, emission activity). The rate is related to the number of such atoms present through the half-life (see above). For example, a certain amount of carbon-14 (^{14}C) is present in all biological components at the Earth's surface. This radioactive carbon is continually formed when nitrogen atoms of the upper atmosphere collide with neutrons produced by the interaction of high-energy cosmic rays with the atmosphere. An organism takes in small amounts of carbon-14, together with the stable (nonradioactive) isotopes carbon-12 (^{12}C) and carbon-13 (^{13}C), as long as it is alive. Once it dies, however, no additional carbon-14 is acquired and the level of radiocarbon in the organism's tissue decreases progressively as a function of half-life. The time that has passed since the organism was alive can be determined by counting the beta emissions from a tissue sample. The number of emissions in a given time period is proportional to the amount of residual carbon-14.

The introduction of an instrument called an accelerator mass spectrometer has brought about a major advance in radiocarbon dating. Unlike the old detector (*e.g.*, the Geiger counter) that counts the few decay particles emitted from a large amount of carbon, the new instrument counts directly all of the carbon-14 atoms in a sample. This increase in instrument sensitivity has made it possible to reduce the sample size by as much as 10,000 times and at the same time improve the precision of ages measured. (For a detailed discussion of radiocarbon age determination, see below *Carbon-14 dating and other cosmogenic methods.*)

In situ analysis of mineral grains

In a similar development, the use of highly sensitive thermal ionization mass spectrometers is replacing the counting techniques employed in some disequilibrium dating (see below). Not only has this led to a reduction in sample size and measurement errors but it also has permitted a whole new range of problems to be investigated. Certain parent-daughter isotopes are extremely refractory and do not ionize in a conventional mass spectrometer. To solve this problem, researchers are developing new instruments in which a small amount of material can be evaporated from the surface with a pulse of energy and ionized with a pulse of laser light. A major trend anticipated in geochronology and isotope geochemistry involves the analysis of mineral grains in place without chemical dissolution and mass spectrometry. This type of analysis requires expensive equipment in which a focused beam of ions is directed at a spot on a mineral sample. This causes atoms to evaporate from the surface, and the ions produced are extracted and measured in a mass spectrometer. Uranium-lead dating of zircon by this method has been pioneered by William Compston at the Australian National University.

MAJOR METHODS OF ISOTOPIC DATING

Isotopic dating relative to fossil dating requires a great deal of effort and depends on the integrated specialized skills of geologists, chemists, and physicists. It is, nevertheless, a valuable resource that allows correlations to be made over virtually all of Earth history with a precision once only possible with fossiliferous units that are restricted to the most recent 12 percent or so of geologic time. Although any method may be attempted on any unit, the best use of this resource requires that every effort be made to tackle each problem with the most efficient technique. Because of the long half-life of some isotopic systems or the high background or restricted range of parent abundances, some methods are inherently more precise. The skill of a geochronologist is demonstrated by the ability to attain the knowledge required and the precision necessary with the least number of analyses. The factors considered in selecting a particular approach are explored here.

Uranium–lead method. As each dating method was developed, tested, and improved, mainly since 1950, a vast body of knowledge about the behaviour of different isotopic systems under different geologic conditions has evolved. It is now clear that with recent advances the uranium–lead method is superior in providing precise age information with the least number of assumptions. The method has evolved mainly around the mineral zircon ($ZrSiO_4$). Because of the limited occurrence of this mineral, it was once true that only certain felsic igneous rocks (those consisting largely of the light-coloured, silicon and aluminum-rich minerals feldspar and quartz) could be dated. Today, however, baddeleyite (ZrO_2) has been found to be widespread in the silica-poor mafic igneous rocks (see above). In addition, perovskite ($CaTiO_3$), a common constituent of some ultramafic igneous rocks, has been shown to be amenable to precise uranium–lead dating. As a result of these developments, virtually all igneous rocks can now be dated. This capability, moreover, has been enhanced because the most advanced geochronological laboratories are able to analyze samples that weigh only a few millionths of a gram. This amount can be found in a comparatively large number of rocks, whereas the amount previously required (about 0.1 gram) cannot. Age determinations also can now be made of low-uranium trace minerals such as rutile (TiO_2), a common constituent found in mineral deposits, adding still further to the number of entities that are datable by the uranium–lead method. Other minerals commonly employed to date igneous and metamorphic rocks include titanite, monazite, and even garnet in certain favourable cases. Additional minerals listed in Table 2 have been tried with varying success.

Double uranium–lead chronometers

The reason why uranium–lead dating is superior to other methods is simple: there are two uranium–lead chronometers. Because there exist two radioactive uranium atoms (those of mass 235 and 238), two uranium–lead ages can be calculated for every analysis. The age results or equivalent daughter–parent ratio can then be plotted one against the other on a concordia diagram, as shown in Figure 5. If the point falls on the upper curve shown, the locus of identical ages, the result is said to be concordant, and a closed-system unequivocal age has been established. Any leakage of daughter isotopes from the system will cause the two ages calculated to differ, and data will plot below the curve. Because each of the daughters has a different half-life, early leakage will affect one system more than the other. Thus there is a built-in mechanism that can prove or disprove whether a valid age has been measured. Historically it had been observed that the uranium–lead systems in the mineral zircon from unmetamorphosed rocks were almost invariably disturbed or discordant but yielded a linear array on the concordia diagram. Given a set of variably disturbed samples, an extrapolation to zero

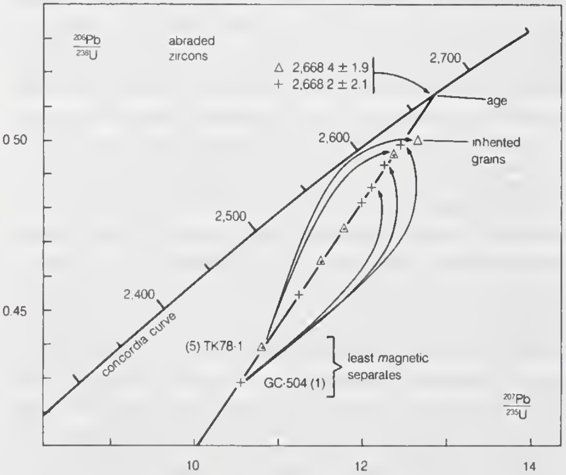

Figure 5: *Concordia diagram.*
Uranium–lead discordia line for isotopic results for zircons from two 2,668-million-year-old granites. Data for different fractions of zircon define a straight line with points plotting between 3 and 18 percent below the curve. The data for the least magnetic fractions represent the starting material in a series of tests designed to obtain data closer to the curve. The grains analyzed to obtain these data at the top of the arrows were selected to be crack-free, and all had natural surfaces removed by abrasion. These give the most reliable age information as extrapolations are reduced (see text).

disturbance was possible (see Figure 5). More recently, it has been found that of all the grains present in a rock a very few still retain closed isotopic systems but only in their interior parts. Thus grains with a diameter comparable to that of a human hair, selected under a microscope to be crack-free and of the highest possible quality, have been found to be more concordant than cracked grains. In addition, it has been shown that most such grains can be made much more concordant by mechanically removing their outer parts using an air-abrasion technique (upper points in Figure 5). Of course, the ability to analyze samples weighing only a few millionths of a gram was essential to this development. As noted earlier, this in turn was possible solely because the lead background contamination had been reduced from 1 × 10^{-6} grams to almost 1 × 10^{-12} grams per analysis. The methods of selection and abrasion used to locate grains with closed isotopic systems could be worked out only because the uranium–lead method has the inherent ability to assess with a single analysis whether or not a closed isotopic system has prevailed.

The presence of two radioactive parents provides a second major advantage because, as daughter products, lead atoms are formed at different rates and their relative abundance undergoes large changes as a function of time. Thus the ratio of lead-207 to lead-206 changes by about 0.1 percent every two million years. Since this ratio is easily calibrated and reproduced at such a level of precision, errors as low as ±2 million years at a confidence level of 95 percent are routinely obtained on lead-207–lead-206 ages. By contrast, errors as high as ±30 to 50 million years are usually quoted for the rubidium–strontium and samarium–neodymium isochron methods (see below).

Significance of zircon

The mineral zircon adds three more fundamental advantages to uranium–lead dating. First, its crystal structure allows a small amount of tetravalent uranium to substitute for zirconium, but excludes with great efficiency the incorporation of lead. (It might be said that one begins with an empty box.) Second, zircon, once formed, is highly resistant to change and has the highest blocking temperature ever observed. Finally, with few predictable exceptions, zircon grows or regrows only in liquid rock or in solid rock reheated to approach its melting point. Combining all of these attributes, it is often possible to measure both the time of crystallization and the time of second melting in different parts of the same grain or in different selected grains from the same rock. Of course, such a high blocking temperature can have its disadvantages. Inherited cores may give a mixed false age when the age of crystallization is sought. For this reason, three or more grain types or parts of a grain are analyzed to establish that material of only one age is present.

Experience with the results of the uranium–lead method for zircons has demonstrated an interesting paradox. If left at low surface temperatures for a geologically long time, the radioactivity within the crystal can destroy the crystal lattice structure, whereas at higher temperatures this process is self-annealing. In fact, when examined by X-ray methods, some zircons have no detectable structure, indicating that at least 25 percent of the initial atoms have been displaced by radiation damage. Under these conditions a low-temperature event insufficient to even reset the potassium–argon system (see below) in biotite can cause lead to be lost in some grains. It is no coincidence that, when criteria were finally found to locate concordant grains, these grains were also found to be those with the lowest uranium content and the lowest related radiation damage.

Determining the time of both the primary and secondary events

Given the two related uranium–lead parent–daughter systems, it is possible to determine both the time of the initial, or primary, rock-forming event and the time of a major reheating, or secondary, event. This is illustrated in Figure 6. Here, the uranium–lead isotopes in the mineral titanite ($CaTiSiO_5$) from a series of rocks that have a common geologic history plot on a straight line. The minerals first formed 1,651 million years ago but were later heated and lost varying amounts of lead 986 million years ago. In many cases, new titanite, distinguishable on the basis of colour, has formed in the same rock, while older, partly reset titanite is still present. Data points 14 and 7 in the figure represent such a pair. On this diagram, the presence of surface-correlated lead loss will displace data from the titanite line toward the time of loss close to zero age on the concordia curve. The uranium–lead data then would plot below the line shown, and neither the primary nor secondary age would be defined. The importance of eliminating recent loss, as discussed above, is clearly evident. It should be noted that, if these ages had been measured by any of the other schemes that have only a single parent–daughter pair, a whole series of different numbers spanning the time from 1.65 billion to 988 million years ago would be observed. There would be no way of telling which of the measured ages, if any, was valid.

Uranium–lead dating relies on the isolation of very high-quality grains or parts of mineral grains that are extremely rare but nevertheless present in most igneous, metamorphic, and sedimentary rock units. Samples weighing 10 to 50 kilograms are collected, crushed, and ground into a fine sand, and the various minerals are isolated on the basis of specific gravity, grain size, and magnetic properties. The minerals used are not visible in the field, but their presence can be inferred from the easily identified major minerals present.

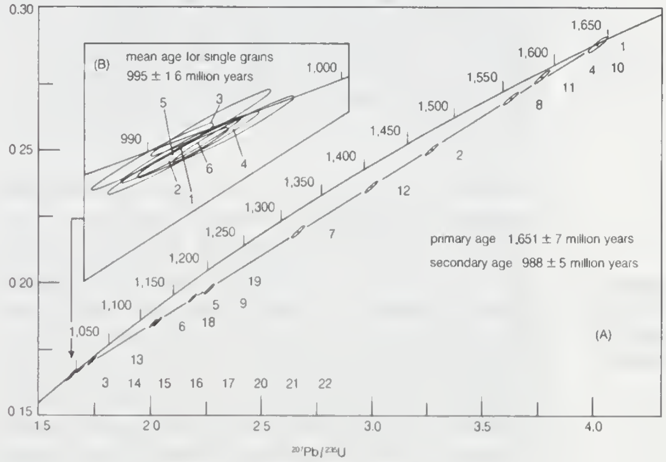

Figure 6: *Titanite discordia.*
(A) Uranium–lead isotopic data for a suite of titanite samples collected from a region in Labrador, Can., where rocks with titanite that initially formed 1,651 million years ago were subjected to a major heating event 988 million years ago. Variable amounts of lead lost by solid diffusion from the titanite from different samples at 988 million years produced the discordia line shown. Totally reset or newly grown grains plot at the lower end of the line. (B) The time of the second event also can be determined by dating zircon formed in rock melted during the second event. Replicate analysis of single zircon grains from this melt demonstrate the reproducibility of the method. The data average 0.4 percent discordant and indicate an uncertainty of ±3.5 million years for a single analysis and ±1.6 million years for the mean lead-207–lead-206 age of 995 million years at a confidence level of 95 percent. Grains analyzed weighed between 6 and 14 × 10^{-6} gram each.

One of the most interesting applications of the improved uranium–lead zircon technique has to do with its ability to achieve nearly concordant results from single grains extracted from sandstone. This is possible because zircon is chemically inert and is not disturbed during weathering and because single grains with a diameter about the thickness of a human hair contain sufficient uranium and lead for analysis in the most advanced laboratories. The examples given in Figure 7 indicate that a sandstone that underlies most of the province of Nova Scotia in Canada was probably originally deposited off the coast of North Africa and thrust over the continent before the opening of the Atlantic Ocean. This follows because the ages observed occur in North Africa, whereas those common in North America are absent.

Another sample, this one from sandstone deposited by a large river in northern Scotland (Figure 8), must have been derived from continental rocks whose ages are represented by those determined for the individually dated sand grains. In this case, the continent from which the sand was

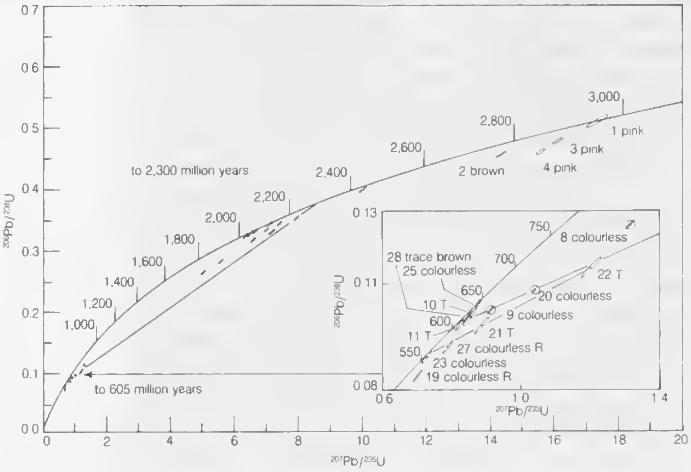

Figure 7: Uranium-lead results for single and multigrain zircon fractions from a type of sandstone that underlies most of Nova Scotia, Can. The cluster of ages around 600 million, 2,000 to 2,300 million, and 2,800 to 3,000 million years suggests that North Africa may have been the source of this sediment. It should be noted that the ages between 1,000 and 1,800 million years common in North America are absent (see text).

derived has moved away as a result of continental drift, but it can be identified by the ages measured.

Application of the isochron method

Rubidium–strontium method. The radioactive decay of rubidium-87 (^{87}Rb) to strontium-87 (^{87}Sr) was the first widely used dating system that utilized the isochron method. Rubidium is a relatively abundant trace element in the Earth's crust and can be found in many common rock-forming minerals in which it substitutes for the major element potassium. Because rubidium is concentrated in crustal rocks, the continents have a much higher abundance of the daughter isotope strontium-87 compared with the stable isotopes. This relative abundance is expressed as the ^{87}Sr/^{86}Sr ratio, where strontium-86 is chosen to represent the stable isotopes strontium-88, strontium-86, and strontium-84, which occur in constant proportions in natural materials. Thus a precise measurement of the ^{87}Sr/^{86}Sr ratio in a modern volcano can be used to determine age if recycled older crust is present. A ratio for average continental crust of about 0.72 has been determined by measuring strontium from clamshells from the major river systems. In contrast, the Earth's most abundant lava rocks, which represent the mantle and make up the major oceanic ridges, have values between 0.703 and 0.705. This difference may appear small, but considering that modern instruments can make the determination to a few parts in 70,000, it is quite significant. Dissolved strontium in the oceans today has a value of 0.709 that is dependent on the relative input from the continents and the ridges. In the geologic past changes in the activity of these two sources has produced varying ^{87}Sr/^{86}Sr ratios over time. Thus if well-dated, unaltered fossil shells containing strontium from ancient seawater are analyzed, changes in this ratio with time can be observed and applied in reverse to estimate the time when fossils of unknown age were deposited.

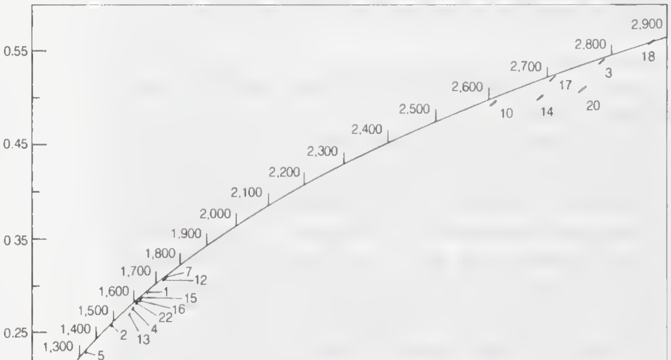

Figure 8: Uranium-lead age results for single zircon grains extracted from sandstone deposited by a river in northern Scotland. The source continent must have had rocks whose ages clustered around 1,100 to 1,320 million, 1,550 to 1,830 million, and 2,600 to 2,860 million years ago. Northern Labrador in Canada has rocks with such an age distribution and thus is a possible source for the sediment (see text).

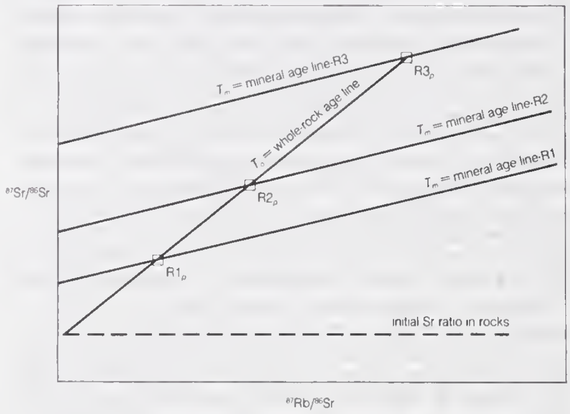
Dating simple igneous rocks. The rubidium–strontium pair is ideally suited for the isochron dating of igneous rocks. As a liquid rock cools, first one mineral and then another achieves saturation and precipitates, each extracting specific elements in the process. Strontium is extracted in many minerals that are formed early, whereas rubidium is gradually concentrated in the final liquid phase. At the time of crystallization, this produces a wide range in the Rb/Sr ratio in rocks that have identical ^{87}Sr/^{86}Sr ratios. On the isochron diagram shown in Figure 4 above, the samples would plot initially at points R_1 to R_3 along a line representing the initial ratio designated $(^{87}Sr/^{86}Sr)_0$.



T_m = mineral age line-R3
$R3_p$
T_0 = whole-rock age line
T_m = mineral age line-R2
T_m = mineral age line-R1
$R2_p$
$R1_p$
$^{87}Sr/^{86}Sr$
initial Sr ratio in rocks
$^{87}Rb/^{86}Sr$

Figure 9: *Rubidium–strontium isochron diagram.* Hypothetical diagram for three rock samples with present-day isotopic values that plot at $R1_p$, $R2_p$, and $R3_p$ and define the whole rock age (T_0) and initial ratio shown. Minerals within each rock exchanged strontium isotopes during metamorphism, so that they have achieved identical initial ratios. Exchange between rocks has not taken place, however; thus, data for each rock plot on a primary isochron, while data for minerals define a series of parallel isochrons that indicate the time since metamorphism.

Over geologic time, this ratio is increased in proportion to the ^{87}Rb/^{86}Sr ratio, as discussed earlier, and the line rotates with a slope equal to $(e^{\lambda t} - 1)$ that represents the time elapsed; thus, the present-day ratio $(^{87}Sr/^{86}Sr)_p$ equals the initial ratio $(^{87}Sr/^{86}Sr)_0$ plus radiogenic additions, or $(^{87}Sr/^{86}Sr)_p = (^{87}Sr/^{86}Sr)_0 + {}^{87}Rb/^{86}Sr\ (e^{\lambda t} - 1)$. This equation is that of a straight line of the form $y = b + xm$, where $y = (^{87}Sr/^{86}Sr)_p$, the value measured today; b represents $(^{87}Sr/^{86}Sr)_0$, the value initially present; x stands for the ^{87}Rb/^{86}Sr ratio; and m is the slope of the line $(e^{\lambda t} - 1)$.

In practice, rock samples weighing several kilograms each are collected from a suite of rocks that are believed to have been part of a single homogeneous liquid prior to solidification. The samples are crushed and homogenized to produce a fine representative rock powder from which a fraction of a gram is withdrawn and dissolved in the presence of appropriate isotopic traces, or spikes. Strontium and rubidium are extracted and loaded into the mass spectrometer, and the values appropriate to the x and y coordinates are calculated from the isotopic ratios measured. Once plotted as $R1_p$ (*i.e.*, rock 1 present values), $R2_p$, and $R3_p$, as in Figure 9, the data are examined to assess how well they fit the required straight line. Using estimates of measurement precision, the crucial question of whether or not scatter outside of measurement error exists is addressed. Such scatter would constitute a geologic component, indicating that one or more of the underlying assumptions has been violated and that the age indicated is probably not valid. For an isochron to be valid, each sample tested must (1) have had the same initial ratio,

(2) have been a closed system over geologic time, and (3) have the same age.

Well-preserved, unweathered rocks that crystallized rapidly and have not been subjected to major reheating events are most likely to give valid isochrons. Weathering is a disturbing influence, as is leaching or exchange by hot crustal fluids, since many secondary minerals contain rubidium. Volcanic rocks are most susceptible to such changes because their minerals are fine-grained and unstable glass may be present. On the other hand, meteorites that have spent most of their time in the deep freeze of outer space can provide ideal samples.

Suitability of potassium-bearing minerals for rubidium–strontium dating

Dating minerals. Potassium-bearing minerals including several varieties of mica, are ideal for rubidium–strontium dating as they have abundant parent rubidium and a low abundance of initial strontium. In most cases, the changes in the $^{87}Sr/^{86}Sr$ ratio are so large that an initial value can be assumed without jeopardizing the accuracy of the results. Considered in terms of Figure 9, this would mean that the slope is determined from a single point that plots so far to the right and so far above the diagram that the actual initial value on the y axis can be easily estimated. When minerals with a low-rubidium or a high-strontium content are analyzed, the isochron-diagram approach can be used to provide an evaluation of the data. As discussed above, rubidium–strontium mineral ages need not be identical in a rock with a complex thermal history, so that results may be meaningful in terms of dating the last heating event but not in terms of the actual age of a rock.

Dating metamorphic rocks. Should a simple igneous body be subjected to an episode of heating or of deformation or of a combination of both, a well-documented special data pattern develops. With heat, daughter isotopes diffuse out of their host minerals but are incorporated into other minerals in the rock. Eventually the $^{87}Sr/^{86}Sr$ ratio in the minerals becomes identical. When the rock again cools, the minerals close and again accumulate daughter products to record the time since the second event. Remarkably, the isotopes remain within the rock sample analyzed, and so a suite of whole rocks can still provide a valid primary age. This situation is easily visualized on an isochron diagram such as that in Figure 9, where a series of rocks plots on a steep line showing the primary age, but the minerals in each rock plot on a series of parallel lines that indicate the time since the heating event. If cooling is very slow, the minerals with the lowest blocking temperature, such as biotite mica, will fall below the upper end of the line.

A more dramatic presentation of this phenomenon is found when the changes in the $^{87}Sr/^{86}Sr$ ratios in a variety of minerals in a single rock are depicted as a function of geologic time, as in Figure 10. Here, an essentially rubidium-free, strontium-rich phase like apatite retains its initial $^{87}Sr/^{86}Sr$ ratio over time, whereas the value in such rubidium-rich, strontium-poor minerals as biotite increases rapidly with time. The rock itself gives the integrated, more gradual increase. At the time of heating, identical $^{87}Sr/^{86}Sr$ ratios are again achieved as described above, only to be followed by a second episode of isotopic divergence.

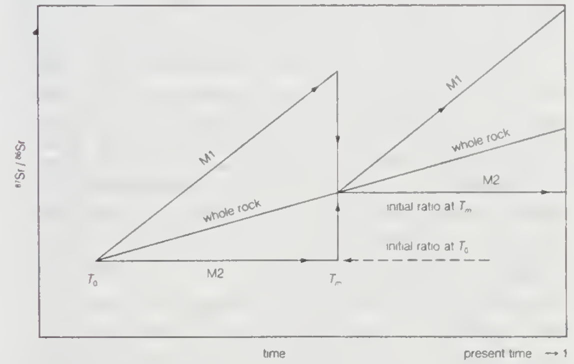


Figure 10: *Rubidium–strontium evolution diagram.* Isotopic changes in different minerals from the same rock are shown here as a function of time. Minerals formed at T_0 develop different isotopic ratios in proportion to their $^{87}Rb/^{86}Sr$ ratios, which are represented as the slope. Isotopic homogenization occurs at the time of metamorphism (T_m), but the isotopic ratios in different minerals again diverge toward their present values. Mineral M1 represents a rubidium-rich, strontium-poor mineral such as mica, while M2 represents a rubidium-poor, strontium-rich phase like apatite or plagioclase. The rock-growth line is the integrated result for all minerals present (see text).

Approaches to this ideal case are commonly observed, but peculiar results are found in situations where the heating is minimal. If one assumes for a moment that only the mineral with the lowest blocking temperature loses its daughter isotope, it is easy to imagine that other low-temperature minerals formed at this time may acquire extremely high $^{87}Sr/^{86}Sr$ ratios. Epidote, a low-temperature alteration mineral with a very high concentration of radiogenic strontium, has been found in rocks wherein biotite has lost strontium by diffusion. The rock itself has a much lower ratio, so that it did not take part in this exchange.

Impact of the rubidium–strontium method

Although rubidium–strontium dating is not as precise as the uranium–lead method, it was the first to be exploited and has provided much of the prevailing knowledge of Earth history. The procedures of sample preparation, chemical separation, and mass spectrometry are relatively easy to carry out, and datable minerals occur in most rocks. Precise ages can be obtained on high-level rocks (*i.e.,* those closer to the surface) and meteorites, and imprecise but nevertheless valuable ages can be determined for rocks that have been strongly heated. The mobility of rubidium in deep-level crustal fluids and melts that can infiltrate other rocks during metamorphism as well as in fluids involved in weathering can complicate the results.

Samarium–neodymium method. The radioactive decay of samarium of mass 147 (^{147}Sm) to neodymium of mass 143 (^{143}Nd) has been shown to be capable of providing useful isochron ages for certain geologic materials. Both parent and daughter belong to the rare earth element group, which is itself the subject of numerous geologic investigations. All members of this group have similar chemical properties and charge, but differ significantly in size. Because of this, they are selectively removed as different minerals are precipitated from a melt. In the opposite sense, their relative abundance in a melt can indicate the presence of certain residual minerals during partial melting. Unlike rubidium, which is enriched over strontium in the crust, samarium is relatively enriched with respect to neodymium in the mantle. Consequently, a volcanic rock composed of melted crust would have elevated radiogenic strontium values and depressed radiogenic neodymium values with respect to the mantle. As a parent–daughter pair, samarium-147 and neodymium-143 are unique in that both have very similar chemical properties, and so loss by diffusion may be reduced. Their low concentrations in surface waters indicates that changes during low-temperature alteration and weathering are less likely. Their presence in certain minerals in water-deposited gold veins, however, does suggest mobility under certain conditions. In addition, their behaviour under high-temperature metamorphic conditions is as yet poorly documented.

The exploitation of the samarium–neodymium pair for dating only became possible when several technical difficulties were overcome. Procedures to separate these very similar elements and methods of measuring neodymium isotope ratios with uncertainties of only a few parts in 100,000 had to be developed.

Dating igneous rocks

In theory, the samarium–neodymium method is identical to the rubidium–strontium approach (see above). Both use the isochron method to display and evaluate data. In the case of samarium–neodymium dating, however, the chemical similarity of parent and daughter adds another complication because fractionation during crystallization is extremely limited. This makes the isochrons short and adds further to the necessity for high precision. The result is that, with few exceptions, uncertainties in measured ages are as large as 30 to 100 million years, even for the oldest rocks and meteorites. Mineral isochrons provide the best results.

The equation relating present-day neodymium isotopic abundance as the sum of the initial ratios and radiogenic additions is that of a straight line, as discussed earlier for rubidium–strontium.

Figure 11 shows the successful application of the samarium–neodymium method to a sample of basalt from the Moon. Here, the constituent minerals plagioclase, ilmenite, and pyroxene provide enough spread in the ^{147}Sm/^{143}Nd ratio to allow an age of 3,700 ± 70 million years to be calculated. Other successful examples have been reported where rocks with open rubidium–strontium systems have been shown to have closed samarium–neodymium systems. In other examples, the ages of rocks with insufficient rubidium for dating have been successfully determined. There is considerable promise for dating garnet, a common metamorphic mineral, because it is known to concentrate the parent isotope.

From Geochimica et Cosmochimica Acta, Proceedings of the 6th Lunar Science Conference, 1975

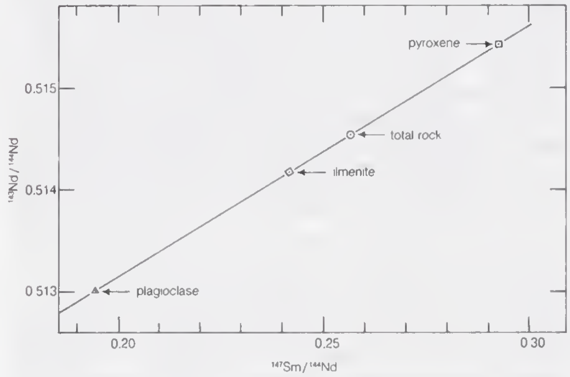

Figure 11: *Samarium–neodymium isochron for lunar basalt.* In this samarium–neodymium evolution diagram for a sample of medium-grained lunar basalt returned by the Apollo 17 astronauts, the data points for the total rock and for the plagioclase, ilmenite, and pyroxene mineral separates form a precise linear array. The "best-fit" line through these points represents a mineral isochron and yields a crystallization age of 3,700 ± 70 million years at a confidence level of 95 percent. The initial ^{143}Nd/^{144}Nd ratio is 0.50825 ± 12.

Dating meteorites and lunar rocks

In general, the use of the samarium–neodymium method as a dating tool is limited by the fact that other methods (mainly the uranium–lead approach) are more precise and require fewer analyses. In the case of meteorites and lunar rocks where samples are limited and minerals for other dating methods are not available, the samarium–neodymium method can provide the best ages possible.

Rhenium–osmium method. The decay scheme in which rhenium-187 is transformed to osmium-187 shows promise as a means of studying mantle–crust evolution but has displayed only limited potential for isotopic dating. Technical difficulties have yet to be overcome. Osmium is strongly concentrated in the mantle and extremely depleted in the crust, so that crustal osmium must have exceedingly high radiogenic-to-stable ratios while the mantle values are low. In fact, crustal levels are so low that they are extremely difficult to measure with current technology. Most work to date has centred around rhenium- or osmium-enriched minerals. Another problem that is still under investigation involves the difficulty of ionizing osmium in a mass spectrometer. A number of new approaches are being studied. In one method, success has been demonstrated in ionizing osmium in an instrument called an ion microprobe. This instrument bombards the sample target with a beam of ions of such high energy that atoms in the sample evaporate into a vacuum and a relatively small number becomes ionized. The ions are then extracted into a mass spectrometer, and the desired isotopic abundances are determined. Another related approach being tested involves the evaporation of the sample by a short pulse of ions, with a subsequent pulse of laser light tuned to ionize the desired element. Once the technical difficulties are surmounted, the distribution of rhenium and radiogenic and stable osmium isotopes will be explored. The greatest potential for this method might be in studies concerning the origin and age of mineral deposits since rhenium and osmium are known to occur in such materials.

Use of an ion microprobe

Potassium–argon methods. The radioactive decay scheme involving the breakdown of potassium of mass 40 (^{40}K) to argon gas of mass 40 (^{40}Ar) formed the basis of the first widely used isotopic dating method. Since radiogenic argon-40 was first detected in 1938 by the American geophysicist Lyman T. Aldrich and A.O. Nier, the method has evolved into one of the most versatile and widely employed methods available. Potassium is one of the 10 most abundant elements that together make up 99 percent of the Earth's crust and is therefore a major constituent of many rock-forming minerals. In fact, potassium-40 decays to both argon-40 and calcium-40, but because argon is absent in most minerals while calcium is present, the argon produced is easier to detect and measure. Most of the argon in the Earth's atmosphere has been created by the decay of potassium-40 as the argon-40 abundance is about 1,000 times higher than expected from cosmic abundances. Argon dating involves a different technology from all the other methods so far described because argon exists as a gas at room temperature. Thus it can be purified as it passes down a vacuum line by freezing out or reacting out certain contaminants. It is then introduced into a mass spectrometer through a series of manual or computer-controlled valves. Technical advances, including the introduction of the argon-40–argon-39 method and laser heating, that have improved the versatility of the method, are described below.

In conventional potassium–argon dating, a potassium-bearing sample is split into two fractions: one is analyzed for its potassium content, while the other is fused in a vacuum to release the argon gas. After purification has been completed, a spike enriched in argon-38 is mixed in and the atomic abundance of the daughter product argon-40 is measured relative to the argon-38 added. The amount of the argon-36 present is then determined relative to argon-38 to provide an estimate of the background atmospheric correction. In this case, relatively large samples, which may include significant amounts of alteration, are analyzed. Since potassium is usually added by alteration, the daughter–parent ratio and the age might be too low.

Argon-40–argon-39 method

A method designed to avoid such complexities was introduced by the geochronologists Craig M. Merrihue and Grenville Turner in 1966. In this technique, known as the argon-40–argon-39 method, both parent and daughter can be determined in the mass spectrometer as some of the potassium atoms in the sample are first converted to argon-39 in a nuclear reactor. In this way, the problem of measuring the potassium in inhomogeneous samples is eliminated and smaller amounts of material can be analyzed. An additional advantage then becomes possible. The sample can be heated in stages at different temperatures and the age calculated at each step. If alteration is evident, the invalid low-temperature age can be eliminated and a valid high-temperature age determined. In some cases, partly reset systems also may be detected.

As in all dating systems, the ages calculated can be affected by the presence of inherited daughter products. In a few cases, argon ages older than that of the Earth which violate local relative age patterns have even been determined for the mineral biotite. Such situations occur mainly where old rocks have been locally heated, which released argon-40 into pore spaces at the same time that new minerals grew. Under favourable circumstances the isochron method may be helpful, but tests by other techniques may be required. For example, the rubidium–strontium method would give a valid isotopic age of the biotite sample with inherited argon.

As techniques evolved, argon background levels have been reduced and the method has become more and more sensitive. Capitalizing on this, it is now possible to measure the minute amount of argon released when a single spot on a crystal is heated by an intense laser beam. For geologically old potassium-rich materials, a single spot may produce sufficient gas for analysis, whereas single millimetre-sized grains may be required in very young materials. Progressive refinement of the method has made new areas of research possible, and the ability to understand complexities encountered in earlier investigations has increased. In one study the age of volcanic ash as young as 215,000 ± 4,000 years and the presence of inherited older grains in another ash sample were thoroughly documented. This was done by melting single millimetre-sized grains with a laser and measuring individual argon-40–argon-39 ages with a highly sensitive gas mass spectrometer. In Figure 12A an age line between present atmospheric argon ratios and that of the volcanic ash source dated at 215,000 ± 4,000 years old is defined. Figure 12B shows that another sample of similar volcanic ash yielded comparable data, but many grains with older age components that plot below the line are present.

From P. van den Bogaard *et al*, reprinted by permission from *Nature*, vol. 342, pp 523-24, copyright © 1989 Macmillan Magazines Ltd

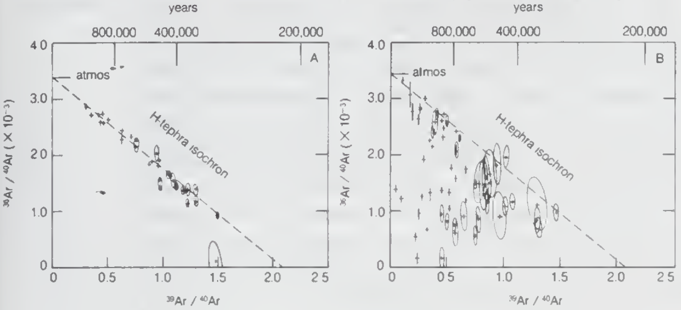

Figure 12: Potassium–argon isotope correlation diagram based on data for one of the youngest rocks ever dated by the potassium–argon method. In (A), data for single millimetre-sized feldspar grains plot on a line between the values for present-day atmospheric argon (atmos) and argon from a source 215,000 ± 4,000 years old (error quoted is at the 66-percent confidence level). Data for the same mineral from a different volcanic ash, shown in (B), indicate a similar age, but in this case many data points plot below the age line, suggesting that much older grains are present as well.

The potassium–argon method has provided a great deal of information about the Earth's recent and ancient past. It has been instrumental, for example, in determining the ages of the stripes of alternating normally and reversely magnetized volcanic rocks that parallel the axis of the mid-oceanic ridges. In ancient shield areas large segments of crust that were uplifted and cooled at the same time—*i.e.*, geologic provinces—have been identified by the potassium–argon method. The technique is highly responsive to thermal events in a relatively predictable fashion, so the cooling history of a region may be established. (T.E.Kr.)

Fission-track dating. This is a special type of dating method that makes use of a microscope rather than a mass spectrometer, and capitalizes on damaged zones, or tracks, created in crystals during the spontaneous fission of uranium-238. In this unique type of radioactive decay, the nucleus of a single parent uranium atom splits into two fragments of similar mass with such force that a trail of crystal damage is left in the mineral. Immersing the sample in an etching solution of strong acid or base enlarges the fission tracks into tube-shaped holes large enough to be seen under a high-powered microscope. The number of tracks present can be used to calculate the age of the sample if the uranium content is known. Fortunately the uranium content of precisely the spot under scrutiny can be obtained by a similar process when working with a polished crystal surface. The sample is bombarded with slow (thermal) neutrons in a nuclear reactor, resulting in induced fission of uranium-235 (as opposed to spontaneous fission of uranium-238). The fission tracks produced by this process are recorded by a thin plastic film placed against the surface of the sample. The uranium content of the material can then be calculated so long as the neutron dose is known. The age of the sample is obtained using the equation, age $= N \times Ds/Di \times 6 \times 10^{-8}$, in which N is the total neutron dose expressed as neutrons per square centimetre and Ds is the observed track density for spontaneous fission while Di is that for induced fission.

Spontaneous fission of uranium-238

The preservation of crystal damage (*i.e.*, the retention of fission tracks) is highly sensitive to temperature and varies from mineral to mineral. The technique can be used to determine mild thermal events as low as 100° C. Alternately, primary ages can be calculated if the rock was formed at the surface and cooled quickly. Under these conditions the calculated fission-track ages of two minerals with widely different annealing temperatures would be identical. The accuracy achieved depends on the number of tracks counted, so that artificial glass coloured with 10 percent uranium can be dated as soon as 30 years after manufacture. With uranium levels of a few parts per million, samples as young as 300,000 years can be dated by counting tracks for one hour. When dealing with very old materials, high-uranium samples must be avoided because there are so many interlocking tracks that they can no longer be counted.

A special feature of fission-track dating lies in its ability to map the uranium distribution within mineral grains. Figure 13 shows such a uranium map for single zircon grains. In this case, the outer zones that grew during a major melting event contain much more uranium than the grains originally present. The uranium–lead age would then be highly biased toward the younger event and the primary age could be determined only after the outer zones were removed. In practice, fission-track dates are regarded as cooling ages unless proved otherwise. It might also be noted that uncertainties in results may arise from an uneven distribution of uranium, statistical errors in counting, and inaccurate estimates of neutron flux (dose of neutrons).

Fission-track dating can be used on a wide variety of minerals found in most geologic materials, and it is relatively inexpensive to apply. Because closure temperatures vary widely from, say, 300° C for titanite and zircon to less than 100° C for biotite and apatite, valuable information can be obtained regarding the uplift and cooling rates of crustal rocks.

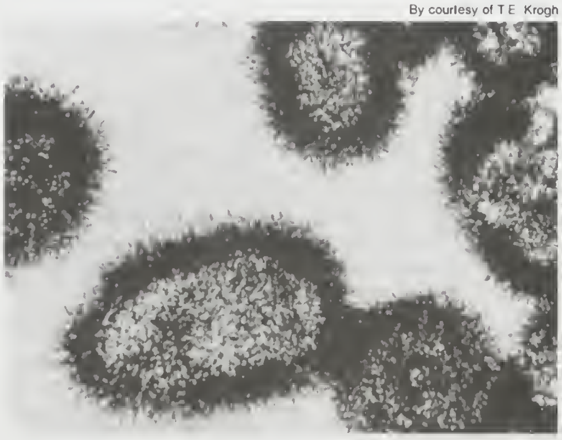

Figure 13: *Fission-track map.*
The uranium distribution within single zircon grains is recorded by a plastic film placed against a polished surface. The tiny black lines represent the etched path of crystal damage caused by the induced fission of uranium-235 in a nuclear reactor. The uranium in the zircon grains is concentrated in the outer rims.

Carbon-14 dating and other cosmogenic methods. The occurrence of natural radioactive carbon in the atmosphere provides a unique opportunity to date organic materials as old as 50,000 years. Unlike most isotopic dating methods, the conventional carbon-14 dating technique is not based on counting daughter isotopes. It relies instead on the progressive decay or disappearance of the radioactive parent with time.

The discovery of natural carbon-14 by Willard Libby of the United States began with his recognition that a process that had produced radiocarbon in the laboratory was also going on in the Earth's upper atmosphere—namely, the bombardment of nitrogen by free neutrons. Newly created carbon-14 atoms were presumed to react with atmospheric oxygen to form carbon dioxide (CO_2) molecules. Radioactive carbon thus was visualized as gaining entrance wherever atmospheric carbon dioxide enters—into land plants by photosynthesis, into animals that feed on the plants, into marine waters and freshwaters as a dissolved component, and from there into aquatic plants and animals. In short, all parts of the carbon cycle were seen to be invaded by the isotope carbon-14.

Discovery of carbon-14

Invasion is probably not the proper word for a component that Libby calculated should be present only to the extent of about one atom in a trillion stable carbon atoms. So low is such a carbon-14 level that no one had detected natural carbon-14 until Libby, guided by his own predictions, set out specifically to measure it. His success initiated a series of measurements designed to answer two questions: Is the concentration of carbon-14 uniform throughout the plant and animal kingdoms? And, if so, has today's uniform level prevailed throughout the recent past?

After showing the essential uniformity of carbon-14 in living material, Libby sought to answer the second question by measuring the radiocarbon level in organic samples dated historically—materials as old as 5,000 years from sources such as Egyptian tombs. With correction for radioactive decay during the intervening years, such old samples hopefully would show the same starting carbon-14 level as exists today. This was just what Libby's measurements indicated. His conclusion was that over the past 5,000 years the carbon-14 level in living materials has remained constant within the 5 percent precision of measurement. A dating method was thus available, subject only to confirmation by actual application to specific chronologic problems.

Since Libby's foundational studies, tens of thousands of carbon-14 measurements of natural materials have been made. Expressed as a fraction of the contemporary level, they have been mathematically converted to ages through equation 5 above. Archaeology has been the chief beneficiary of radioactive-carbon dating, but late glacial and postglacial chronological studies in geology have also been aided greatly.

Variations of the carbon-14 level in nature

Improvements in measurement accuracy and the ever-mounting experience in applying carbon-14 dating have provided superior and more voluminous data with which to better answer Libby's original questions. It is now clear that carbon-14 is not homogeneously distributed among today's plants and animals. The occasional exceptions all involve nonatmospheric contributions of carbon-14-depleted carbon dioxide to organic synthesis. Specifically, volcanic carbon dioxide is known to depress the carbon-14 level of nearby vegetation and dissolved limestone carbonate occasionally has a similar effect on freshwater mollusks, as does upwelling of deep ocean water on marine mollusks. In every case, the living material affected gives the appearance of built-in age.

In addition to spatial variations of the carbon-14 level, the question of temporal variation has received much study. A 2 to 3 percent depression of the atmospheric radioactive-carbon level since 1900 was noted soon after Libby's pioneering work, almost certainly the result of the dumping of huge volumes of carbon-14-free carbon dioxide into the air through smokestacks. Of more recent date was the overcompensating effect of man-made carbon-14 injected into the atmosphere during nuclear-bomb testing. The result was a rise in the atmospheric carbon-14 level by more then 50 percent. Fortunately, neither effect has been significant in the case of older samples submitted for carbon-14 dating. The ultimate cause of carbon-14 variations with time is generally attributed to temporal fluctuations in the cosmic rays that bombard the upper atmosphere and create terrestrial carbon-14. Whenever the number of cosmic rays in the atmosphere is low, the rate of carbon-14 production is correspondingly low, resulting in a decrease of the radioisotope in the carbon-exchange reservoir described above. Studies have revealed that the atmospheric radiocarbon level prior to 1000 BC deviates measurably from the contemporary level. In the year 6200 BC it was about 8 percent above what it is today. In the context of carbon-14 dating, this departure from the present-day level means that samples with a true age of 8,200 years would be dated by radiocarbon as 7,500 years old.

The problems stemming from temporal variations can be overcome to a large degree by the use of calibration curves in which the carbon-14 content of the sample being dated is plotted against that of objects of known age. In this way, the deviations can be compensated for and the carbon-14 age of the sample converted to a much more precise date. Calibration curves have been constructed using dendrochronological data (tree-ring measurements of bristlecone pines as old as 8,200 years); periglacial varve, or lake sediment, data (see above); and, in archaeological research, certain materials of historically established ages. It is clear that carbon-14 dates lack the accuracy that traditional historians would like to have. There may come a time when all radiocarbon ages rest on firmer knowledge of the sample's original carbon-14 level than is now available. Until then, the inherent error from this uncertainty must be recognized.

Carbon-14 contamination

A final problem of importance in carbon-14 dating is the matter of sample contamination. If a sample of buried wood is impregnated with modern rootlets or a piece of porous bone has recent calcium carbonate precipitated in its pores, failure to remove the contamination will result in a carbon-14 age between that of the sample and that of its contaminant. Consequently, numerous techniques for contaminant removal have been developed. Among them are the removal of humic acids from charcoal and the isolation of cellulose from wood and collagen from bone. Today, contamination as a source of error in samples younger than 25,000 years is relatively rare. Beyond that age, however, the fraction of contaminant needed to have measurable effect is quite small, and, therefore, undetected or unremoved contamination may occasionally be of significance.

A major breakthrough in carbon-14 dating occurred with the introduction of the accelerator mass spectrometer. This instrument is highly sensitive and allows precise ages on as little as one milligram of carbon, where the older method might require as much as 25 grams for ancient material. The increased sensitivity results from the fact that all of the carbon atoms of mass 14 can be counted in a mass spectrometer. By contrast, if carbon-14 is to be measured by its radioactivity, only those few atoms decaying during the measurement period are recorded. By using the accelerator mass spectrometer possible interference from nitrogen-14 is avoided since it does not form negative ion beams, and interfering molecules are destroyed by stripping electrons away by operating at several million volts.

Other cosmogenic methods

The development of the accelerator mass spectrometer has provided new opportunities to explore other rare isotopes produced by the bombardment of the Earth and meteorites by high-energy cosmic rays. Many of these isotopes have short half-lives and hence can be used to date events that happened in the past few thousand to a few million years. In one case, the time of exposure, like the removal of rock by a landslide, can be dated by the presence of the rare beryllium-10 (^{10}Be) isotope formed in the newly exposed surface of a terrestrial object or meteoroidal fragment by cosmic-ray bombardment. Other applications include dating groundwater with chlorine-36 (^{36}Cl), dating marine sediments with beryllium-11 (^{11}Be) and aluminum-26 (^{26}Al), and dating glacial ice with krypton-81 (^{81}Kr). In general, the application of such techniques is limited by the enormous cost of the equipment required.

Uranium-series disequilibrium dating. The isotopic dating methods discussed so far are all based on long-lived radioactive isotopes that have survived since the elements were created or on short-lived isotopes that were recently produced by cosmic-ray bombardment. The long-lived isotopes are difficult to use on young rocks because the extremely small amounts of daughter isotopes present are difficult to measure. A third source of radioactive isotopes is provided by the uranium- and thorium-decay chains. As noted in Table 3, these uranium–thorium series radioisotopes, like the cosmogenic isotopes, have short half-lives and are thus suitable for dating geologically young materials. The decay of uranium to lead is not achieved by a single step but rather involves a whole series of different elements, each with its own unique set of chemical properties.

In closed-system natural materials, all of these intermediate daughter elements exist in equilibrium amounts. That is to say, the amount of each such element present is constant and the number that form per unit time is identical to the number that decay per unit time. Accordingly, those with long half-lives are more abundant than those with short half-lives. Once a uranium-bearing mineral breaks down and dissolves, the elements present may behave differently and equilibrium is disrupted. For example, an isotope of thorium is normally in equilibrium with uranium-234 but is found to be virtually absent in modern corals even though uranium-234 is present. Over a long period of time uranium-234, however, decays to thorium-230, which results in a build-up of the latter in old corals and thereby provides a precise measure of time.

Most of the studies using the intermediate daughter elements were for years carried out by means of radioactive counting techniques—*i.e.,* the number of atoms present was estimated by the radioactivity of the sample. The introduction of highly sensitive mass spectrometers that allow the total number of atoms to be measured rather than the much smaller number that decay has resulted in a revolutionary change in the family of methods based on uranium and thorium disequilibrium.

Thorium-230 dating. The insoluble nature of thorium provides for an additional disequilibrium situation that allows sedimentation rates in the modern oceans to be determined. In this case, thorium-230 in seawater, produced principally by the decay of uranium-234, is deposited preferentially in the sediment without the uranium-234 parent. This is defined as excess thorium-230 because its abundance exceeds the equilibrium amount that should be present. With time, the excess decays away and the age of any horizon in a core sample can be estimated from the observed thorium-230-to-thorium-232 ratio in the seawater-derived component of the core. Sedimentation rates between 1 and 20 millimetres per 1,000 years are commonly found with slight variations between the major ocean basins.

Lead-210 dating. The presence of radon gas as a member of the uranium-decay scheme provides a unique method for creating disequilibrium. The gas radon-222 (^{222}Rn) escapes from the ground and decays rapidly in the atmosphere to lead-210 (^{210}Pb), which falls quickly to the surface where it is incorporated in glacial ice and sedimentary materials. By assuming that the present deposition rate also prevailed in the past, the age of a given sample at depth can be estimated by the residual amount of lead-210. (E.A.O./T.E.Kr.)

GEOLOGIC HISTORY OF THE EARTH

The geologic history of the Earth reveals much about the evolution of the continents, oceans, atmosphere, and biosphere. The layers of rock at the Earth's surface contain evidence of the evolutionary processes undergone by these components of the terrestrial environment during the times at which each layer was formed. By studying this rock record from the very beginning, it is thus possible to trace their development and the resultant changes through time.

THE PREGEOLOGIC PERIOD

The history of the Earth spans approximately 4.6 billion years. The oldest known rocks, however, have an isotopic age of only about 3.9 billion years. There is, in effect, a stretch of 700 million years for which no geologic record exists, and the evolution of this pregeologic period of time is not surprisingly the subject of much speculation. To understand this little-known period, the following factors have to be considered: the age of formation at 4.6 billion years ago, the processes in operation until 3.9 billion years ago, the bombardment of the Earth by meteorites, and the earliest zircon crystals.

It is widely accepted by both geologists and astronomers that the Earth is roughly 4.6 billion years old. This age has been obtained from the isotopic analysis of many meteorites as well as of soil and rock samples from the Moon by such dating methods as rubidium–strontium and uranium–lead (see above). It is taken to be the time when these bodies formed and, by inference, the time at which a significant part of the solar system developed. When the evolution of the isotopes of lead-207 and lead-206 is studied from several lead deposits of different age on Earth, including oceanic sediments that represent a homogenized sample of the Earth's lead, the growth curve of terrestrial lead can be calculated, and when this is extrapolated back in time it is found to coincide with the age of about 4.6 billion years measured on lead isotopes in meteorites. The Earth and meteorites thus have had similar lead-isotope histories, and so it is concluded that they condensed or accreted as solid bodies from a primeval cloud of interstellar gas and dust—the so-called solar nebula from which the entire solar system is thought to have formed—at about the same time.

Formation of the Earth

Particles in the solar nebula condensed to form solid grains, and with increasing electrostatic and gravitational influences they eventually clumped together into fragments or chunks of rock. One of these planetesimals developed into the Earth. The constituent metallic elements sank toward the centre of the mass, while lighter elements rose toward the top. The lightest ones (such as hydrogen and helium) that might have formed the first, or primordial, atmosphere probably escaped into outer space. In these earliest stages of terrestrial accretion heat was generated by three possible phenomena: (1) the decay of short-lived radioactive isotopes, (2) the gravitational energy released from the sinking of metals, or (3) the impact of small planetary bodies (or planetesimals). The increase in temperature became sufficient to heat the entire planet. Melting at depth produced liquids that were gravitationally light and thus rose toward the surface and crystallized to form the earliest crust. Meanwhile, heavier liquids rich in iron, nickel, and perhaps sulfur separated out and sank under gravity, giving rise to the core at the centre of the growing planet; and the lightest volatile elements were able to rise and escape by outgassing, which may have been associated with surface volcanic activity, to form the secondary atmosphere and the oceans. This chemical process of melting, separation of material, and outgassing is referred to as the differentiation of the Earth. The earliest thin crust was probably unstable and so foundered and collapsed to depth. This in turn generated more gravitational energy, which enabled a thicker, more stable, longer-lasting crust to form. Once the Earth's interior (or its mantle) was hot and liquid, it would have been subjected to large-scale convection, which may have enabled oceanic crust to develop above upwelling regions. Rapid recycling of crust–mantle material occurred in convection cells, and in this way the earliest terrestrial continents may have evolved during the 700-million-year gap between the formation of the Earth and the beginning of the rock record. It is known from direct observation that the surface of the Moon is covered with a multitude of meteorite craters. There are about 40 large basins attributable to meteorite impact. Known as maria, these depressions were filled in with basaltic lavas caused by the impact-induced melting of the lunar mantle. Many of these basalts have been analyzed isotopically and found to have crystallization ages of 3.9 to 4 billion years. It can be safely concluded that the Earth, with a greater attractive mass than the Moon, must have undergone more extensive meteorite bombardment. According to the English-born geologist Joseph V. Smith, a minimum of 500 to 1,000 impact basins were formed on the Earth within a period of about 100 to 200 million years prior to 3.95 billion years ago. Moreover, plausible calculations suggest that this estimate represents merely the tail end of an interval of declining meteorite bombardment and that about 20 times as many basins were formed in the preceding 300 million years. Such intense bombardment would have covered most of the Earth's surface, with the impacts causing considerable destruction of the terrestrial crust up to 3.9 billion years ago. There is, however, no direct evidence of this important phase of Earth history because rocks older than 3.9 billion years have not been preserved.

Differentiation of the Earth

An exciting discovery was made in 1983 by William Compston and his research group at the Australian National University with the aid of an ion microprobe (see above *Absolute dating: Instruments and procedures*). Compston and his associates found that a water-laid clastic sedimentary quartzite from Mount Narryer in western Australia contained detrital zircon grains that were 4.18 billion years old. In 1986 they further discovered that one zircon in a conglomerate only 60 kilometres away was 4.276 billion years old; 16 other grains were determined to be the same age or slightly younger. This is the oldest dated material on Earth. The rocks from which the zircons in the quartzites and conglomerates were derived have either disappeared or have not yet been found. The ages of these single zircon grains are significantly older than those of the oldest known intact rocks, which are granites discovered near the Great Slave Lake in northwestern Canada. The latter contain zircons that are 3.96 billion years old.

DEVELOPMENT OF THE ATMOSPHERE AND OCEANS

Formation of the secondary atmosphere. The Earth's secondary atmosphere began to develop at the time of planetary differentiation, probably in connection with volcanic activity. Its component gases, however, were most likely very different from those emitted by modern volcanoes. Accordingly, the composition of the early secondary atmosphere was quite distinct from that of today's atmosphere. Carbon monoxide, carbon dioxide, water vapour, and methane predominated; however, free oxygen could not have been present, since even modern volcanic gases contain no oxygen. It is therefore assumed that the secondary atmosphere during the Archean—the time of the oldest known rocks—was anoxygenic. The free oxygen that makes up the bulk of the present atmosphere evolved over geologic time by two possible processes. First, solar ultraviolet radiation (the short-wavelength component of sunlight) would have provided the energy needed to break up water vapour into hydrogen, which escaped into space, and free oxygen, which remained in the atmosphere. This process was in all likelihood important before the appearance of the oldest extant rocks, but after that time the second process, organic photosynthesis, became predominant. Primitive organisms, such as blue-green algae (or cyanobacteria), cause carbon dioxide and water to react by photosynthesis to produce carbohydrates, which they need for growth, repair, and other vital functions, and this reaction releases free oxygen. The discovery of stromatolites (layered or conical sedimentary structures formed by sediment-binding marine algae) in 3.5-billion-year-old limestones in several parts of the world indicates that blue-green algae existed by that time. The presence of such early carbonate sediments is evidence that carbon dioxide was present in the atmosphere, and it has been calculated that it was at least 100 times greater than the amount in the present-day atmosphere. It can be assumed that such abundant carbon dioxide would have caused retention of heat, resulting in a greenhouse effect and a hot atmosphere (see ATMOSPHERE).

What happened to all the oxygen that was released? It might be surprising to learn that it took at least 1 billion years before there was sufficient oxygen in the atmosphere for oxidative diagenesis to give rise to red beds (sandstones that are predominantly red in colour due to fully oxidized iron coating individual grains) and that 2.2 billion years passed before a large number of life-forms could evolve. An idea formulated by the American paleontologist Preston Cloud has been widely accepted as an answer to this question. The earliest primitive organisms produced free oxygen as a by-product, and in the absence of oxygen-mediating enzymes it was harmful to their living cells and had to be removed. Fortunately for the development of life on the early Earth there was extensive volcanic activity, which resulted in the deposition of much lava, the erosion of which released enormous quantities of iron into the oceans. This ferrous iron is water-soluble and therefore could be easily transported, but it had to be converted to ferric iron, which is highly insoluble, before it could be precipitated as iron formations. In short, the organisms produced the oxygen and the iron formations accepted it. Iron formations can be found in the earliest sediments (those deposited 3.8 billion years ago) at Isua in West Greenland, and thus this process must have been operative by this time. Early Precambrian iron formations are so thick and common that they provide the major source of the world's iron. Large quantities of iron continued to be deposited until about 2 billion years ago, after which time the formations decreased and disappeared from the sedimentary record. Sulfides also accepted oxygen in the early oceans to be deposited as sulfates in evaporites, but such rocks are easily destroyed. One finds, nonetheless, 3.5-billion-year-old barite/gypsum-bearing evaporites up to 15 metres thick and at least 25 kilometres in extent in the Pilbara region of Western Australia. It seems likely that the excess iron in the early oceans was finally cleared out by about 1.7 billion years ago, and this decrease in the deposition of iron formations resulted in an appreciable rise in the oxygen content of the atmosphere, which in turn enabled more eolian red beds to form. Further evidence of the lack of oxygen in the early atmosphere is provided by detrital uraninite and pyrite and by paleosols—*i.e.,* fossil soils. Detrital uraninite and pyrite are readily oxidized in the presence of oxygen and thus do not survive weathering processes during erosion, transport, and deposition in an oxygenous atmosphere. Yet, these minerals are well preserved in their original unoxidized state in conglomerates that have been dated to be more than 2.2 billion years old on several continents. Paleosols also provide valuable clues, as they were in equilibrium with the prevailing atmosphere. From analyses of early Precambrian paleosols it has been determined that the oxygen content of the atmosphere 2.2 billion years ago was one hundredth of the present atmospheric level (PAL).

Fossils of eukaryotes, which are organisms that require an oxygen content of about 0.02 PAL, bear witness to the beginning of oxidative metabolism. The first microscopic eukaryotes appeared about 1.4 billion years ago. Life-forms with soft parts, such as jellyfish and worms, developed in profusion, albeit locally, toward the end of the Precambrian about 650 million years ago, and it is estimated that this corresponds to an oxygen level of 0.1 PAL. By the time land plants first appeared, roughly 400 million years ago, atmospheric oxygen levels had reached their present values.

Development of the oceans. Volcanic degassing of volatiles, including water vapour, occurred during the early stages of crustal formation and gave rise to the atmosphere. When the surface of the Earth had cooled to below 100° C (212° F), the hot water vapour in the atmosphere would have condensed to form the early oceans. The existence of 3.5-billion-year-old stromatolites is, as noted above, evidence of the activity of blue-green algae, and this fact indicates that the Earth's surface must have cooled to below 100° C by this time. Also, the presence of pillow structures in basalts of this age attests to the fact that these lavas were extruded under water, and this probably occurred around volcanic islands in the early ocean. The abundance of volcanic rocks of Archean age (3.8 to 2.5 billion years ago) is indicative of the continuing role of intense volcanic degassing, but since the early Proterozoic (from 2.5 billion years ago), much less volcanic activity has occurred. Until about 2 billion years ago there was substantial deposition of iron formations, cherts, and various other chemical sediments, but from roughly that time onward the relative proportions of different types of sedimentary rock and their mineralogy and trace element compositions have been very similar to their Phanerozoic equivalents; it can be inferred from this relationship that the oceans achieved their modern chemical characteristics and sedimentation patterns from approximately 2 billion years ago (Figure 14). By the late Precambrian, some 1 billion years ago, ferric oxides were chemically precipitated, indicating the availability of free oxygen. During Phanerozoic time (the last 570 million years), the oceans have been steady-state chemical systems, continuously reacting with the minerals added to them via drainage from the continents and with volcanic gases at the oceanic ridges.

TIME SCALES

The geologic history of the Earth over nearly four billion years of time is surveyed in the remainder of this article.

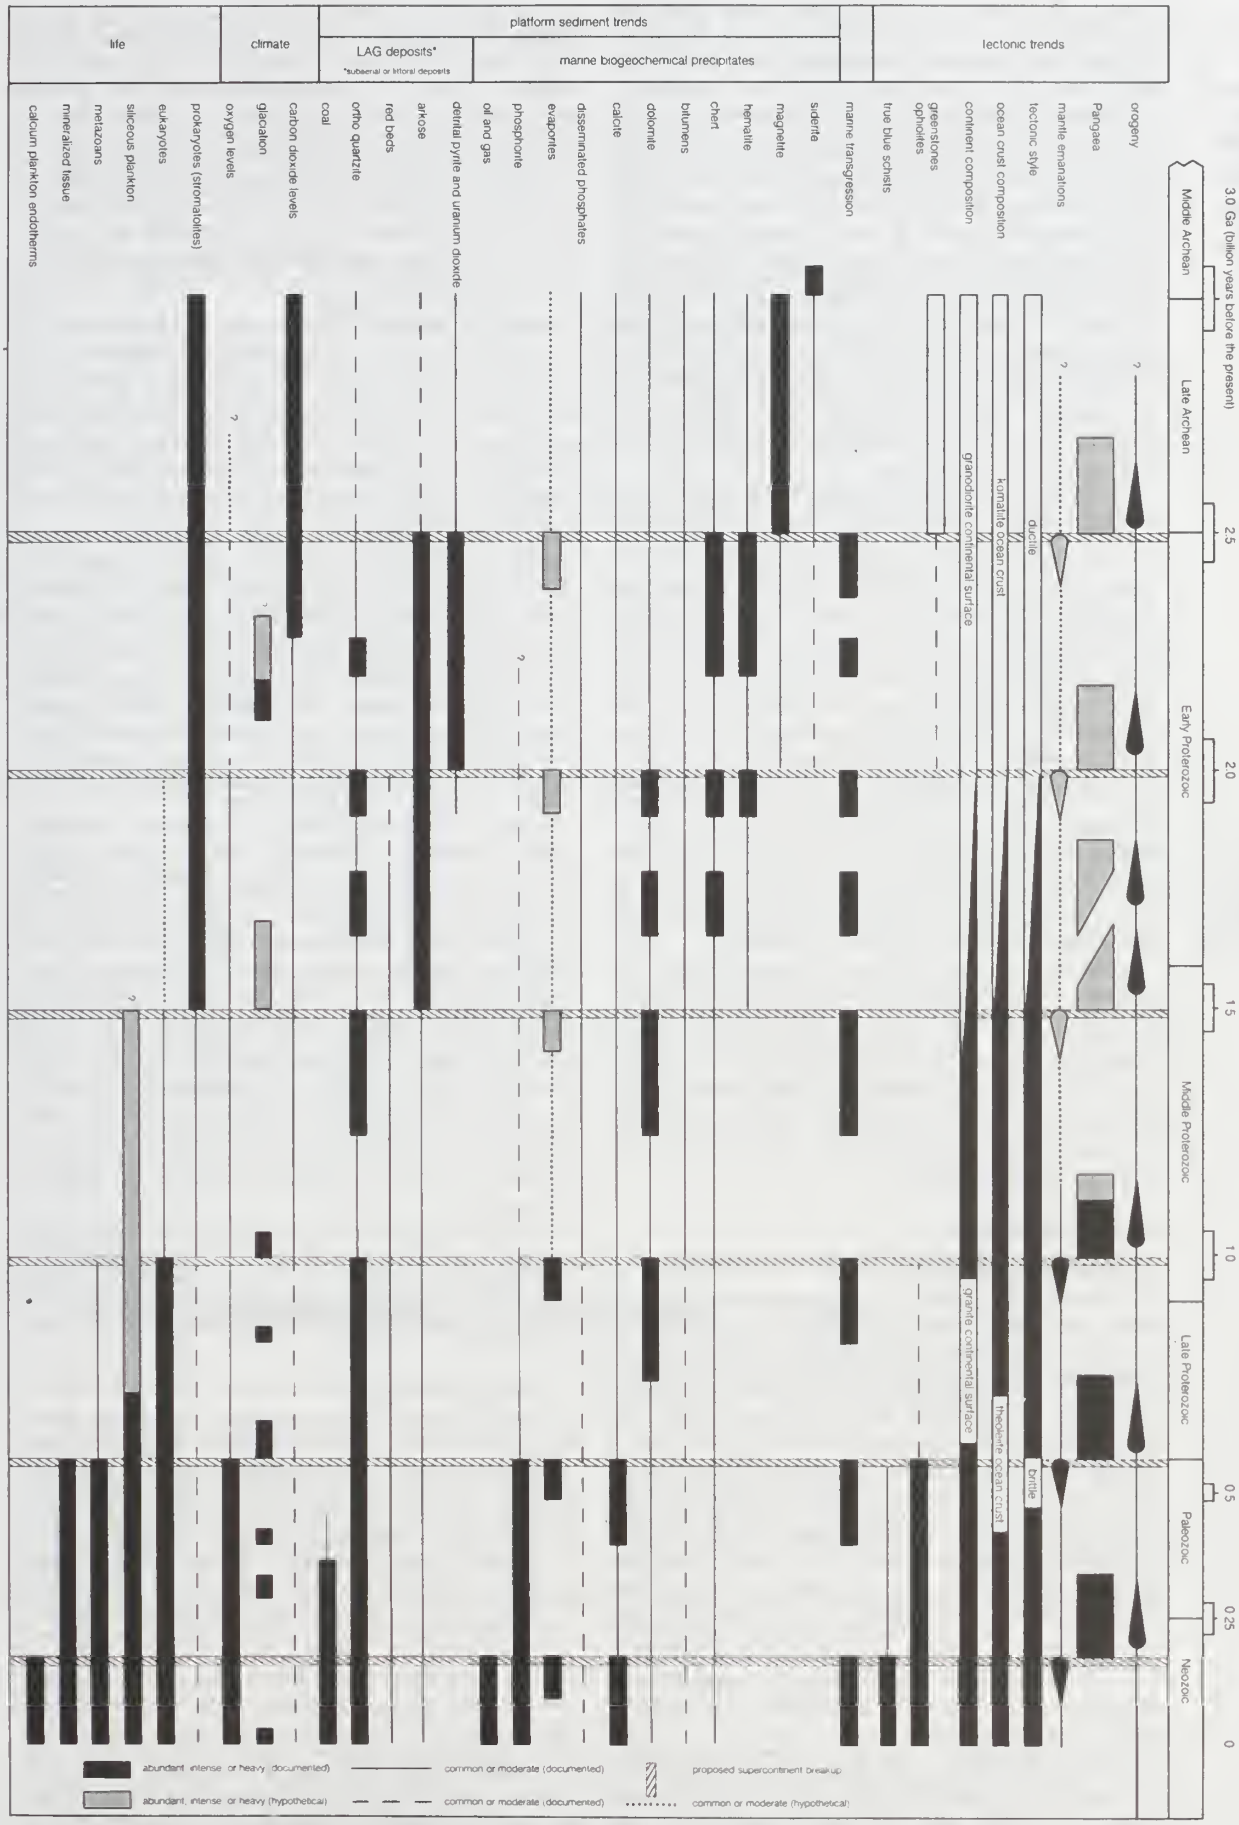

Figure 14: Qualitative summary of Late Archean to present tectonic, platform sediment, climatic, and biotic trends.

Chronostratigraphic and chronometric scales

Different types of phenomena and events in widely separated parts of the world have been correlated using an internationally acceptable, standardized time scale. There are, in fact, two geologic time scales. One is relative, or chronostratigraphic, and the other is absolute, or chronometric. The chronostratigraphic scale has evolved since the mid-1800s and concerns the relative order of strata. Important events in its development were the realization by William Smith that in a horizontal sequence of sedimentary strata what is now an upper stratum was originally deposited on a lower one and the discovery by James Hutton that an unconformity (discontinuity) indicates a significant gap in time. Furthermore, the presence of fossils throughout Phanerozoic sediments has enabled paleontologists to construct a relative order of strata. As was explained earlier, at specific stratigraphic boundaries certain types of fossils either appear or disappear or both in some cases. Such biostratigraphic boundaries separate larger or smaller units of time that are defined as eons, eras, periods, epochs, and ages.

The chronometric scale is of more recent origin. It was made possible by the development of mass spectrometers during the 1920s and their use in geochronological laboratories for radiometric dating (see above). The chronometric scale is based on specific units of duration and on the numerical ages that are assigned to the aforementioned chronostratigraphic boundaries. The methods used entail the isotopic analyses of whole rocks and minerals of element pairs, such as potassium–argon, rubidium–strontium, uranium–lead, and samarium–neodymium. Another radiometric time scale has been developed from the study of the magnetization of basaltic lavas of the ocean floor. As such lavas were extruded from the mid-oceanic ridges, they were alternately magnetized parallel and opposite to the present magnetic field of the Earth and are thus referred to as normal and reversed. A magnetic-polarity time scale for the stratigraphy of normal and reversed magnetic stripes can be constructed back as far as the middle of the Jurassic Period, about 170 million years ago, which is the age of the oldest extant segment of ocean floor.

Time scale of magnetic-polarity reversals

During recent years, various chronostratigraphic and chronometric time scales with relatively small differences have been proposed. The 1983 scale prepared for the Decade of North American Geology (DNAG) has been selected for the present discussion because it takes into account many of the variations of other scales. As can be seen from Table 4, the DNAG geologic time scale gives the major chronostratigraphic boundaries and their assigned chronometric ages, as well as the time scale of magnetic polarity reversals.

Precambrian time

GENERAL CONSIDERATIONS

The Precambrian is defined as the period of time that extends from a little more than 3.9 billion years ago, which is the approximate age of the oldest known rocks, to the beginning of the Cambrian Period, roughly 540 million years ago. The Precambrian era thus represents more than 80 percent of the whole of geologic time. It has long been known that the Cambrian marks the earliest stage in the history of the Earth when many varied forms of life evolved and were preserved extensively as fossil remains in sedimentary rocks. It is not surprising that all life-forms were long assumed to have originated in the Cambrian, and therefore all earlier rocks with no obvious fossils were grouped together into one large era, the Precambrian. However, detailed mapping and examination of Precambrian rocks on most continents have since revealed that primitive life-forms already existed more than 3.5 billion years ago. The original terminology to distinguish Precambrian from all younger rocks, nevertheless, is still used for subdividing geologic time.

Major subdivisions. It is now internationally agreed that Precambrian time should be divided into the Archean and Proterozoic eons, with the time boundary between them at 2.5 billion years. The subdivision of these eons into early, middle, and late eras is not so widely agreed upon, but experts in the field have adopted a scheme according to which the relevant boundaries are at 3.4 billion and 3 billion and at 1.6 billion and 900 million years. These definitions are based on isotopic age determinations, and it is not possible to introduce smaller subdivisions. In the absence of fossils to permit the creation of small-scale subdivisions, relative chronologies of events have been produced for different regions based on such field relationships as unconformities and crosscutting dikes (tabular bodies of intrusive igneous rock that cut across original structures in the surrounding rock), combined with isotopic age determinations of specific rocks, as, for example, granites. This allows for some correlation between neighbouring regions.

Distinctive features. The Archean and Proterozoic are very different and must be considered separately. The Archean–Proterozoic boundary constitutes a major turning point in Earth history. Before that time the crust of the Earth was in the process of growing and so there were no large stable continents, whereas afterward, when such continents had emerged, orogenic belts were able to form marginally to and between continental blocks as they did during Phanerozoic times.

Archean orogenic belts

There are two types of Archean orogenic belts: (1) upper crustal greenstone–granite belts, rich in volcanic rocks which are probably primitive types of oceanic crust and island arcs that formed during the early rapid stage of crustal growth, and (2) granulite–gneiss belts that were recrystallized in the Archean mid-lower crust under metamorphic conditions associated with high-temperature granulite and amphibolite facies. Thus granulites, which typically contain the high-temperature mineral hypersthene, are a characteristic feature of many Precambrian orogenic belts that have been deeply eroded, as opposed to Phanerozoic orogenic belts, in which they are rare.

There are several other rock types that were developed primarily during the Precambrian and rarely later. This restriction is a result of the unique conditions that prevailed during Precambrian times. For example, the banded-iron formation mentioned above is a ferruginous sediment that was deposited on the margins of early iron-rich oceans. Anorthosite, which consists largely of plagioclase, forms large bodies in several Proterozoic belts. Komatiite is a magnesium-rich, high-temperature volcanic rock derived from a very hot mantle; it was extruded in abundance during the early Precambrian when the heat flow of the Earth was higher than it is today. Blueschist contains the blue mineral glaucophane; it forms in subduction zones under high pressures and low temperatures, and its rare occurrence in Precambrian rocks may indicate that temperatures in early subduction zones were too high for its formation.

The bulk of many of the world's valuable mineral deposits (for example, those of gold, nickel, chromite, copper, and iron) also formed during the Precambrian. These concentrations are a reflection of distinctive Precambrian sedimentary and magmatic rocks and their environments of formation.

PRECAMBRIAN ROCKS

General occurrence and distribution. Precambrian rocks as a whole occur in a wide variety of shapes and sizes. There are extensive Archean regions, up to a few thousands of kilometres across, that may contain either greenstone–granite belts or granulite–gneiss belts or both and that are variously designated in different parts of the world as cratons, shields, provinces, or blocks. Some examples are the North Atlantic craton that includes northwestern Scotland, central Greenland, and Labrador; the Kaapvaal and Zimbabwean cratons in southern Africa; the Dhārwār craton in India; the Aldan and Anabar shields in Siberia in Russia; the Baltic Shield that includes much of Sweden, Finland, and the Kola Peninsula of far northern Russia; the Superior and Slave provinces in Canada; and the Yilgarn and Pilbara blocks in Western Australia. There are linear belts, up to several thousand kilometres long, that are frequently though not exclusively of Proterozoic age, such as the Limpopo, Mozambique, and Damaran belts in Africa, the Labrador Trough in Canada, and the Eastern Ghāts belt in India. Also, small relict areas, only about

a few hundred kilometres across, exist within or against Phanerozoic orogenic belts, as, for instance, the Lofoten islands of Norway, the Lewisian Complex in northwestern Scotland, and the Adirondack Mountains in the northeastern United States. Some extensive areas of Precambrian rocks are still overlain by a blanket of Phanerozoic sediments, as under the European and Russian platforms and under the central United States; these are mostly known from borehole samples (see Figure 15).

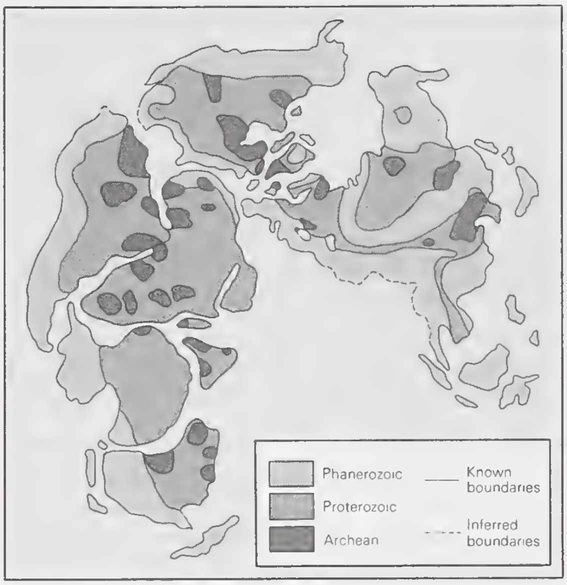

Figure 15: Archean regions within Proterozoic cratons surrounded by Phanerozoic mobile belts. This distribution is shown here on a Permian predrift map of the continents.

Archean rock types. Archean rocks occur in greenstone–granite belts that represent the upper crust, in granulite–gneiss belts that formed in the mid-lower crust, and in sedimentary basins, basic dikes, and layered complexes that were either deposited on or intruded into the first two types of belts.

Greenstone–granite belts. These belts occur on most continents. The largest extend several hundred kilometres in length and measure several hundred metres in width. They range from aggregates of several belts (as in the southern Superior province of Canada) to irregular, even triangular-shaped belts (such as Barberton in South Africa) to synclinal basins (as in the Indian Dhārwār craton). Today, many greenstone–granite belts are regarded as tectonic slices that have been thrust between or against older rocks, such as gneisses. The irregular and synclinal shapes are commonly caused by the diapiric intrusion of younger granites. Important occurrences are the Barberton belt in South Africa; the Sebakwian, Belingwean, and Bulawayan–Shamvaian belts of Zimbabwe; the Yellowknife belts in the Slave province of Canada; the Abitibi, Wawa, Wabigoon, and Quetico belts of the Superior province of Canada; the Dhārwār belts in India; and the Warrawoona belt in the Pilbara block and the Yilgarn belts in Australia.

Greenstone–granite belts developed at many different times throughout the long Archean Eon. In the Zimbabwean craton they formed over three successive periods: the Selukwe belt at about 3.75–3.8 billion years ago, the Belingwean belts at about 2.9 billion, and the Bulawayan–Shamvaian belts at 2.7–2.6 billion. The Barberton belt in the Kaapvaal craton and the Warrawoona belt in the Pilbara block are 3.5 billion years old. Globally the most important period of formation was from 2.7 to 2.6 billion years ago, especially in the Slave and Superior provinces of North America, the Yilgarn block in Australia, and the Dhārwār craton in India. Some of the better documented belts seem to have formed within about 50 million years. It is important to note that while the Bulawayan–Shamvaian belts were forming in the Zimbabwean craton, flat-lying sediments and volcanics were laid down in the Pongola rift and the Witwatersrand Basin not far to the north.

The greenstone sequence in many belts is divisible into a lower volcanic group and an upper sedimentary group. The volcanics are made up of ultramafic and basaltic lavas noted for magnesian komatiites that probably formed in the oceanic crust, overlain by basalts, andesites, and rhyolites whose chemical composition is much like that of modern island arcs. Especially important is the presence in the Barberton and Yellowknife belts of sheeted basic dike complexes cutting across gabbros and overlain by pillow-bearing basalts. The uppermost sediments are typically terrigenous shales, sandstones, quartzites, graywackes, and conglomerates. The overall stratigraphy suggests an evolution from extensive submarine eruptions of komatiite and basalt (ocean floor) to more localized stratovolcanoes (island arcs), which become increasingly emergent with intervening and overlying clastic basins. There are, however, regional differences in the volcanic and sedimentary makeup of some belts. The older belts in southern Africa and Australia have more komatiites and basalts, more shallow-water banded-iron formations, cherts, and evaporites, and fewer terrigenous sediments. On the other hand, the younger belts in North America have a higher proportion of andesites, rhyolites, and terrigenous and turbidite debris, but fewer shallow-water sediments. These differences reflect a change from the older oceanic-type volcanism (effusion of lava from submarine fissures) to the younger, more arc-type phenomenon (explosive eruption of pyroclastic materials and lava from steep volcanic cones), an increasing amount of trench turbidites and graywackes with time, and an increasing availability of continental crust with time as a source for terrigenous debris.

Regional differences in component rocks

Granitic rocks and gneisses occur within, adjacent to, and between many greenstone sequences. Some paragneisses, as in the Quetico belt in Canada, are derived from graywackes and were probably deposited in a trench or accretionary prism at the mouth of a subduction zone between the island arcs of the adjacent greenstone sequences. Many early granitic plutons were deformed and converted into orthogneiss. Late plutons commonly intruded the greenstones that were downfolded in synclines between them, or they intruded along the borders of the belts, deflecting them into irregular shapes.

The structure of many belts is complex. Their stratigraphic successions are upside down and deformed by thrusts and major horizontal folds (nappes) and have been subsequently refolded by upright anticlines and synclines. The result of this thrusting is that the stratigraphic successions have been repeated and thus may be up to 10–20 kilometres thick. Also, there may be thrusts along the base of the belts, as in the case of Barberton, showing that they have been transported from elsewhere. In other instances, the thrusts may occur along the borders of the belts, indicating that they have been forced against and over adjacent gneissic belts. The conclusion from structural studies is that many belts have undergone intense subhorizontal deformation during thrust transport and that subsequent compression, assisted by the diapiric rise of late granitic plutons, created synformal shapes and subvertical structures.

All the greenstone sequences have undergone recrystallization during metamorphism of greenschist facies at relatively low temperatures and pressures. In fact, the presence of the three green metamorphic minerals chlorite, hornblende, and epidote has given rise to the term greenstone for the recrystallized basaltic volcanics. Ultramafic rocks are commonly altered to talc schists and tremolite–actinolite schists, which may contain asbestos veins of economic value. There are some indications that several phases of metamorphism exist—namely, seafloor metamorphism associated with the action of hydrothermal brines perhaps at mid-oceanic ridges, syntectonic metamorphism related to thrust-nappe tectonics, and local thermal contact metamorphism caused by late intrusive granitic plutons.

One finds abundant mineralization in greenstone–granite belts. These belts constitute one of the world's principal depositories of gold, silver, chromium, nickel, copper, and zinc. In the past they were termed gold belts because the gold rushes of the 19th century took place, for example,

Mineralization in greenstone–granite belts

at Kalgoorlie in the Yilgarn belt of Western Australia, in the Barberton belt of South Africa, and at Val d'Or in the Abitibi belt of southern Canada. The mineral deposits occur in all the major rock groups: chromite, nickel, asbestos, magnesite, and talc in ultramafic lavas; gold, silver, copper, and zinc in basaltic to rhyolitic volcanics; iron ore, manganese, and barite in sediments; and lithium, tantalum, beryllium, tin, molybdenum, and bismuth in granites and associated pegmatites. Important occurrences are chromite at Selukwe in Zimbabwe, nickel at Kambalda in southwestern Australia, tantalum in Manitoba in Canada, and copper–zinc at Timmins and Noranda in the Canadian Abitibi belt.

Clearly there are different types of greenstone–granite belts. In order to understand their origin and mode of evolution, it is necessary to correlate them with comparable modern analogues. Some, like the Barberton and Yellowknife belts, consist of oceanic-type crust and have sheeted dike swarms that occur in many Mesozoic–Cenozoic ophiolites, such as Troodos in Cyprus. They are a hallmark of modern oceanic crust that formed at a mid-oceanic ridge. Also, like modern ophiolites, a few seem to have been obducted by thrusting onto continental crust. Many belts, like those in the Superior province of Canada, are very similar to modern island arcs. The Wawa belt, for example, has been shown to consist of an immature island arc built on oceanic crust and overlain by a more mature arc. The Abitibi belt began as an island arc that was rifted to form an intra-arc basin in which developed a second arc. Between the Wawa and Wabigoon island arcs lies the Quetico belt, consisting of metamorphosed turbidites and slices of volcanics that probably developed in an imbricated accretionary prism in an arc–trench system, as seen today in the Japanese arcs. The Pilbara belts are similar to modern active continental margins, and they have been interthrust with older continental orthogneisses to form a very thick crustal pile that was intruded by diapiric crustal-melt granites. This scenario is quite comparable to that of a Himalayan type of orogenic belt formed by collisional tectonics. In conclusion, most greenstone–granite belts are today regarded by geologists as different parts of interthrust oceanic trench–island arc systems that collided with continental gneissic blocks.

High-grade metamorphism

Granulite–gneiss belts. The granulites, gneisses, and associated rocks in these belts were metamorphosed to a high grade in deep levels of the Archean crust; metamorphism occurred at a temperature of 750° to 980° C and at a depth of about 15–30 kilometres. These belts, therefore, represent sections of the continents that have been highly uplifted, with the result that the upper crust made up of volcanics, sediments, and granites has been eroded. Accordingly, the granulite–gneiss belts are very different from the greenstone–granite belts. They occur in a variety of environments. These may be extensive regions, such as the North Atlantic craton, which measures 1,000 by 2,000 kilometres across and includes, in its pre-Atlantic fit, the Scourian complex of northwestern Scotland, the central part of Greenland, and the coast of Labrador; the Aldan and Ukrainian shields of continental Europe; eastern Hopeh (Hebei) and Liaoning provinces of northeastern China; large parts of the Superior province of Canada and the Yilgarn block in Australia; and the Limpopo belt in southern Africa. Or they may be small areas, such as the Ancient Gneiss Complex of Swaziland; the Minnesota River valley and the Beartooth Mountains of the United States; the Peninsular gneisses and Sargur supracrustals of southern India; the English River gneisses of Ontario in Canada that form a narrow strip between greenstone–granite belts; the Sand River gneisses that occupy a small area between greenstone–granite belts in Zimbabwe; and the Napier complex in Enderby Land in Antarctica. Granulite–gneiss belts are commonly surrounded by younger, mostly Proterozoic belts that contain remobilized relicts of the Archean rocks, and the granulites and gneisses must underlie many Archean greenstone–granite belts and blankets of Phanerozoic sediment. In light of this, the granulite–gneiss belts may be regarded as minimally exposed and preserved sections of a widespread continental basement.

Isotopic age determinations from the granulite–gneiss belts record an evolution from about 4.3 to 2.5 billion years—more than a third of geologic time. Most important are the few but well-determined detrital zircons at Mount Narryer and Jack Hills in Western Australia that are more than 4 billion years old (see above). Several regions have a history that began in the period dating from 3.9 to 3.6 billion years ago—*e.g.*, West Greenland, Labrador, the Limpopo belt, Enderby Land, and the Aldan Shield. Most regions of the world went through a major tectonic event that may have involved intrusion, metamorphism, and deformation in the period between 3.1 and 2.8 billion years ago; and some of these regions, like the Scourian in northwestern Scotland, show no evidence of any older crustal growth. The best-documented region is West Greenland, which has a long and complicated history from 3.8 to 2.5 billion years ago.

Most common rock type

Orthogneisses of deformed and recrystallized tonalite and granite constitute the most common rock type. The geochemical signature of these rocks closely resembles that of modern equivalents that occur in granitic batholiths in the Andes. Where such rocks have been metamorphosed under conditions associated with amphibolite facies, they contain hornblende or biotite or a combination of the two. However, where they have been subjected to conditions of higher temperature associated with the granulite facies, the rocks contain pyroxene and hypersthene and so can be called granulites.

The granulites and gneisses enclose a wide variety of other minor rock types in layers and lenses. These types include schists and paragneisses, which were originally deposited on the Earth's surface as shales and which now contain high-temperature metamorphic minerals, such as biotite, garnet, cordierite, staurolite, sillimanite, or kyanite. There also are quartzites, which were once sandstones; marbles, which were either limestones or dolomites; and banded-iron formations, which were deposited as ferruginous sediments. Commonly intercalated with these metasediments are amphibolites, which locally contain relict pillows, demonstrating that they are derived from basaltic lavas deposited underwater. These amphibolites have a trace element chemistry quite similar to that of modern seafloor basalts. The amphibolites are often accompanied by chromite-layered anorthosite, gabbro, and ultramafic rocks, such as peridotite and dunite. All these rocks occur in layered igneous complexes, which in their well-preserved state may be up to 1 kilometre thick and 100 kilometres long. Such complexes occur at Fiskenaesset in West Greenland and in the Limpopo belt in southern Africa, as well as in southern India. These complexes may have formed at a mid-oceanic ridge in a magma chamber that also fed the basaltic lavas. In many cases, the complexes, the basaltic amphibolites, and the sediments were extensively intruded by the tonalites and granites that were later deformed and recrystallized, with the result that all these rocks may now occur as metre-sized lenses in the orthogneisses and granulites.

The structure of the granulite–gneiss belts is extremely complex, since the constituent rocks have been highly deformed several times. In all likelihood, it seems that the basalts and layered complexes from the oceanic crust were interthrust with shallow-water limestones, sandstones, and shales, with tonalites and granites from Andean-type batholiths, and with older basement rocks from a continental margin. All these rocks, which are now mutually conformable, were folded in horizontal nappes and then refolded. The picture that emerges is one of a very mobile Earth, where no rocks remained long after their formation before they were compressed and thrust against other rocks.

The mid-lower crust is relatively barren of ore deposits, as compared to the upper crust with its sizable concentrations of greenstones and granites, and so little mineralization is found in the granulite–gneiss belts. The few exceptions include a nickel–copper sulfide deposit at Selebi–Pikwe in the Limpopo belt in Botswana that is economic to mine and banded-iron formations in gneisses in the eastern Hopeh and Liaoning provinces of northwestern China that form the foundation of a major steel industry. There are uneconomic chromitite seams in anorthosites in West Greenland, southern India, and the Limpopo belt, a banded-iron formation in a 3.8-billion-year-old sedimentary–volcanic belt at Isua in West Greenland, and minor tungsten mineralization in amphibolites in West Greenland.

Correlation

It is impossible to correlate the rocks in different granulite–gneiss belts. One granitic gneiss is essentially the same as another, but it may be of vastly different age. There is a marked similarity in the anorthosites in various belts throughout the world, and their similar relationship with the gneisses suggests that the belts have undergone comparable stages of evolution, although each has its own distinctive features. Little correlation can be made with rocks of Mesozoic–Cenozoic age, because few modern orogenic belts have been eroded sufficiently to expose their mid-lower crust. The lack of modern analogues for comparison makes it particularly difficult to interpret the mode of origin and evolution of the Archean granulite–gneiss belts.

Sedimentary basins, basic dikes, and layered complexes. During the Late Archean (3 to 2.5 billion years ago), relatively stable, post-orogenic conditions developed locally in the upper crust, especially in southern Africa, where the development of greenstone–granite and granulite–gneiss belts was completed much earlier than in other parts of the world. The final chapters of Archean crustal evolution can be followed by considering specific key sedimentary basins, basic (basaltic) dikes, and layered complexes.

Pongola Rift

Along the border of Swaziland and South Africa is the Pongola Rift, which is the oldest such continental trough in the world; it is 2.95 billion years old, having formed only 50 million years after the thrusting of adjacent greenstone–granite belts. If there were earlier rifts, they have not survived, or more likely this was the first time in Earth history that the upper crust was sufficiently stable and rigid for a rift to form. It is 30 kilometres wide and 130 kilometres long, and within it is an 11-kilometre-thick sequence of lavas and sediments. It seems most likely that the rift developed as the result of the collapse of an overthickened crust following the long period of Archean crustal growth and thrusting in the Kaapvaal craton.

The 200-by-350-kilometre Witwatersrand Basin contains an 11-kilometre-thick sequence of lavas and sediments that are 2.8 billion years old. The basin is famous for its very large deposits of gold and uranium that occur as detrital minerals in conglomerates. These minerals were derived by erosion of the surrounding greenstone–granite belts and transported by rivers into the shoreline of the basin. In all probability, the gold originally came from the komatiitic and basaltic lavas in the early Archean oceanic crust.

Great Dyke of Zimbabwe

The Great Dyke, thought to be more than 2.5 billion years old, transects the entire Zimbabwe craton. It is 480 kilometres long and 8 kilometres wide and consists of layered ultrabasic rocks—gabbros and norites. The ultrabasic rocks have several layers of chromite and an extensive platinum-bearing layer that form economic deposits. The Great Dyke represents a rift that has been filled in with magma.

The Stillwater Complex is a famous, 2.7-billion-year-old, layered ultrabasic-basic intrusion in the Beartooth Mountains of Montana, U.S. It is 48 kilometres long and has a stratigraphic thickness of 6 kilometres. It was intruded as a subhorizontal body of magma that underwent crystal settling to form the layered structure. It is notable for a three-metre-thick layer enriched in platinum minerals, which forms a major economic deposit.

The basins, dikes, and complexes described above cannot be mutually correlated. They most resemble equivalent structures that formed at the end of plate-tectonic cycles in the Phanerozoic. They represent the culmination of Archean crustal growth.

Proterozoic rock types. What happened geologically at the time of the Archean–Proterozoic boundary 2.5 billion years ago is uncertain. It seems to have been a period of little tectonic activity, and so it is possible that the earlier intensive Archean crustal growth had caused the amalgamation of continental fragments into a supercontinent, perhaps similar to Pangaea in the Permo–Triassic. The fragmentation of this supercontinent and the formation of new oceans gave rise to many continental margins on which a variety of distinctive sediments were deposited. Much evidence suggests that in the period from 2.5 billion to 570 million years ago Proterozoic oceans were formed and destroyed by plate-tectonic processes and that most Proterozoic orogenic belts arose by collisional tectonics. Sedimentary, igneous, and metamorphic rocks that formed in this period are widespread throughout the world. There are many swarms of basic dikes, important sedimentary rifts, basins, and layered igneous complexes, as well as many orogenic belts. The rocks commonly occur in orogenic belts that wrap around the borders of Archean cratons. The characteristic types of Proterozoic rocks are considered below, as are classic examples of their occurrence in orogenic belts. With a few exceptions the following types of rocks were formed during the Early, Middle, and Late Proterozoic, indicating that similar conditions and environments existed throughout this long period of time.

Basic dikes. The continents were sufficiently stable and rigid during the Proterozoic for an extremely large number of basic dikes to be intruded into parallel, extensional fractures in major swarms. Individual dikes measure up to several hundred metres in width and length, and there may be hundreds or even thousands of dikes in a swarm, some having transcontinental dimensions. For example, the 1.2-billion-year-old Mackenzie swarm is more than 500 kilometres wide and 3,000 kilometres long and extends in a northwesterly direction across the whole of Canada from the Arctic to the Great Lakes. The 1.95-billion-year-old Kangamiut swarm in West Greenland is only about 250 kilometres long but is one of the world's densest continental dike swarms. Many of the major dike swarms were intruded on the continental margins of Proterozoic oceans in a manner similar to the dikes that border the present-day Atlantic Ocean.

Layered igneous intrusions. There are several very important layered, mafic to ultramafic intrusions of Proterozoic age that were formed by the accumulation of crystals in large magma chambers. The well-known ones are several tens or even hundreds of kilometres across, have a dikelike or sheetlike (stratiform) shape, and contain major economic mineral deposits. The largest and most famous is the Bushveld Complex in South Africa, which is 9 kilometres thick and covers an area of 66,000 square kilometres. It was intruded nearly 2.1 billion years ago and is the largest repository of magmatic ore deposits in the world. The Bushveld Complex consists of stratiform layers of dunite, norite, anorthosite, and ferrodiorite and contains deposits of chromite, iron, titanium, vanadium, nickel, and, most important of all, platinum. The Sudbury Complex in southern Canada, which is about 1.9 billion years old, is a basin-shaped body that extends up to 60 kilometres across. It consists mostly of layered norite and has deposits of copper, nickel, cobalt, gold, and platinum. It is noted for its high-pressure structures and other manifestations of shock metamorphism, which suggest that the intrusion was produced by an enormous meteorite impact (see CONTINENTAL LANDFORMS: *Formation of impact craters*).

World's largest repository of magmatic ore deposits

Shelf-type sediments. Quartzites, dolomites, shales, and banded-iron formations make up sequences that reach up to 10 kilometres in thickness and that amount to more than 60 percent of Proterozoic sediments. Minor sediments include sandstones, conglomerates, red beds, evaporites, and cherts. The quartzites typically have cross-bedding and ripple marks, which are indicative of tidal action, and the dolomites often contain stromatolites similar to those that grow today in intertidal waters. Also present in the dolomites are phosphorites that are similar to those deposited on shallow continental margins against areas of oceanic upwelling during the Phanerozoic. Several early-middle Proterozoic examples of such dolomites have been found in Finland and northern Australia, as well as in the Marquette Range of Michigan in the United States, in the Aravalli Range of Rājasthān in northwestern India, and at Hamersley and Broken Hill in Australia. Still another constituent of these dolomites is evaporite, which contains casts and relicts of halite, gypsum, and anhydrite and which occurs, for example, at Mount Isa in Australia (1.6 billion years old) and in the Belcher Group in Canada (1.8 billion years old). These evaporites were deposited by brines in very shallow pools, like those encountered today in the Persian Gulf.

Ophiolites. Phanerozoic ophiolites are considered to be fragments of ocean floor that have been trapped between island arcs and continental plates that collided or that have been thrust onto the shelf sediments of continental margins. They consist of a downward sequence of oceanic sediments such as cherts, pillow-bearing basalts, sheeted (100-percent) basic dikes, gabbros, and certain ultramafic rocks (*e.g.*, serpentinized harzburgite and lherzolite). Comparable ophiolites occur in several Proterozoic orogenic belts and provide strong evidence of the existence of oceanic plates like those of today. The oldest is an ophiolite in the Cape Smith belt on the south side of Hudson Bay in Canada whose age has been firmly established at 1.999 billion years. There is a 1.8-billion-year-old ophiolite in the Svecofennian belt of southern Finland, but most Proterozoic ophiolites are 1 billion to 570 million years old and occur in the Pan-African belts of Saudi Arabia, Egypt, and The Sudan, where they occur in sutures between a variety of island arcs.

Greenstones and granites. Greenstone–granite belts, like those of the Archean, continued to form in the Proterozoic albeit in greatly reduced amounts. They are characterized by abundant volcanic rocks that include pillowed subaqueous basalt flows and subaerial and subaqueous volcaniclastic rocks. Magnesian komatiites are for the most part absent, however. Intrusive plutons are typically made of granodiorite. Examples occur at Flin Flon in central Canada and in the Birrimian Group in West Africa. Generally such rocks resemble those in modern island arcs and back-arc basins.

Intrusive plutons of granodiorite

Granulites and gneisses. These highly deformed and metamorphosed rocks are similar to those of the Archean and occur in many Proterozoic orogenic belts, such as the Grenville in Canada, the Pan-African Mozambique belt in eastern Africa, the Musgrave and Arunta ranges in Australia, and in Lapland in the northern Baltic Shield. They were brought up from the mid-lower crust on major thrusts as a result of continental collisions.

Orogenic belts. Some of the classic Proterozoic orogenic belts of the world are considered in this section.

One such belt is the Wopmay Orogen, situated in the Arctic in the northwestern part of the Canadian Shield. (It is beautifully exposed and has been well described by Paul F. Hoffman and his colleagues at the Geological Survey of Canada.) It formed within a relatively short time between 1.9 and 1.8 billion years ago and provides convincing evidence of tectonic activity of a modern form in the early Proterozoic. On the eastern continental margin occur red beds (sandstones), which pass oceanward and westward into stromatolite-rich dolomites deposited on the continental shelf to a thickness of four kilometres; these dolomites pass into submarine turbidite fans that were deposited on the continental rise. An island arc and a continental margin are found to the west. The history of the Wopmay Orogen can be best interpreted in terms of subduction of oceanic crust and collision tectonics.

The Svecofennian Orogen of the Baltic Shield extends in a southeasterly direction from northern Sweden through southern Finland to the adjoining part of western Russia. It formed in the period from 1.9 to 1.7 billion years ago. A major lineament across southern Finland consists of the suture zone on which occur ophiolite complexes representing the remains of oceanic crust. At Outokumpu one encounters copper mineralization in these oceanic crust rocks similar to that in the Cretaceous ophiolite at Troodos in Cyprus. On the northern side of the suture is a shelf-type sequence of sediments and on the southern side a volcanic-plutonic arc. To the south of this arc lies a broad zone with thrusted gneisses intruded by tin-bearing crustal-melt granites, called rapakivi granites after their coarse, zoned feldspar megacrysts (*i.e.*, crystals that are significantly larger than the surrounding fine-grained matrix). The rocks in this zone are predictably equivalent to those that occur today under the Tibetan Plateau at a depth of about 20 kilometres.

Grenville Orogen

The Grenville Orogen is a deeply eroded and highly uplifted orogenic belt that extends from Labrador in northeastern Canada to the Adirondack Mountains and southwestward under the coastal plain of the eastern United States. It developed from about 1.5 to 1 billion years ago. Apart from an island arc situated today in Ontario, most of the Grenville Orogen consists of highly metamorphosed and deformed gneisses and granulites, which have been brought to the present surface on major thrusts from the mid-lower crust. A result of the terminal continental collision that occurred at about 1.1 billion years ago was the formation of the Midcontinent (or Keweenawan) rift system that extends southward for more than 2,000 kilometres from Lake Superior.

A type of crustal growth—one very different from that described above—took place in what is now Saudi Arabia, Egypt, and The Sudan in the period from 1.1 billion to 500 million years ago. This entire shield, called the Arabian–Nubian Shield, is dominated by volcanic lavas, tuffs (consolidated rocks consisting of pyroclastic fragments and ash), and granitic plutons that formed in a variety of island arcs separated by several sutures along which occur many ophiolite complexes. Some of the ophiolites contain a complete stratigraphy that is widely accepted as a section through the oceanic upper mantle and crust. The final collision of the arcs was associated with widespread thrusting and followed by the intrusion of granitic plutons containing tungsten, tin, uranium, and niobium ore deposits. The island arcs grew from the subduction of oceanic crust in a manner quite comparable to that taking place today throughout Indonesia.

The Mozambique belt is one of the many Pan-African orogenic belts that formed in the period between 1 billion and 500 million years ago. It extends along the eastern border of Africa from Ethiopia to Kenya and Tanzania. It consists largely of highly metamorphosed, mid-crustal gneisses within which are a few peridotite bodies that may be relicts of ophiolites. The structure of the Mozambique belt is dominated by eastward-dipping thrusts very similar to the thrusts on the southern side of the Himalayas that resulted from the collision of India with Tibet during the Tertiary Period hundreds of millions of years later.

Riphean and Sinian basins

During the Middle and Late Proterozoic, thick sequences of sediment were deposited in many basins throughout Asia. The Riphean sequence spans the period from 1.7 billion to 900 million years ago and occurs in what was formerly the Soviet Union. The Sinian in China extends from 850 to 540 million years ago (the end of the Precambrian) and roughly approximates the Vendian in Russia and certain other one-time Soviet states. The sediments are terrigenous debris characterized by conglomerates, sandstone, siltstone, and shale, some of which are oxidized red beds, along with stromatolite-rich dolomite. Total thicknesses reach over 10 kilometres. The terrigenous sediments were derived from the erosion of Proterozoic orogenic belts.

Correlation. The fact that Phanerozoic sediments have been so successfully subdivided and correlated is attributable to the presence of abundant fossil remains of life-forms that evolved and underwent changes over time. The fact that Precambrian sediments lack such fossils prevents any comparable correlations. There are, however, stromatolites in Precambrian sediments ranging in age from about 3.5 billion to 540 million years, and they reached their peak of development in the Proterozoic. Stromatolites underwent sufficient evolutionary changes that Russian biostratigraphers were able to use them to subdivide the Riphean into four main zones throughout widely separated areas of former Soviet territory. Similar stromatolite-based stratigraphic divisions have been recognized in the Norwegian islands of Spitsbergen, China, and Australia. This stromatolite biostratigraphy still has relatively limited application, however. As a consequence, it is the chronometric time scale that is used to subdivide Precambrian time and to correlate rocks from region to region and from continent to continent.

The rocks within Proterozoic orogenic belts are invariably too deformed to allow correlation of units between different belts. Nonetheless, the techniques of geochronology have improved considerably in recent years, with the result that rocks of approximately similar age on different continents can be mutually compared and regarded as equivalent. Archean rocks have in general been far too highly deformed and metamorphosed to be correlated to any significant degree.

PRECAMBRIAN ENVIRONMENT

In this section the types of environment that may have existed during Precambrian time are considered. Several rock types, notably banded-iron formations, paleosols, and red beds, are very useful for deriving information about the conditions of the atmosphere, and tillites (indurated sedimentary rocks formed by the lithification of glacial till; see below) reveal what the climatic patterns were like during Precambrian glaciations.

Continental drift and sediment deposition

Paleogeography. One of the most important factors controlling the nature of sediments deposited today is continental drift. This follows from the fact that the continents are distributed at different latitudes, and latitudinal position affects the temperature of oceanic waters along continental margins; in short, sedimentary deposition is climatically sensitive. At present, most carbonates and oxidized red soils are being deposited within 30 degrees of the equator, phosphorites within 45 degrees of it, and evaporites within 50 degrees. Most fossil carbonates, evaporites, phosphorites, and red beds of Phanerozoic age dating back to the Cambrian have a similar bimodal distribution with respect to their paleoequators. If the uniformitarian principle that the present is the key to the past is valid, then in the Precambrian such sediments would have likewise been controlled by the movement and geographic position of the continents. Thus it can be inferred that the stromatolite-bearing dolomites of the Riphean in the former Soviet Union were deposited in warm tropical waters. Even the 3.5-billion-year-old, extensive evaporites in the Pilbara region of northwestern Australia could not have been formed close to their paleopole. Today, phosphate sediments are deposited primarily along the western side of continents, where they receive upwelling, nutrient-rich currents as they move toward the equator. The major phosphorite deposits in the Proterozoic Aravalli belt of Rājasthān in northwestern India are associated with stromatolite-rich dolomites and were most likely deposited within the tropics on the western side of a continental mass.

Significant geologic events. Outlined below are some of the main geologic events that occurred throughout the long history of the Precambrian and that reveal something about prevailing conditions and environments.

Oldest minerals and rocks. As was previously noted, the oldest minerals on Earth, the zircons from western Australia, crystallized 4.276 billion years ago. The most significant thing about them is that the environment in which they formed is totally unknown. The rocks from which they came may have been destroyed by some kind of tectonic process or by a meteorite impact. On the other hand, the rocks may still exist on the Earth's surface but simply have not been found. Perhaps their very absence is indicative of something important about early terrestrial processes. Comparisons with the Moon indicate that the Earth must have been subjected to an enormous number of meteorite impacts about 4 billion years ago, but there is no geologic evidence of such events.

The oldest known rocks on Earth are found near Canada's Great Slave Lake; their age has been established radiometrically at 3.96 billion years. These rocks are of a granitic variety and are thought to have evolved from older basaltic crustal material that was melted and remelted by tectonic processes.

Archean events. During the first third of geologic history, until about 2.5 billion years ago, the Earth developed in a broadly similar manner. Greenstone–granite belts formed in the upper Archean crust and granulite–gneiss belts in the mid-lower crust. This was a time when the overall rate of heat production by the breakdown of radioactive isotopes was several times greater than it is today. This condition was manifested by very rapid tectonic processes, probably by some sort of primitive plate tectonics. Most of the heat that escapes from the Earth today does so at the mid-oceanic ridges, and it probably did likewise during the Archean but in much larger amounts. To permit this release of heat, the mid-oceanic ridges of the Archean were more abundant and longer and opened faster than those in the modern oceans. Although the amount of newly generated crust was probably enormous, a large part of this material was inevitably destroyed by equally rapid plate subduction processes. The main results of this early growth that can still be seen today are the many island arcs in greenstone–granite belts and the voluminous Andean-type tonalites that were deformed to orthogneiss in granulite–gneiss belts. Although most of the Archean oceanic crust was subducted, a few ophiolitic-type complexes have been preserved in greenstone–granite belts.

Rapid tectonic processes

The Late Archean was an important interval of time because it marks the beginning of the major changeover from Archean to Proterozoic types of crustal growth. Significant events of this time were the formation of the first major rifts (such as the Pongola), the intrusion of the first major basic dikes (*e.g.,* the Great Dyke) and of the first large stratiform layered igneous complexes (*e.g.,* the Stillwater), and the formation of the first large sedimentary basins (as, for example, the Witwatersrand). All of these structures indicate that the continental crust had for the first time reached a mature stage with considerable stability and rigidity. The Late Archean represents the culmination that followed the rapid tectonic processes of the Early and Middle Archean. Because crustal growth was diachronous (*i.e.,* cut across time planes) throughout the world, similar structures can be found in the Early Proterozoic.

The Archean–Proterozoic boundary. There is no record of tectonic activity of any sort at the time corresponding to the Archean–Proterozoic boundary—about 2.5 billion years ago. This probably means that a supercontinent was created by the amalgamation of innumerable smaller continental blocks and island arcs. Accordingly, this was a period of tectonic stability that may have been comparable to the Permo–Triassic when the supercontinent of Pangaea existed. The main geologic events would have been the intrusion of basic dikes and the formation of sedimentary basins, like the Huronian on the U.S.–Canadian border, into which large volumes of clastic sediment were deposited. Such sediments would have been derived by erosion of high plateaus and mountains that are characteristic of a large continental mass.

Proterozoic developments. During the Early Proterozoic large amounts of quartzite, carbonate, and shale were deposited on the shelves and margins of many continental blocks. This would be consistent with the breakup of a supercontinent into several or many smaller continents with long continental margins. Examples of shelf sequences of this kind are found along the margins of orogenic belts, such as the Wopmay bordering the Slave province and the Labrador Trough bordering the Superior province in Canada, and the Svecofennian in Finland.

Development of long, linear mountain belts

The fact that stable continental blocks existed by the Early Proterozoic meant that orogenic belts were able to develop against them by some form of collision tectonics. This was the first time that long, linear orogenic belts could form by "modern-style" plate-tectonic processes that involved seafloor spreading, ophiolite obduction, subduction that created island arcs and Andean-type granitic batholiths in active continental margins, and the collision of arcs and continents that gave rise to sutures with ophiolites and to Himalayan-type thrust belts with abundant crustal-melt granites. These were key events in the evolution of the continents, and such processes have continued throughout Earth history.

During the Late Proterozoic some orogenic belts continued to develop, as in the case of the Pan-African belts of Saudi Arabia and East Africa. The intense crustal growth and the many orogenic belts that formed throughout the Proterozoic, however, began to create large continental blocks, which amalgamated to form a new supercontinent by the end of the Precambrian. Therefore, in the Late

Proterozoic many sedimentary basins that were infilled with conglomerates and sandstones—the aforementioned Riphean and Sinian, for example—were able to form on extensive cratons of continental crust.

Climatic conditions. During the long course of Precambrian time the climatic conditions of the Earth must have changed considerably. Evidence of this can be seen in the sedimentary record, which suggests that the composition of the atmosphere and oceans changed appreciably over time. More importantly, however, the presence of tillites indicates that extensive glaciations occurred several times during the Precambrian. The tillites provide evidence of glacial conditions, although not necessarily at high latitudes. In general, they are complementary to the carbonates, evaporites, and red beds that are climatically sensitive and restricted to low latitudes.

Evidence of Precambrian glaciation

The oldest extensive glaciation occurred 2.3 billion years ago during the Early Proterozoic. It can be recognized from the rocks and structures that the glaciers and ice sheets left behind on several continents. The most extensive occurrences are found in North America in a belt nearly 3,000 kilometres long extending from Chibougamau in Quebec through Ontario to Michigan and southwestward to the Medicine Bow Mountains of Wyoming. This probably represents the area of the original ice sheet. Most details are known from the Gowganda Formation in Ontario, which contains glacial deposits that are up to 200 metres thick and that occupy an area of about 20,000 square kilometres. Evidence that these rocks were of glacial origin has been obtained by comparing them with the rocks left behind by the Quaternary ice sheets and with the deposits associated with modern glaciers. The Early Proterozoic examples have the following features: The main glacial sediment is a tillite. This lithified till contains abundant pebbles and fragments of up to boulder size of various rocks distributed randomly in a fine-grained silty matrix. The surfaces of some pebbles have parallel scratches caused by having been rubbed against harder pebbles during ice transport. Locally, the basement rocks below the tillite also have been scratched, or striated, by the movement of the overlying boulder-strewn ice. Another type of glacial deposit is a laminated varved sediment composed of alternating millimetre-to-centimetre-thick layers of silt and clay, which closely resemble the layered varves that are laid down in modern glacial lakes at the front of retreating glaciers or ice sheets, each layer defining an annual accumulation of sediment. Within the Gowganda varved sediment are dropstones, which are fragments of rock that have dropped from an overlying floating ice sheet and that have sunk into and depressed the varved layers beneath them. When all these features are found together, they provide good evidence of an ancient glaciation. Similar, roughly contemporaneous glacial deposits can be found in the Transvaal and Cape Province in South Africa, where they reach only 30 metres in thickness but extend over an area of 20,000 square kilometres. Such deposits also are encountered in the Hamersley Basin of Western Australia, in east-central Finland and the adjoining part of northwestern Russia, near Lake Baikal in Siberia, and in central India. These occurrences suggest that there was one or more extensive glaciation during the Early Proterozoic.

The largest glaciation in the history of the Earth occurred during the Late Proterozoic in the period between 1 billion and 600 million years ago. It left its mark almost everywhere. The principal occurrences of the glacial deposits are in Europe (Scotland, Ireland, Sweden, Norway, France, the Czech Republic, and Slovakia), the Western Cordillera (Yukon Territory, Can., to California, U.S.) and the Appalachians of the United States, East Greenland, Brazil, much of Africa (Congo, Angola, Namibia, Zambia, Zaire, and South Africa), and much of Russia, China, and Australia. One of the best-described occurrences is in the Flinders Range of South Australia, where there is a 4-kilometre-thick sequence of tillites and varved sediments occupying an area of 400-by-500 kilometres. Detailed stratigraphy and isotopic dating show that three glaciations took place at 850–800, 750, and 720–670 million years ago. The Port Askaig tillite on the island of Islay off northwestern Scotland is only 750 metres thick, but it records 17 ice advances and retreats and 27 periglacial periods, which are indicated by infilled polygons that formed under ice-free permafrost conditions. There are two major tillites in central Africa and Namibia (910–870 and 720–700 million years old, respectively) and two other such consolidated tills in East Greenland. What is the explanation for all these occurrences? It is interesting that some paleomagnetic studies have shown that the tillites in Scotland, Norway, Greenland, central Africa, North America, and South Australia were deposited in low or near-equatorial paleolatitudes. Such conclusions are, however, controversial, because it has also been suggested that the poles may have migrated across the globe, leaving a record of glaciations in high and low latitudes. There is the possibility that floating ice sheets could have traveled to low latitudes, depositing glacial sediments and dropstones below them. Whatever the answer, the existence of such vast quantities of tillites and of such extensive glaciations is intriguing and enigmatic. There is at present no broad agreement that resolves this Late Proterozoic phenomenon.

PRECAMBRIAN LIFE

Precambrian rocks were long ago defined to predate the Cambrian and therefore to predate all life, although the term Proterozoic was later coined from the Greek for "early life." It is now known that Precambrian rocks do in fact contain the evidence of the very beginnings of life on Earth (and thus the record of its evolution for more than 3 billion years), of the explosion of life-forms without skeletons before the Cambrian, and even of the development of sexual reproduction on Earth.

The first evidence of terrestrial life is found in the Early Archean sedimentary rocks of the greenstone–granite belts of Barberton in South Africa and of Warrawoona in the Pilbara block of Western Australia, which are both about 3.5 billion years old. There are two types of these early, simple, biological structures: microfossils and stromatolites.

Microfossils and stromatolites

The microfossils occur in cherts and shales and are of two varieties. One type consists of spherical carbonaceous aggregates, or spheroids, which may measure as much as 20 millimetres in diameter. These resemble algae and cysts of flagellates and are widely regarded as biogenic. The other variety of microfossils consists of carbonaceous filamentous threads, which are curving, hollow tubes up to 150 micrometres (0.006 inch) long. These tubes are most likely the fossil remains of filamentous organisms, and hundreds of them can be found in some rock layers. The 2.8-billion-year-old goldreefs (conglomerate beds with rich gold deposits) of the Witwatersrand Basin contain carbonaceous columnar microfossils up to seven millimetres long that resemble modern algae, fungi, and lichens. They probably extracted gold from the environment in much the way that modern fungi and lichens do.

Stromatolites are, as previously explained, stratiform, domal, or columnar structures made of sheetlike mats precipitated by communities of microorganisms, particularly filamentous blue-green algae. The Early Archean examples form domes as tall as about 10 centimetres (see Figure 16). Stromatolites occur in many of the world's greenstone–granite belts. In the 2.7-billion-year-old Steep Rock Lake belt in Ontario, Can., they reach three metres in height and diameter. Stromatolites continued to form all the way through the geologic record and today grow in warm intertidal waters, for example, at Shark Bay in Western Australia. They provide indisputable evidence that by 3.5 billion years ago life had begun on Earth by algal photosynthesis in complex, integrated biological communities.

These Archean organisms were prokaryotes that were incapable of cell division. They were relatively resistant to ultraviolet radiation and were able to survive during the early history of the Earth when the atmosphere lacked an ozone layer to block out such radiant energy. The prokaryotes were predominant until about 1.4 billion years ago, when they were overtaken by the eukaryotes. The latter make use of oxygen in metabolism and for growth and thus developed profusely in the increasingly oxygenic atmosphere of the Middle Proterozoic. The eukaryotes were

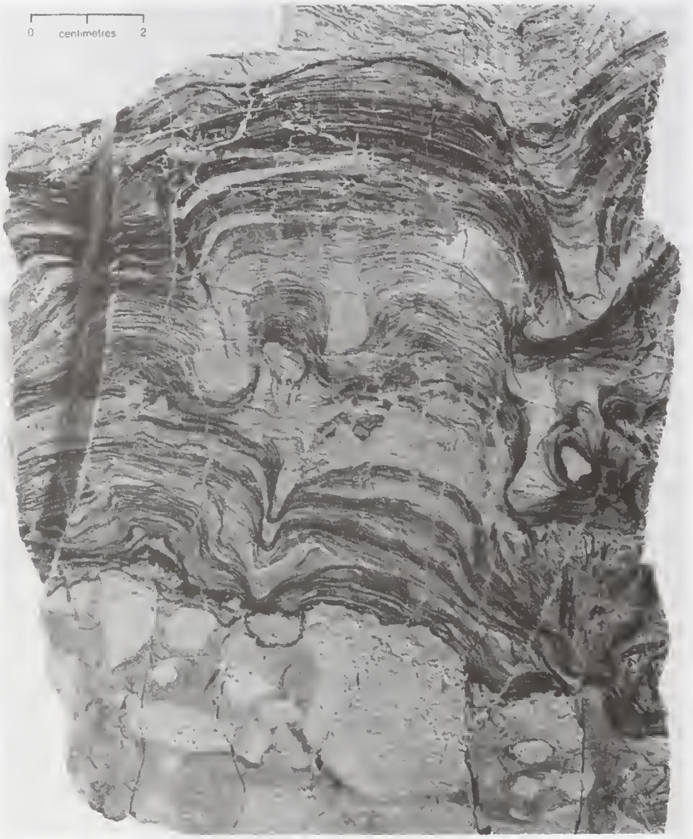

Figure 16: Stromatolites overlying the brecciated top of an ultramafic lava flow in Barberton Mountain Land, South Africa. The domal forms along the base are covered by larger, somewhat asymmetrical domes (see text).

capable of cell division, which allowed DNA (deoxyribonucleic acid), the genetic coding material, to be passed on to succeeding generations.

By Early Proterozoic time both microfossils and stromatolites had proliferated. The best-known occurrence of microorganisms is in the two-billion-year-old, stromatolite-bearing Gunflint iron formation in the Huronian Basin of southern Ontario. These microbial fossils include some 30 different types with spheroidal, filamentous, and sporelike forms up to about 20 micrometres across. Sixteen species in 14 genera have been classified so far. Microfossils of this kind are abundant, contain beautifully preserved organic matter, and are extremely similar to such present-day microorganisms as blue-green algae and microbacteria. There are comparable microfossils of the Early Proterozoic in Minnesota and Michigan in the United States, the Belcher Islands in Hudson Bay in Canada, southern Greenland, Western Australia, and northern China. These microbiota lived at the time of the transition from an anoxygenic to an oxygenic atmosphere.

During the Late Proterozoic stromatolites reached their peak of development and became distributed worldwide. The first metazoa (multicelled organisms whose cells are differentiated into tissues and organs) also appeared at this time. The stromatolites diversified into complex, branching forms. From about 700 million years ago, however, they began to decline significantly in number. Possibly the newly arrived metazoa ate the stromatolitic algae, and their profuse growth destroyed the habitats of the latter.

Ediacaran fossils

Metazoa developed rapidly from the beginning of the Cambrian, when they acquired protective shells and hard skeletons, which contributed to their preservation in fossil form. More primitive metazoa without skeletons, however, appeared before that time—at the outset of the Ediacaran period about 700 to 670 million years ago. The type locality for these remarkable organisms is the Ediacara Hills in the Flinders Range north of Adelaide in South Australia, where there are an enormous number of well-preserved impressions in shallow-water quartzite stratigraphically situated some 500 metres below the base of the Cambrian System (see below *Cambrian life*). These are impressions of soft-bodied organisms that resemble modern jellyfish, worms, sponges, and sea pens, among which more than 60 species have been named. Comparable impressions are known from many parts of the world in the youngest Precambrian sediments, such as those at Charnwood in central England and in Ukraine, Siberia in Russia, Namibia, southeastern Newfoundland in Canada, and North Carolina in the eastern United States. Finally, there is the intriguing question as to when sexual division arose in life-forms. The American paleobiologist J. William Schopf has pointed out that in the abundant microflora of the 900-million-year-old Bitter Springs Formation of central Australia, some eukaryotic algae have cells in various stages of division into tetrahedral sporelike forms. These resemble the tetrad of spore cells of living plants known to develop by sexual division. In effect, by the end of the Precambrian the conditions were set for the explosion of life at the start of the Phanerozoic that ultimately led to the emergence of humankind. (B.F.W.)

Paleozoic Era

Major divisions

The Paleozoic (from the Greek for ancient life) is bounded by major events in the history of life. It began about 540 million years ago with an extraordinary diversification of marine animals and ended about 245 million years ago with the greatest extinction event in Earth history. The major divisions of the Paleozoic Era, from oldest to youngest, are the Cambrian, Ordovician, Silurian, Devonian, Carboniferous, and Permian periods. Some geologists recognize the Mississippian and Pennsylvanian periods in place of the Carboniferous (see Table 4).

Paleozoic rocks are widely distributed on all continents. Most are of sedimentary origin, and many show evidence of deposition in or near shallow oceans. Among the more useful guide fossils for correlation are trilobites (Cambrian to Ordovician), graptolites (Ordovician to Silurian), conodonts (Ordovician to Permian), ammonoids (Devonian to Permian), and fusulinids (Carboniferous to Permian).

On a global scale, the Paleozoic was a time of continental assembly. Cambrian continents were scattered, but none covered either pole, and the average world climate was probably warmer than it is today. The continent of Laurentia, composed mostly of present-day North America and Greenland, lay across the equator and remained there even after joining with other continents. By Ordovician time the large continent of Gondwana, consisting primarily of present-day Africa, Antarctica, Australia, South America, southern Europe, much of the Middle East, and India, began to move over the South Pole. The distribution of extensive glacial deposits has been used to track the movement of parts of Gondwana over and around the South Pole during the remainder of the Paleozoic. Parts of Gondwana, because of its large size, also extended into tropical latitudes. Siberia, essentially the large Asian part of what is now Russia, was a separate continent during the early and middle Paleozoic, when it moved from equatorial to north temperate latitudes. Baltica, composed mostly of present-day northern Europe (including Scandinavia), moved across the equator from southern cool temperate into northern warm latitudes during the Paleozoic, and it collided with and joined Laurentia during early Devonian time. Continued tectonic plate movements resulted in the final assembly of the supercontinent of Pangaea by the end of the Paleozoic. Such mountainous regions as the Appalachians, Caledonides, and Urals were originally deformed by the Paleozoic collision of the lithospheric plates. Large areas of all continents were episodically inundated by shallow seas, with the greatest inundations during the Ordovician and early Carboniferous periods.

At the beginning of the Paleozoic, animals were restricted to the oceans, and land plants had not appeared. About half of all animal phyla, especially those with hard shells and mineralized skeletons, originated during the early and middle Cambrian. The biota rapidly diversified throughout the Cambrian and Ordovician as life-forms adapted to virtually all marine environments. In numbers of described marine species, trilobites are the dominant kind of fossil in Cambrian rocks, whereas brachiopods predominate in Ordovician to Permian rocks.

Conquest of the land by life-forms

Several different kinds of organisms independently adapted to living on land, primarily during the middle Paleozoic. Leafless vascular plants (psilophytes) and invertebrate animals (centipede-like arthropods) were both established on land at least by Silurian time. Vertebrate animals made the transition to land via evolution of amphibians from air-breathing crossopterygian fish during the Devonian. Further conquest of the land became possible during the Carboniferous as dependence on moist environments for depositing spores and shell-less eggs was overcome, as plants evolved seeds (seed-fern origin), and as animals evolved amniote eggs with protective shells (reptile origin). Flight was first achieved also during the Carboniferous, as insects evolved wings.

The great extinction event at the end of the Paleozoic Era eliminated such major invertebrate groups as the blastoids, fusulinids, and trilobites. Other major groups, as, for example, the ammonoids, brachiopods, bryozoans, corals, and crinoids, were severely decimated but managed to survive. It has been estimated that as many as 95 percent of the marine invertebrate species perished during the late Permian. Extinction rates were much lower among vertebrates, both aquatic and terrestrial, and among plants. Causes of the extinction are not clear, but they may be related to changing climate and exceptionally low sea level. Although of lesser magnitude, other important mass extinctions occurred at the end of the Ordovician and during the late Devonian.

CAMBRIAN PERIOD

General considerations. The Cambrian, the earliest time division of the Paleozoic Era, extended from about 540 to 505 million years ago. Rocks formed or deposited during this time are assigned to the Cambrian System, which was named in 1835 by Adam Sedgwick for successions of slaty rocks in southern Wales and southwestern England. The corresponding period and system names are derived from Cambria, the Roman name for Wales.

As originally described, the Cambrian System was overlain by the Silurian System, which was named, also in 1835, by Roderick I. Murchison. Subsequent disagreement between Sedgwick and Murchison over the definition and placement of the Cambrian–Silurian boundary led to a bitter controversy that involved many British geologists. The problem persisted until after the deaths of both Sedgwick and Murchison in the 1870s and the eventual adoption of an intervening system, the Ordovician, which was proposed in 1879 by Charles Lapworth.

Rocks in the Cambrian-type area were divided by Sedgwick into what he called Lower, Middle, and Upper Cambrian. These rocks, however, are so poorly exposed, structurally complicated, and sparsely fossiliferous that they have had little influence on development of modern concepts of the Cambrian and its subdivisions. In fact, much of the type Cambrian has been reassigned to either the Precambrian or the Ordovician. Rocks in Wales that are now assigned to the Cambrian System roughly correspond to Sedgwick's Lower Cambrian.

Boundaries and subdivisions. The lower boundary of the Cambrian System is defined at a formal global stratotype section and point (GSSP), which was ratified by the International Union of Geological Sciences (IUGS) in 1992. The stratotype section is located at Fortune Head on the Burin Peninsula of southeastern Newfoundland in Canada. It contains a thick and continuous marine succession of mostly shale, siltstone, and sandstone. The stratotype point, representing a moment in time, is in the lower part of the Chapel Island Formation. It coincides with the base of the *Phycodes pedum* biozone and is close to the lowest stratigraphic occurrence of diverse shelly fossils. Many supplementary sections were investigated at boundary localities around the world before the stratotype was selected in Newfoundland. All these supplementary sections are important references for reconstructing the physical and biological histories of the boundary interval. Among the more thoroughly studied supplementary sections are those along the Aldan River of eastern Siberia and near K'un-ming in the Yunnan province of southern China.

The lower boundary of the Ordovician System indirectly defines the upper boundary of the Cambrian System. A formal boundary stratotype has not been selected, but work toward its selection is at an advanced stage. A working group sponsored by the IUGS has agreed to select a boundary stratotype close in age to the base of the Tremadoc Series, which has its type area in northern Wales. British geologists have traditionally assigned rocks and fossils of Tremadoc age to the Cambrian, whereas many others have assigned them to the Ordovician (see below *Ordovician Period: General considerations*). The stratotype for the Cambrian–Ordovician boundary is expected to be placed at the base of one of three closely spaced conodont zones and near the first appearance of planktonic (floating) graptolites. In rocks of this age, conodonts (toothlike microfossils produced by an extinct group of small, free-swimming marine animals) are among the best guide fossils for global time correlation, and planktonic graptolites have been used in defining the base of the Tremadoc Series and for zonation of the Ordovician System.

Cambrian series and stages

In most regions of the world, Cambrian rocks have been divided into lower, middle, and upper series (Table 5). The series boundaries, however, are not necessarily synchronous, because of differences in definition as well as problems in correlation. Some series have been further divided into stages, but these are mostly identifiable only within individual regions.

Cambrian rocks have a special biological significance, because they are the earliest to contain diverse fossils of animals. These rocks also include the first appearances of most animal phyla that have fossil records. Proliferation of organic lineages is called adaptive radiation, but Cambrian evolution produced such an extraordinary array of new body plans that the event has been referred to as the "Cambrian explosion." The beginning of this remarkable adaptive radiation has been used to divide the history of life on Earth into two unequal eons. The older, approximately 3-billion-year Cryptozoic Eon began with the appearance of life on Earth, and it is represented by rocks with mainly bacteria, algae, and similar primitive organisms. The younger, approximately half-billion-year Phanerozoic Eon, which began with the Cambrian explosion and continues to the present day, is characterized by rocks with conspicuous animal fossils.

Economic significance. Cambrian rocks are of moderate economic importance, as they provide a variety of resources. For example, ore bodies rich in such metals as lead, zinc, silver, gold, and tungsten have secondarily replaced Cambrian carbonate rocks, especially in parts of North America and Australia. Other carbonate rocks have been widely used as building stone and for making lime and portland cement. Large Cambrian phosphorite deposits are major sources of agricultural fertilizer in northern Australia, southwestern China, and southern Kazakhstan. Other Cambrian resources in China are mercury, uranium, and salt. Eastern Russia also has salt deposits of Cambrian age, as well as those of bauxite, the chief commercial source of aluminum. Some oil fields in southern Siberia produce oil from Lower Cambrian rocks.

Cambrian rocks. *Types and distribution.* Rocks of Cambrian age occur on all of the continents, and individual sections may range up to thousands of metres thick. The most fossiliferous and best-studied deposits are principally from marine continental-shelf environments. Among the thicker and better-documented sections are those in the Cordilleran region of western North America, the Siberian Platform of eastern Russia, and areas of central and southern China. Other well-documented, fossiliferous, but thinner sections are in Australia (especially western Queensland), the Appalachian Mountains of eastern North America, Kazakhstan, and the Baltic region (notably Sweden).

Lateral changes in the composition of Cambrian rocks resulted from regional differences in environments of deposition. Nearshore deposits are commonly composed of

Development of carbonate platforms

siliceous sandstone. This usually grades seaward into siltstone and shale, which formed by accumulation of finer-grained sediment in deeper water where the seafloor was less affected by wave action. Extensive carbonate platforms, analogous to the modern Bahama Banks, developed along some continental shelves that were in low latitudes during Cambrian time. Rapid production of carbonate sediment in this warm, shallow-water environment resulted in massive deposits of Cambrian limestone and dolomite. Examples are exposed in the Cordilleran region of North America, in north-central Australia, along the Yangtze River in central China, and along the Lena River emanating in Siberia. Few Cambrian rocks from land environments have been documented, and most of those are of limited areal extent. They mainly represent deposits of floodplains and windblown sand. Without plants or animals, the desolation of Cambrian landscapes must have rivaled that of any present-day desert. In the absence of plants with roots to hold soil in place, Cambrian lands in general probably eroded more rapidly than they do now.

Probable causes of the rise in Cambrian sea level

Relative sea level rose significantly during the Cambrian, but with fluctuations. This is indicated by both the geographic distribution and the stratigraphic succession of sedimentary deposits. In North America, for example, early Cambrian marine deposits covered only marginal areas, but late Cambrian marine deposits covered much of the continent. A similar distribution of marine rocks is present on other continents. In stratigraphic sections from continental shelves that were in low latitudes it is common for a basal, nearshore sandstone to be overlain by a transgressive succession of more seaward shale and carbonate rocks. Shelf sections from high latitudes may be mostly or entirely sandstone, or a basal sandstone may grade upward into shale, but most of these sections contain evidence of marine transgression. Exceptions to the general Cambrian sea-level pattern are commonly attributable either to local tectonism or to different rates of sediment accumulation. The most likely explanation fór the general rise in Cambrian sea level seems to be increased thermal activity and related swelling of spreading ridges between lithospheric plates, which would displace vast quantities of seawater. It has been suggested that the general Cambrian transgression exerted an influence on adaptive radiation by greatly increasing the area of shallow seas where life was most abundant.

Correlation. Time correlation of Cambrian rocks has been based almost entirely on fossils. The most common fossils in Cambrian rocks are trilobites (Figure 17), which evolved rapidly and are the principal guide fossils for biostratigraphic zonation in all but rocks below the Atdabanian Stage or those of equivalent age (Table 5). Until the mid-1900s almost all trilobite zones were based on members of the order Polymerida. Such trilobites usually have more than five segments in the thorax, and the order includes about 95 percent of all trilobite species. Most polymeroids, however, lived on the seafloor, and genera and species were mostly endemic to the shelves of individual Cambrian continents. Therefore, polymeroid trilobites are useful for regional correlation but have limited value for intercontinental correlation, which has been difficult and subject to significant differences in interpretation.

Use of agnostoid fossils for intercontinental correlation

From the 1960s, investigators began to recognize that many species of the trilobite order Agnostida have intercontinental distributions in open-marine strata. These trilobites are small, rarely exceeding a few millimetres in length, and they have only two thoracic segments. Specialized appendages, which were probably useful for swimming but unsuitable for walking on the seafloor, suggest that they were pelagic. Agnostoids make up less than 5 percent of all trilobite species, but individuals of some agnostoid species are abundant. This fact, together with their wide geographic distribution and rapid evolution, makes them valuable for refined intercontinental correlation. Agnostoids first appear in upper Lower Cambrian rocks but did not become common or diversify significantly until the middle of the Cambrian. Therefore, agnostoids have their greatest biostratigraphic value in the upper half of the Cambrian System. A comprehensive trilobite zona-

tion in Sweden has frequently been cited as a standard for correlation.

Other kinds of fossils have had more limited use in Cambrian biostratigraphy and correlation. Among them are the archaeocyathan sponges in the Lower Cambrian and brachiopods throughout the Cambrian, but use of both groups has been hampered by problems of endemism. Small mollusks and other small shelly fossils, mostly of problematic affinities, have been employed for biostratigraphy in the Tommotian Stage, but their utility is also limited by endemism. Conodonts appear in the uppermost Precambrian but are rare in most Cambrian rocks except those of latest Cambrian age, when adaptive radiation of conodont animals accelerated. Wide species distributions, rapid evolution, and abundance make conodonts excellent indexes for global biostratigraphy in uppermost Cambrian to uppermost Triassic rocks.

Since roughly the 1980s, trace fossils have been used with limited precision to correlate uppermost Precambrian and basal Cambrian strata. Although the biostratigraphic use of such fossils has many problems, they nevertheless demonstrate progressively more complex and diverse patterns of locomotion and feeding by benthic (bottom-dwelling) marine animals. For example, *Phycodes pedum,* which initially appears in basal Cambrian deposits, is the first regularly branching burrow pattern.

Cambrian environment. *Paleogeography.* The geography of the Cambrian world differed greatly from that of the present. The geographic reconstruction in Figure 18 is based on integrated geologic and biological evidence. Fossils in continental-shelf deposits indicate the presence of at least three major faunal provinces during much of the Cambrian Period.

The most distinct faunal province surrounded the continent of Laurentia. Paleomagnetic evidence indicates that Laurentia was located over the equator during most or all of Cambrian time. This geographic interpretation is supported by the presence of thick, warm-water, carbonate-platform deposits that accumulated in a broad belt encircling the continent. These carbonates are commonly flanked on the inner shelf by lagoonal shale and nearshore sandstone. On the outer shelf, the carbonates commonly grade into laminated mudstone and shale that accumulated in deeper water. At times, two almost mutually exclusive subfaunas were separated by temperature and salinity barriers in the shallow water on the carbonate platforms. Inner, restricted-shelf deposits are characterized by sparse, low-diversity faunas that tend to be highly endemic. Outer, open-shelf deposits are characterized by common to abundant, high-diversity faunas that are widely distributed around the continent. Fossils are usually most abundant and most diverse near the outer margin of the carbonate platform. Because Laurentia has remained nearly intact structurally, it is ideal for studying the relationships between Cambrian environments and faunas around a low-latitude Cambrian continent.

Another Cambrian faunal province surrounded the small continent of Baltica, which was located in middle to high southern latitudes. Cambrian shelf deposits of Baltica are relatively thin, rarely exceeding 250 metres in thickness, and are composed of primarily sandstone and shale. Seemingly as a consequence of cool-water environments, carbonate deposits are relatively minor and very thin. The wide distribution of many species from the nearshore to deep-shelf environments of Baltica suggests no significant restriction in shelf dispersal like that caused by the shallow carbonate platforms of Laurentia.

Largest Cambrian faunal province

The largest Cambrian faunal province is that around the continent of Gondwana, which extended from the low northern latitudes to the high southern latitudes, just short of the South Pole. Rocks and faunas of Gondwana show major changes that correspond to its great size and wide range of climates and environments. The Antarctic and Australian sectors of Gondwana were in low latitudes and have extensive carbonate deposits, although those of Antarctica are poorly exposed through the present-day polar ice cap. Faunal differences and paleomagnetic evidence suggest that present-day North and South China were on separate tectonic plates. Extensive carbonate deposits in both regions, however, indicate that both plates were in low latitudes. South China has strong faunal similarities to both Australia and Kazakhstan, but details of the Cambrian geographic relationships remain unclear.

Several terranes seem to have been near or attached along the margin of Gondwana in high southern latitudes (the northern Africa sector), but many details of their Cambrian geographic relations are unknown. (Terranes are fault-bounded fragments of the Earth's crust characterized by a geologic history markedly different from that of neighbouring crustal segments.) These terranes now make up much of southern Europe and parts of eastern North America. Cambrian deposits in all the terranes are chiefly sandstone and shale and include few or no carbonates. Their faunas closely resemble those of Baltica at generic and higher taxonomic levels, but differences at the species level suggest some geographic separation.

Siberia was a separate continent located in the low latitudes between Laurentia and Gondwana. Faunal affinities suggest that it lay relatively close to equatorial Gondwana.

Present-day Kazakhstan seems to be composed of several microcontinental blocks that were in all likelihood separated during the Cambrian. These blocks were amalgamated after the Cambrian, and the composite continent, Kazakhstania, collided with Siberia during the late Paleozoic.

Few Cambrian faunas from continental-slope and deep-ocean environments are known. Limited information from these is important, however, for demonstrating affinities between deep, cool-water faunas from all latitudes and shallow, cool-water faunas from high latitudes. Close similarity between the observed distribution patterns of Cambrian and modern marine arthropods has been used as persuasive evidence for thermally stratified Cambrian oceans in lower latitudes and for a thermocline separating warm-water and cool-water layers (Figure 19). The inferred thermocline as well as wide oceanic separation were likely causes for the high endemism of the Laurentian faunal province. This interpretation is supported by Middle Cambrian deposits in North Greenland where, in a few tens of kilometres, normal Laurentian shelf-margin trilobite faunas grade into deepwater faunas like those in the shallow-shelf deposits of Baltica. In a similar pattern, trilobite species in deepwater faunas of Late Cambrian age in the western United States and southeastern China are the same, but shallow-water faunas of the same age in the two regions have few genera in common.

As large lithospheric plates continued to move during the Phanerozoic Eon, terranes of various sizes were displaced. Endemic Cambrian fossils, in conjunction with such other geologic evidence as physical stratigraphy, have been useful in helping to identify the geographic origins of some terranes, particularly those that have undergone substantial displacement. Examples are northern Scotland with Laurentian faunas, eastern Newfoundland with Baltic faunas, southern Mexico (Oaxaca) with Gondwanan (South American) faunas, and west-central Argentina (Precordillera) with Laurentian faunas.

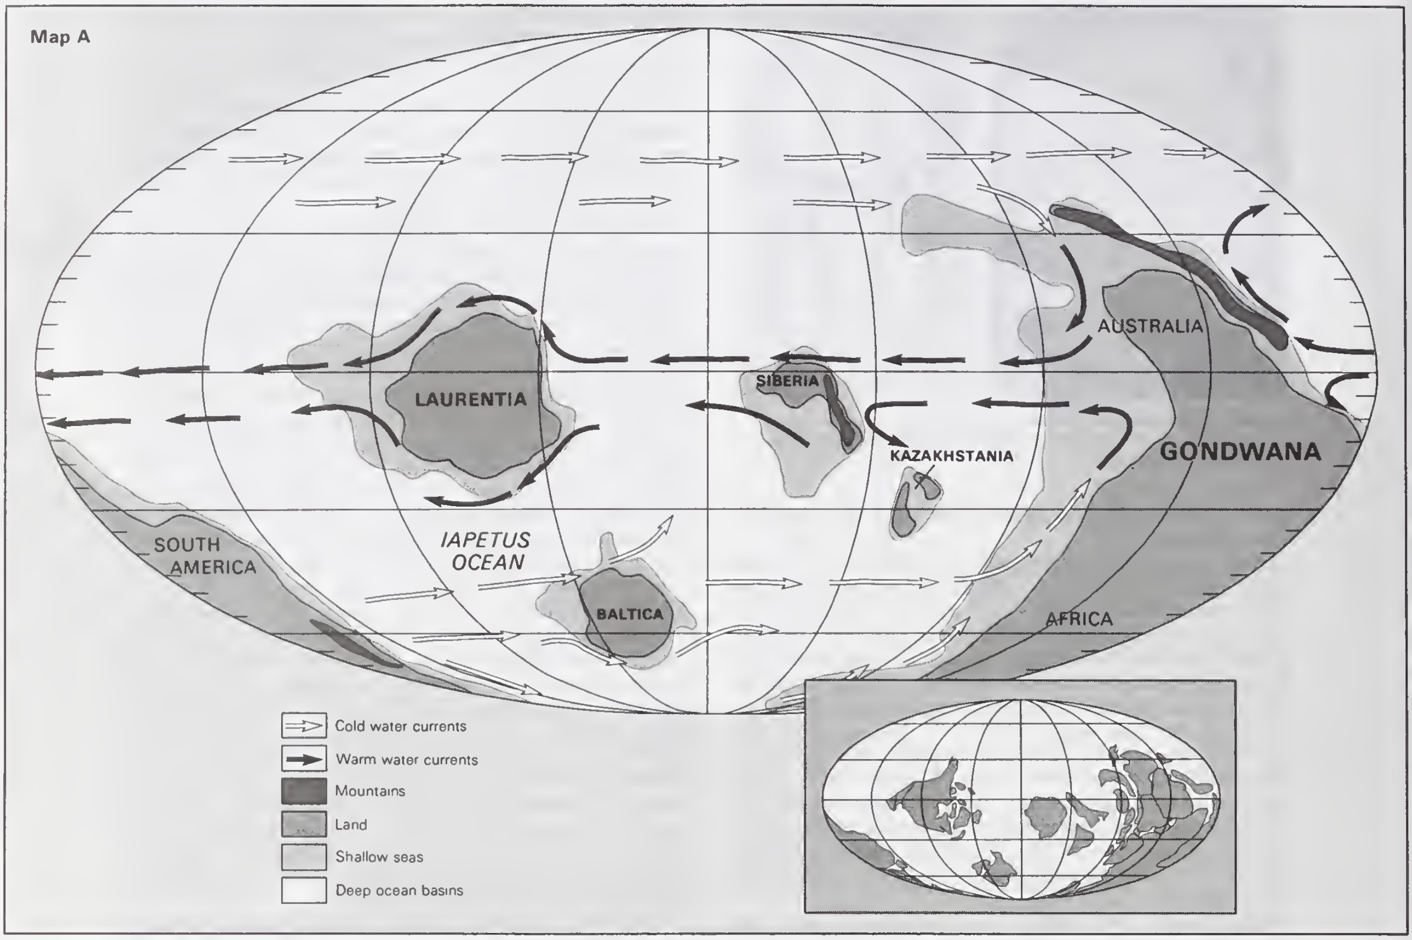

Figure 18: Distribution of landmasses, mountainous regions, shallow seas, and deep ocean basins during the Late Cambrian. Included in the paleogeographic reconstruction are cold and warm ocean currents. The present-day coastlines and tectonic boundaries of the configured continents are shown in the inset at the lower right. Map B provides a "backside" view of the reconstruction shown in Map A.

Adapted from C R Scotese, The University of Texas at Arlington

Another important consequence of continued plate movement has been the formation of large mountain ranges by crumpling where plates have collided. Pressure and heat generated during collisions since the Cambrian have folded, faulted, and metamorphosed significant volumes of Cambrian rock, especially that from the outer margins and slopes of many continental shelves. No crustal rocks in today's oceans have been found to be older than Mesozoic in age, and apparently most pre-Mesozoic deposits that accumulated in the deep ocean basins have been destroyed by subduction into the Earth's interior.

Abrupt global changes in sea level

Relatively abrupt changes in sea level may have significantly influenced Cambrian environments and life. A global drop in sea level is suggested by extensive unconformities (*i.e.,* interruptions in the continuity of depositional sequence) and changes in sedimentary rocks near the Early–Middle Cambrian boundary. The time represented by such unconformities in sectors of Laurentia and Baltica bounding the Iapetus Ocean has been called the Hawke Bay event. An apparent absence of a coeval unconformity in western North America seems to be an anomaly. Thick, uninterrupted shelf deposits in this sector of Laurentia, however, may have resulted from abnormal shelf subsidence caused by cooling of crustal rocks following a late Precambrian plate-rifting event. Temporal correlations with unconformities on other continents lack precision. Nevertheless, it is perhaps significant that a number of characteristic Early Cambrian animal groups were either exterminated or severely restricted in their geographic distribution at about the same time in the world's shallow-shelf environments. Among biostratigraphically important trilobites, the olenellids were exterminated around Laurentia, the holmiids were killed off around Baltica, and the redlichiids vanished around Gondwana. Also, diverse and abundant reef-dwelling archaeocyathans disappeared from most low-latitude, warm-water continental shelves.

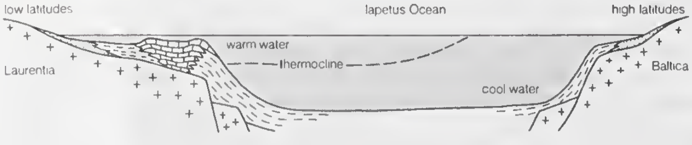

Figure 19: Hypothetical cross section of the Iapetus Ocean during Middle Cambrian time (vertical scale greatly exaggerated).

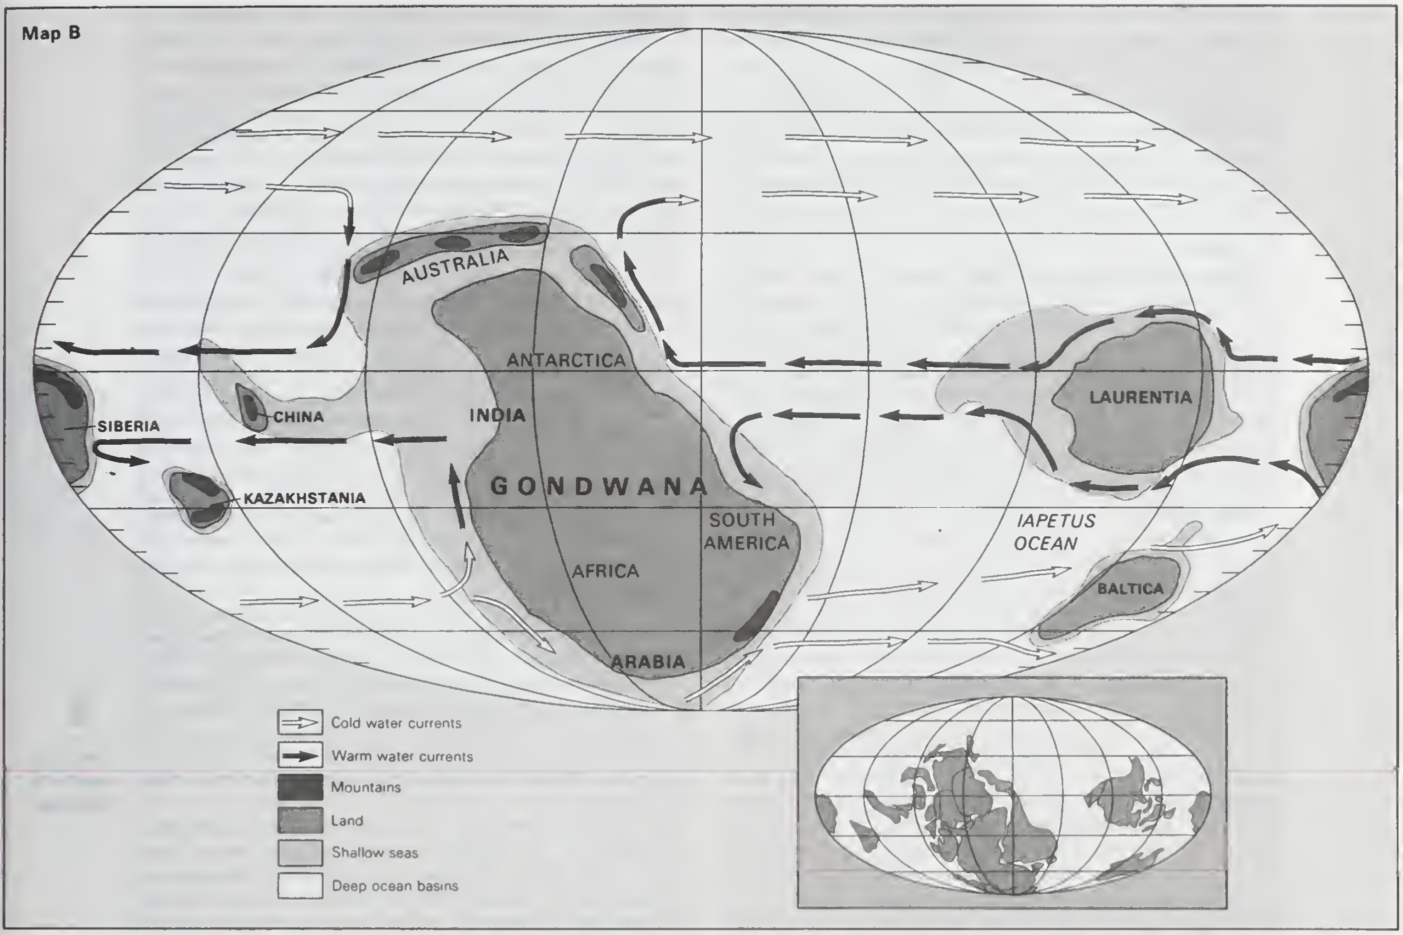
A significant rise in sea level is suggested by rather abrupt and extensive displacements in sedimentary environments and biotas in the middle Middle Cambrian (the *Ptychagnostus gibbus* zone). Lowland areas were flooded, as in parts of Baltica. In warm-water shelf sections of the world, it is common for coarse-grained, shallow-water, carbonate rocks to be abruptly overlain by fine-grained, deeper-water, laminated limestone or shale. Adaptive radiation of the pelagic agnostoid trilobites was greatly accelerated in open-oceanic environments following this event, perhaps in response to expanded habitats.

Missing faunas and an unconformity, which define the boundary between the Dresbachian and Franconian stages in peripheral areas of North America, suggest another significant drop in sea level during the early Late Cambrian. Evidence for two other lesser changes in Cambrian sea level has been identified near the Cambrian–Ordovician boundary. Associated minor unconformities have provided a problem for selection of a boundary stratotype, which ideally should be located in an uninterrupted stratigraphic section.

Sites of volcanic activity

Several regions of Cambrian volcanism have been identified. Australia was especially active, with large areas in the

Map B



northern and central regions covered by flood basalts during the Early Cambrian and with residual activity into the Middle Cambrian. Basalts and mafic intrusives in southeastern Australia formed in a volcanic island-arc setting during the Early and Middle Cambrian. Volcanic suites of similar age also are present in New Zealand and in parts of Antarctica (northern Victoria Land, Ellsworth Mountains, and Pensacola Mountains). Other significant Lower and Middle Cambrian volcanic deposits are present in southern Siberia and western Mongolia (Altai and Sayan mountains), eastern Kazakhstan and northwestern China (Tien Shan), and northeastern China. Cambrian volcanics are scattered along the easternmost margin of the United States, but most are probably island-arc deposits that were accreted to Laurentia after the Cambrian. In the southern United States (Oklahoma), granitic intrusives and basaltic and rhyolitic extrusives are associated with a large tectonic trough that was formed by Early and Middle Cambrian crustal extension.

Minor volcanic deposits, mainly ash beds and thin flows, are widely known. In general, these have received little study, but some are suitable for determination of isotopic ages. Zircons from a lower Lower Cambrian (pre-Tommotian) volcanic ash bed in New Brunswick, Can., have a uranium-lead age of 531 million years. Volcanic tuffs near inferred Tommotian–Atdabanian boundaries in both Morocco and southwestern China have yielded similar dates of 521 million years.

The tectonic history of the Paleozoic is much better known than that of the Precambrian. In general, however, late Precambrian history seems to have been characterized by continental fragmentation, whereas Paleozoic history was characterized by continental accretion. The Cambrian was a period of transition between those tectonic modes, and continents were scattered, apparently by fragmentation of a late Precambrian supercontinent. Major Cambrian and early Ordovician tectonism affected large areas of Gondwana in what are now Australia, Antarctica, and Argentina. Multiphase tectonism in Antarctica is called the Ross Orogeny, and in Australia it is known as the Delamerian Orogeny. At least some of the volcanic activity noted above, particularly that of volcanic island arcs, is evidence that seafloor spreading and crustal subduction were active geologic processes.

Paleoclimate. Global climate during Cambrian time was probably warmer and more equable than it is today. An absence of Cambrian glacial deposits and an abundance of widespread, warm-water, carbonate deposits both suggest higher average temperatures than at present. The absence of glacial deposits of Cambrian age is more notable because such deposits are common and widespread in the upper Precambrian, and they accumulated again during the Ordovician in northern Africa as Gondwana began to move over the South Pole. An apparent absence of either land or landlocked seas at the Cambrian poles may have prevented the accumulation of polar ice caps.

Cambrian life. The long history of life on Earth has been punctuated by relatively abrupt changes. Some have argued that the greatest change of all occurred in marine environments near the Precambrian–Cambrian boundary. Fossils from Cambrian rocks include the oldest representatives of most animal phyla having mineralized shells or skeletons. A lack of observed connecting links suggests that processes of biomineralization evolved independently in several phyla. Whether or not soft-bodied representatives of some of these phyla originated during the Precambrian but have no preserved record is a debated question. Nevertheless, the hard parts of Cambrian animals had a much greater potential for preservation than soft parts, and they mark the beginning of a diverse fossil record.

Fossil record of the Precambrian–Cambrian transition

Preservation of the record of the Precambrian–Cambrian transition was significantly affected by global changes in sea level. During latest Precambrian time, the sea level was relatively low, resulting in areally restricted oceans and expanded continents. Throughout much of the Cambrian, rising seas gradually flooded vast land areas. Sediment was eroded from the continents and deposited in adjacent seas. Because of low sea level, the sedimentary and fossil records of the Precambrian–Cambrian transition are generally most complete toward the outer margins of continental shelves. As a corollary, the time gap represented by the boundary surface generally increases in landward directions. Absence or serious incompleteness of a transitional record in most areas, particularly in those of classical Cambrian studies, contributed significantly to the long-held notion of an abrupt or sudden appearance of Cambrian fossils. This was compounded by a general deficiency in knowledge of Precambrian biotas before the mid-1900s.

Considering the biological importance of the Precambrian–Cambrian transition, it is somewhat surprising that the primary impetus for its detailed study came from a project undertaken to establish international agreement on a suitable boundary stratotype. Before the project was initiated in 1972, reasonably complete stratigraphic sections across the transition were either largely unrecognized or ignored. Since 1972, information about the transition has accumulated at an accelerating rate. Although many details remain to be learned, the general history of this momentous interval is becoming clear.

The Precambrian–Cambrian biotic transition, once thought to be sudden or abrupt, has been found to include a succession of events spread over many millions of years. It commences with the appearance of the animal kingdom (*i.e.,* multicelled organisms that ingest food), but the date and details of that event remain obscure. At least three informal phases in the transition can be identified by progressively more diverse and complex biotas.

The earliest phase, of late Precambrian age, is characterized by fossils of soft-bodied animals known from many localities around the world. These organisms may have appeared as early as 650 million years ago and are commonly called the Ediacaran fauna (see above *Precambrian time: Precambrian life*). The fossils are predominantly the imprints of soft-bodied animals. Their extraordinary preservation, usually in sandstone or shale, was probably the result of rapid burial and protection by smothering sediment. Most of the fossils are relatively simple, and many resemble worms, sea pens, and jellyfish. Dwelling traces like those of modern sea anemones are also common. Higher taxonomic assignments are controversial, however, because critical diagnostic features are not evident. Some paleontologists have assigned Ediacaran body fossils to the extant phyla Annelida, Coelenterata, and Arthropoda, whereas others have regarded them as members of extinct taxonomic groups of high rank. Some adherents of the latter viewpoint have suggested that the Ediacaran fauna was terminated by a major extinction event, but direct evidence of an abrupt faunal replacement has not been detected in any stratigraphic section.

Other kinds of fossils also provide valuable clues about life during Ediacaran time. Photosynthetic organisms include unicellular blue-green algae (cyanobacteria) and acritarchs (probable algae), both of low diversity. Individuals of some species were probably abundant, however, and may have been an important source of food for Ediacaran animals. Hard parts of animals, primarily known from Africa and China, are mainly dwelling tubes composed of calcium carbonate and other compounds. Most were probably secreted by sessile, filter-feeding, wormlike animals. Although rare and of low diversity, these forms are significant because they signal the advent of biomineralization. The oldest unequivocal trace fossils, mainly crawling trails, are also of Ediacaran age. The trails suggest that locomotion of the trace makers was accomplished by waves of muscular contraction, like that in annelids and sea slugs, and not by legs. All but the latest Ediacaran trace fossils are relatively simple, suggesting limited and primitive behaviour patterns. Their low diversity further suggests that few kinds of mobile animals lived on the Ediacaran seafloor.

Oldest trace fossils

The second phase of the Precambrian–Cambrian biotic transition is characterized by a marked increase in the diversity of its shelly fauna and a lack of trilobites. It is near the lowest stratigraphic occurrence of this fauna that the Precambrian–Cambrian boundary stratotype has been placed. The fauna includes that of the Tommotian Stage, as applied in Russia, and it has often been referred to as the Tommotian fauna. It is known from many localities around the world, but time correlations lack precision. A general acceleration in biotic diversity during this second phase is the beginning of the so-called Cambrian explosion.

Fossils of the second phase, which may be locally abundant, represent several new animal groups of Paleozoic aspect. Calcified archaeocyathan sponges diversified rapidly and were the first skeletal metazoans to develop a modular growth habit. They also evolved a complex symbiotic relationship with reef-building blue-green algae. Mollusks, preserved in both shale and limestone, include at least four classes (Monoplacophora, Gastropoda, Hyolitha, and Rostroconchia). Brachiopods made their appearance but are low in diversity. Several problematic groups are represented by an astonishing array of small mineralized tubes, scales, and spicules. The presence of arthropods, the first animals to develop legs, is indicated by characteristic trace fossils. The skeletal remains of arthropods are not preserved in the fauna, ˛however, presumably because they were not mineralized. Other trace fossils show a marked increase in abundance and diversity as well as an expansion of behaviour patterns that reflect improvements in locomotion, greater ability to penetrate sediment, and new foraging strategies.

The third phase of the Precambrian–Cambrian biotic transition commenced with the appearance of mineralized trilobite skeletons, which approximately correlates with the base of the Atdabanian Stage of the Lower Cambrian, as conceived in Russia. Subsequent adaptive radiation of the trilobites was exceptional, and their remains dominate most later Cambrian deposits. For this reason, the Cambrian Period has sometimes been called the "Age of Trilobites."

Predominance of trilobites

The known Cambrian biota was restricted to marine environments. At least 11 extant animal phyla (Annelida, Arthropoda, Brachiopoda, Chordata, Ctenophora, Echinodermata, Hemichordata, Mollusca, Onychophora, Porifera, and Priapulida), including most of those with a fossil record, first appear in Cambrian rocks. Most of these rapidly diversified as they seemingly adapted to numerous unfilled ecological niches. Another five phyla (Nemertea, Phoronida, Platyhelminthes, Pogonophora, and Sipuncula) are questionably known from Cambrian fossils. The only extant animal phylum with a good fossil record that is not known from Cambrian rocks is the Bryozoa, which first appears in rocks of Early Ordovician age. A summary of the principal biotic groups of the Cambrian is given below.

Cambrian photosynthetic organisms, the primary food of animals, are entirely unicellular. These organisms include a variety of bacteria and algae of the kingdoms Monera and Protista. Their evolution, like that in associated animals, shows a marked acceleration in adaptive radiation and biomineralization near the base of the Cambrian. A new calcareous benthic (bottom-dwelling) flora dominated by blue-green algae appeared. Some of these organisms formed mounds on the seafloor. Others formed small, concentrically laminated, marble- or biscuit-shaped structures called oncoids, which were locally abundant. Although it was rarely preserved, there existed a noncalcareous benthic flora that also was dominated by blue-green algae. By at least Middle Cambrian time, some noncalcareous green algae (Chlorophyta) had become common. In North America and Siberia, the axes of one species, *Margaretia dorus,* exceeded two centimetres in diameter and were probably more than one metre in height. Such large size is attained by modern green algae only in warm, equatorial oceans. The phytoplankton, consisting of acritarchs and blue-green algae, also diversified near the base of the Cambrian. Acritarchs are widespread in many kinds of marine rocks and seem to have potential for an improved zonation of Lower Cambrian rocks. They are difficult to study, however, because of their microscopic size.

Cambrian faunas, like those of the present day, are commonly dominated in numbers and kind by members of the phylum Arthropoda. Calcification of skeletons by the beginning of Atdabanian time contributed to an abundant fossil record of the class Trilobita, of which some details have been discussed above. Many hundreds of genera and thousands of species of Cambrian trilobites have been described worldwide. Rates of evolution in Cambrian trilobites were relatively rapid, resulting in short stratigraphic ranges and giving them much value for biostratigraphic correlation. Representatives of the class Ostracoda, characteristically enclosed by a bivalved carapace, also appeared near the base of the Atdabanian. Compared to trilobites, however, ostracods are generally rare and of low diversity throughout the Cambrian, except in some rocks of Australia and China. Extraordinary preservation at rare localities indicates that many other kinds of arthropods were at least locally more abundant and more diverse than the trilobites. These other arthropods had unmineralized skeletons, and some may represent extinct classes.

Abundance of sponges

Sponges (phylum Porifera) are commonly represented in Cambrian faunas. Archaeocyathan sponges, characterized by cup-shaped skeletons with double calcareous walls and numerous pores, are abundant and diverse in some Early Cambrian deposits. They have been used for provincial biostratigraphic zonation, especially in Australia and Siberia, and archaeocyathan taxa define all but the lowest one of the five Lower Cambrian stages in Siberia (Table 5). Archaeocyathans are common only in regions that were in low Cambrian latitudes, including Antarctica, Australia, China, Kazakhstan, Siberia, and North America. Their latitudinal distribution is similar to that of modern colonial corals, suggesting adaptation to similar ecological controls in warm shallow seas. Archaeocyathans nearly disappeared at the end of the Early Cambrian, but rare species survived until middle Late Cambrian time, after which the group became extinct. Other common Cambrian sponges had skeletons of siliceous spicules, which readily disaggregated after death, making their identification at lower taxonomic levels difficult, if not impossible. At rare localities where preservation is exceptional, including articulated skeletons and associated soft-bodied taxa, spicular sponges are second only to arthropods in species diversity. This suggests that Cambrian sponges were much more common and more diverse than is indicated by the known fossil record. Limited information indicates that species of spicular sponges evolved slowly during the Cambrian, resulting in relatively long stratigraphic ranges.

Brachiopod shells are present in many Cambrian continental-shelf deposits. In total number of species that have been described from Cambrian rocks, brachiopods are second only to trilobites. Species diversity, however, is generally low to moderate at most localities. Phosphatic shells of the class Inarticulata are normally much more common and more diverse than are calcareous shells of the class Articulata. These abundance and diversity relationships are usually reversed in post-Cambrian rocks.

The phylum Echinodermata (some present-day representatives of which are sea urchins and starfish) had a major adaptive radiation during the Cambrian Period. The number of classes increased from three in the Early Cambrian to eight in the Middle Cambrian. Only one of these, the Eocrinoidea, is known from many species, but the described record seems to be grossly incomplete. Skeletal plates in early echinoderms were not rigidly connected, and they readily disaggregated after the death of an animal. Consequently, it is rare to find articulated skeletons that can be identified at lower taxonomic levels. In some Cambrian limestones, however, skeletal plates of echinoderms are a dominant sedimentary constituent, indicating the existence of innumerable animals and suggesting far greater diversity, especially at low taxonomic levels, than has been recorded. As in some modern echinoderm species, it is common for those in the Cambrian to show evidence of a gregarious habit and patchy distribution. Most of the Cambrian echinoderms were suspension and detritus feeders, and it was only after the Cambrian that herbivores and carnivores became common. All classes of echinoderms that were present during the Cambrian, except the Crinoidea, subsequently became extinct.

Proliferation of mollusks

The phylum Mollusca also underwent significant adaptive radiation during the Cambrian, with the appearance of the classes Monoplacophora, Gastropoda, Pelecypoda (synonymous with Bivalvia), Cephalopoda, Polyplacophora, Rostroconchia, Hyolitha, and Stenothecoida. (The latter three are now extinct.) The only molluscan class that appeared after the Cambrian is the Scaphopoda (tusk or tooth shells), which originated during the Ordovician. A small variety of mollusks is present in the shelly fauna of the earliest Cambrian. Mollusk shells usually are absent or rare in later Cambrian rocks, but at a few localities they are common to abundant. The small conical shells of hyoliths are the kind most commonly preserved in Cambrian rocks.

Other new Cambrian phyla largely lack biomineralization and have a poor fossil record. The Hemichordata is represented by rare sessile graptolites (order Dendroidea) of the class Graptolithina, which appeared during the Middle Cambrian. Appearance of the more common planktonic graptolites (order Graptoloidea) has been informally used to define the Cambrian–Ordovician boundary, and the formal boundary stratotype is expected to be established close to this biohorizon. Cambrian worm phyla include the Annelida, Priapulida, and probable Pogonophora, but these are mainly known from localities where preservation was extraordinary. Other rarely represented phyla are the Onychophora, with leglike lobopodia, and Ctenophora (comb jellies).

The origin of the phylum Chordata is unclear. If primitive conodont-like fossils (paraconodonts) are included, as argued by some paleontologists, the phylum appeared during the late Precambrian. Rare, soft-bodied, possible chordates have been described from Lower Cambrian rocks. The oldest unequivocal chordate remains are isolated bony plates of jawless fish in Upper Cambrian rocks of the western United States.

Trace fossils, as discussed above, provide independent evidence of accelerated animal diversification and a distinct increase in the complexity of animal behaviour near the beginning of the Cambrian Period. Other evidence from trace fossils indicates changes in Cambrian bioturbation, the churning and stirring of seafloor sediment by animal forms. Late Precambrian (Ediacaran) trace fossils from around the world are in the main surface trails and show little evidence of sediment burrowing. Quantitative study in the western United States has shown that a significant increase in bioturbation occurs between pre-trilobite (Tommotian) and trilobite-bearing (Atdabanian) Lower Cambrian rocks. Throughout the Cambrian, bioturbation was more intensive in nearshore and inner-shelf environments than in more offshore settings. The depth of bioturbation in carbonate environments of the inner shelf was consistently less than a few centimetres throughout Cambrian time.

Cambrian deposits with soft-bodied organisms

Modern biotas are largely dominated by soft-bodied organisms, whereas the fossil record is overwhelmingly dominated by the hard parts of organisms. Rare deposits of fossils with soft parts are therefore of great importance in helping to establish the original diversity and ecology of ancient biotas. Among the most famous soft-bodied biotas is that in the Burgess Shale of western Canada (British Columbia), which is early Middle Cambrian in age. Tens of thousands of complete specimens, many with soft parts preserved in remarkable detail, were apparently buried by submarine slumping of sediment on the continental shelf of Laurentia. Fossils from the Burgess Shale have been used to demonstrate the presence of a complex community as diverse in habit, structure, and adaptation as many modern communities. If isolated, fossils with hard parts would constitute a typical Cambrian fauna, but they represent only about 40 percent of the genera in the Burgess Shale, a proportion similar to that in modern faunas on continental shelves.

Other less diverse Cambrian deposits with soft-bodied organisms have been discovered in such places as South Australia, China (Yunnan), North Greenland, Sweden, and the United States (Utah and Pennsylvania). Some of these are important in demonstrating that the biota of the Burgess Shale is unusual only in preservation and not in composition. They also demonstrate that some of the soft-bodied taxa have substantial geologic ranges and wide geographic distributions. Extraordinary preservation of Late Cambrian arthropods in Sweden is especially notable, as the bodies and appendages remain largely uncrushed and the integument retains many fine structures, including setae and pores.

Minor extinction events occurred sporadically throughout the Cambrian Period. One near the end of the Early Cambrian was apparently related to global marine regression. At least three Late Cambrian events primarily affected low-latitude shelf faunas and have been used in North America to define biostratigraphic units called biomeres. (Such units are bounded by sudden nonevolutionary changes in the dominant elements of a phylum.) Each of the Cambrian biomere events eliminated several trilobite families, which collectively contained most of the genera and species that were living on the continental shelves. Less attention has been paid to extinction patterns among other invertebrates, but some evidence of corresponding extinctions among brachiopods and conodonts is available. Geochemical evidence suggests that the biomere extinctions were probably caused by abrupt drops in water temperature. Oxygen isotopes from the skeletons of bottom-dwelling trilobites associated with one biomere boundary in Texas indicate a drop in water temperature of about 5° C (9° F) at the boundary. A comparable decrease in temperature would kill the larvae of many modern marine invertebrates that live in warm oceans. Following each Cambrian extinction, shelf environments were repopulated by low-diversity trilobite faunas of relatively simple form, which apparently emigrated from deeper and cooler off-shelf environments. In effect, every one of the biomere events was followed by an adaptive radiation of new taxa, especially among the trilobites. (R.A.R.)

ORDOVICIAN PERIOD

General considerations. The Ordovician, the second oldest period of the Paleozoic Era, is thought to have covered the span of time between 505 and 438 million years ago (see Table 4), though radiometric age determinations may range from as much as 515 to 435 million years ago. The rocks that originated during the period make up the Ordovician System. The designation Ordovician was proposed in 1879 by the English geologist Charles Lapworth, who derived it from Ordovices, the name of a Celtic tribe that had inhabited a part of North Wales at the time of the Roman invasion of Britain. Lapworth applied the term to a segment of rocks exposed in the Arenig mountains located roughly 40 kilometres west of the Welsh–English border and eastward to the Bala area of North Wales. This area constitutes a type area (or section), because the fossil faunas in the rocks are, as Lapworth recognized, characteristic of a unique geologic time interval. The stratigraphic position of the Ordovician rocks above those bearing fossil faunas typical of the Cambrian and beneath those bearing faunas representative of the Silurian is readily demonstrable. This section lies between an anticlinorium on the west in which Cambrian rocks are exposed and a synclinorium on the east in which fossiliferous Silurian rocks occur. (An anticlinorium is a large anticline on which minor folds are superimposed, while a synclinorium is a large syncline on which such folds are superimposed.)

Ordovician type area

Lapworth had in mind faunal aggregates as the basis for establishing not only the Ordovician but also the Cambrian and Silurian, stating that he saw

> three distinct faunas, as broadly marked in their characteristic features as any of those typical of the accepted systems of a later age. The necessity for tripartite grouping of Lower Palaeozoic rocks and fossils, in partial accordance with this fact, has been very generally acknowledged for the last thirty years.

With this discussion, Lapworth resolved a long-standing debate among British geologists concerning the division of the Lower Paleozoic rocks—those beneath the Devonian Old Red Sandstone. (R.I. Murchison had asserted that only the Silurian encompassed the Lower Paleozoic, while A. Sedgwick had proposed that the latter be divided into two periods, the Cambrian and the Silurian. For a fuller discussion of this controversy, see the sections *Cambrian Period* and *Silurian Period.*)

Trilobites, brachiopods, and graptolites were the major organisms considered in identifying Ordovician rocks. The distinctive brachiopod–trilobite–graptolite faunas regarded as characteristic of the Ordovician by Lapworth have been found in fossil-bearing rocks on all the continents. Notable, too, is the fact that Ordovician rocks have the distinction of being the topographically highest rocks on Earth. Fossiliferous Ordovician carbonates underlie the uppermost part of Mount Everest, the world's tallest mountain, located on the Nepal–Tibet border.

Ordovician series

Boundaries and subdivisions. In Great Britain the Ordovician System is divided into six series. From oldest to youngest, they are the Tremadoc, Arenig, Llanvirn, Llandeilo, Caradoc, and Ashgill. Each series is based on a group of rocks bearing characteristic fossils exposed in a type area. Type Tremadoc rocks are found around Tremadoc Bay in North Wales. Type Arenig rocks and faunas occur near Arenig Fawr in North Wales. The type Llanvirn occurs in sea cliffs and related exposures near Saint David's in South Wales. Llandeilo rocks and fossil faunas are evident in the environs of Llandeilo, Wales. Caradoc rocks and fossils occur near the Onny River in Shropshire, east of Wales. Ashgill strata and faunas occur in the English Lake District. Brachiopods and trilobites constitute the characteristic faunal aggregates of each series, except the Llanvirn in which graptolites are common.

These Ordovician series have been used widely in Europe in discussing Earth and life history during the Ordovician. Although attempts have been made to apply these divisions around the world, the faunas that typify each series appear to be limited to Europe in their distribution. Accordingly, alternative divisions of the Ordovician have been proposed in other countries (see Table 6).

In Lapworth's original definition, the base of the Arenig was the base of the Ordovician. However, the recovery of the remains of the extinct marine colonial organisms, graptolites, from Tremadoc rocks resulted in the inclusion of the Tremadoc in the Ordovician System. Planktonic graptolite remains do not occur below the Tremadoc Series.

The presence of graptolites in Ordovician strata led Lapworth and two of his students, Gertrude Elles and Ethel M.R. Wood, to propose graptolite zones as divisions of such strata. Lapworth formulated a graptolite zonal scheme in 1879. It was refined in 1918 by Elles and Wood, following extensive studies of British graptolite-bearing rock successions.

Establishment of the Lapworth and Elles–Wood graptolite zonal divisions of the Ordovician resulted from recognition that two distinct suites, or sets of strata, existed among Ordovician rocks. These two suites could be distinguished on the basis of the prominent fossil content of the rocks. One suite included strata containing the remains of graptolites. The second suite included rocks bearing the fossils of brachiopods, bryozoans, corals, and

other organisms that secreted shells. The two basic suites of fossiliferous rock came to be called the graptolitic and the shelly-fossil facies. Because most graptolites are limited to the graptolitic facies and most shelly fossils occur only in the shelly facies, establishing synchroneities (*i.e.,* time correlations) between the graptolite zones and shelly-fossil divisions has been and continues to be an important area of study.

Economic significance. Ordovician rocks have proved commercially useful. Several varieties are used as building stone, in glass manufacture, and in cement making. In addition, certain dark shales are sources of petroleum, while some limestones, notably those in the Missouri River valley area of the United States, are hosts for lead and zinc ores.

Ordovician rocks. *Types and distribution.* Fossiliferous Ordovician strata occur on all present-day continents. In general, these rocks may be divided into shelly-fossil-bearing facies and graptolitic facies, as noted above. The shelly facies may be subdivided into two major rock suites. One of them, the carbonate suite, includes limestones and dolomites formed in supratidal to moderate-depth shelf-sea environments. Such environments and sediment accumulations occur most commonly in the latitudinal range of 30°–35° S to 30°–35° N latitude. The carbonate rock suite formed in shelf-sea environments on lithospheric plates that were within the tropics during the Ordovician. The second shelly-fossil-bearing rock suite consists primarily of siliclastic rocks, including various types of sandstones and siltstones and some mud rocks. The siliclastic shelly-fossil rock suite formed in marine shelf environments around Gondwana in nontropical latitudes and in environments where plate motion led to the development of a landmass. Such a landmass was formed along what is today the Appalachian Mountain region in eastern North America and the site of the ancient Caledonian orogenic belt that extended from Ireland and Scotland northeastward through Scandinavia.

Major rock suites

Thinly laminated, nonbioturbated (sediments undisturbed by organisms), black, graptolite-bearing shales are found rimming many successions of siliclastic rock containing shelly fossils. Similarly, thinly laminated, black, nonbioturbated graptolitic limestones rim shelly-fossil-bearing carbonates. The rocks with graptolites accumulated in marine environments that ranged from the deeper parts of the continental shelf, slope, and rise to parts of the open sea. The source of the graptolite-bearing rocks was primarily the materials accumulating in the shallow shelf and intertidal environments.

Several plates—including Laurentia, Siberia, Kazakhstania, North China, part of Southeast Asia, Australia, and part of Antarctica—that were aligned in the tropics during the Ordovician (Figure 20) are sites of Ordovician carbonate rock suites. Dolomites and evaporites (in the main gypsum and anhydrite) commonly occur in the central parts of these plates. Limestones rim the dolomite and gypsum–anhydrite–salt sequences. The dolomite–gypsum–anhydrite–salt sequences appear to have formed in the shallowest tropical shelf-sea environments. Since these sequences may be more than 2,000 metres thick and may have accumulated during only a part of the Ordovician, the plates are thought to have been subsiding throughout the period. Whether or not this plate subsidence is related to some form of lateral plate motion has not been documented. The movement of the Balto–Scanian plate into the tropics during the Ordovician was accompanied by the accumulation of carbonates in shelf-sea environments on that plate as it moved northward.

Siliclastic shelly-fossil rocks occur in western South America, North Africa, the Middle East, southern Europe and the British Isles, and parts of southern China. Glaciomarine sequences are common in the Late Ordovician (Late Caradoc and Ashgill) parts of the rock sequence in these areas. The Late Ordovician segment of the rock succession in central northern Africa contains glacial materials, including moraines and kame terrace deposits.

Correlation. Correlations among the Ordovician facies and rock suites are difficult, because graptolites rarely occur with shelly fossils and shelly-fossil-bearing rocks are seldom found in rocks with graptolitic facies. Most of the synchroneities that have been established between the facies are achieved by finding rock debris that contains shelly fossils or gravity-flow materials in graptolitic sequences. Because the several carbonate suite-bearing plates appear to have been separated longitudinally, synchroneities among rock suites on each plate have proved to be difficult to achieve. A set of Ordovician divisions is recognized for application in rock sequences on each plate. Correlations among these divisions have not been established definitively, however. Certain correlations among rock suites are shown in Table 6.

Gondwana

Ordovician environment. *Paleogeography and paleoclimate.* During the Ordovician, the major landmass, Gondwana, extended from the South Pole northward into the tropics (see Figure 20). The geologic history of areas included in Gondwana indicates that the continent fragmented during post-Ordovician time (see below *Mesozoic Era*). A number of major lithospheric plates developed from those that made up Ordovician Gondwana. Moreover, several large plates already existed within the tropics during the period. Most of them appear to have been centred approximately on the equator. As can be seen from the map, the Northern Hemisphere north of the tropics consisted primarily of open ocean. The plate on which modern Scandinavia and the Baltic area are situated moved from south of the tropics into the tropics during the Ordovician. Continental glaciers formed in the area of modern central and northern Africa. This area was close to the South Pole during the Late Ordovician. Pronounced glacio-eustatic lowering of sea level, perhaps as much as 100 metres, took place as a consequence of the South Polar glaciation. Late Ordovician glaciation persisted for about 8 to 10 million years.

Significant worldwide marine regressions occurred near the end of the Tremadocian and Llanvirnian ages. These regressions appear to have resulted from plate motion rather than from glaciation.

Ordovician environmental controls on organismal distribution. Geochemical and fossil analyses of Ordovician rocks suggest that the carbonate suite formed in shelf-sea environments analogous to those of the modern Florida Keys and Bahama Banks. The fossil content of the dolomites and associated limestones is primarily algae (notably the mat-forming variety) and nautiloids and small snails. The limestones bear the remains of brachiopods, bryozoans, crinoids, tetracorals, tabulate corals, and sponges and spongelike organisms. Trilobite fossils are not as common in the carbonate rocks as they are in the siliclastic sequences. The latter, on the other hand, contain significantly fewer brachiopods, bryozoans, corals, and crinoids than do the limestones. Besides the remains of trilobites, diverse trace fossils are found more commonly in the siliclastics.

Most siliclastic successions formed in Southern Hemispheric, nontropical marine shelf environments in which surface waters were cooler than in tropical shelf seas. Source terrains may have been relatively nearby; thus many of the shallow-shelf environments could have been sites of (at least seasonally) turbid waters. Graptolitic sequences appear to have formed in marine shelf, slope, and open ocean environments in which waters beneath the surface had little to no oxygen. Geochemical studies of Ordovician rocks suggest that the oxygen content of the atmosphere and, accordingly, of the surface ocean water was less than it is today. If this were indeed the case, then most marine environments would have had less dissolved oxygen than analogous modern environments. Because there is less dissolved oxygen in warm waters than in cool waters, the tropical shelf seas could have contained very little oxygen close to the water–sediment interface. Nontropical shelf seas could have been mixed by storms, perhaps seasonally. In addition, because the oxygen content of these shelf seas was greater than that of the tropical shelf seas, relatively more oxygen was available for benthic organisms living in marine shelf-sea environments in nontropical latitudes.

Effects of low oxygen content of oceanic waters

During the Ordovician, waters analogous to those of the modern oceanic-oxygen minimum zone may have been anoxic. Furthermore, such oxygen-depleted waters probably extended markedly deeper in the Ordovician oceans than they do in modern oceans. Certain Ordovician deep-seafloor sediments, notably red mudstones and cherts found in western Newfoundland, suggest that the deep oceans were at least moderately ventilated.

Effect of plate positions on oceanic circulation

Ordovician oceanic circulation. Plate positions based on the analyses of remanent magnetism, faunal provinces, and rock facies have implications for oceanic surface-water circulation. The absence of major plates in the Northern Hemisphere north of the tropics suggests zonal surface-water circulation above 30° N latitude. Insolation of the Earth's surface indicates that polar waters (those from the pole to 60° latitude) were colder than those south or north of 60° latitude. Accordingly, the surface waters between 60° and 90° N flowed east to west, and those between 30° and 60° N flowed west to east, in general. Tropical water flow across and around the plates in the tropics resulted in western boundary currents on the west side of Laurentia, Siberia, and the Middle East–South China region during much of the Ordovician Period. Oceanic surface circulation in the Ordovician Southern Hemisphere was influenced by the positions of plates bearing lands and shallow shelf seas. In addition, closure between the Balto-Scanian plate and Laurentia altered surface circulation between the two during the Ordovician. A western boundary current probably flowed northward along the Balto-Scanian plate during much of the period.

The presence of the major mass of Gondwana in tropical as well as in temperate latitudes suggests that monsoonal seasonal conditions could have developed near and over it. If this were so, then, by analogy with the surface circulation of the modern Indian Ocean, circulation of surface waters on the western side of Gondwana could have reversed seasonally. The mixing of tropical- and temperate-water planktonic faunas (graptolites) in rock sequences in southern China implies that such a surface circulation reflective of seasonal monsoon conditions could have taken place. Moreover, the richness of these faunas indicates that the western boundary currents along the Middle East–South China coasts created upwelling conditions for most of the Ordovician.

Ordovician life. The close of the Cambrian Period was marked by a mass mortality among the trilobites. As they had been the predominant shelf-sea marine invertebrate, the sharp reduction in their numbers opened many marine environments to colonization by other animal forms. Orthid brachiopods radiated (*i.e.,* rapidly dispersed into different environments) noticeably during the Ordovician. Strophomenid and rhynchonelloid brachiopods appeared and moved into many shelf-sea environments. Bryozoans, crinoids, and both tabulates and tetracorals appeared for the first time. Their appearance and initial radiation was in Ordovician tropical shelf-sea environments. Trilobites reradiated, particularly in the siliclastic, nontropical shelf seas. Bivalve mollusks diversified modestly in nearshore siliclastic environments. Nautiloids radiated significantly in the shallow, algae-rich tropical shelf seas early in the Ordovician. During that time, many nautiloids evolved to nektonic modes of life, possibly as a result of the ability to generate gas in their shells. Snails and monoplacophorans lived in the same shallow-shelf, carbonate environments as the nautiloids.

Graptolites with planktonic modes of life appeared during the Tremadocian Age. During the remainder of the Ordovician, planktonic graptolites underwent a major transformation, changing from colonies with many branches to those with only a few. In connection with this development, graptolite colonies that formed from two branches appeared. In the early varieties of such graptolite

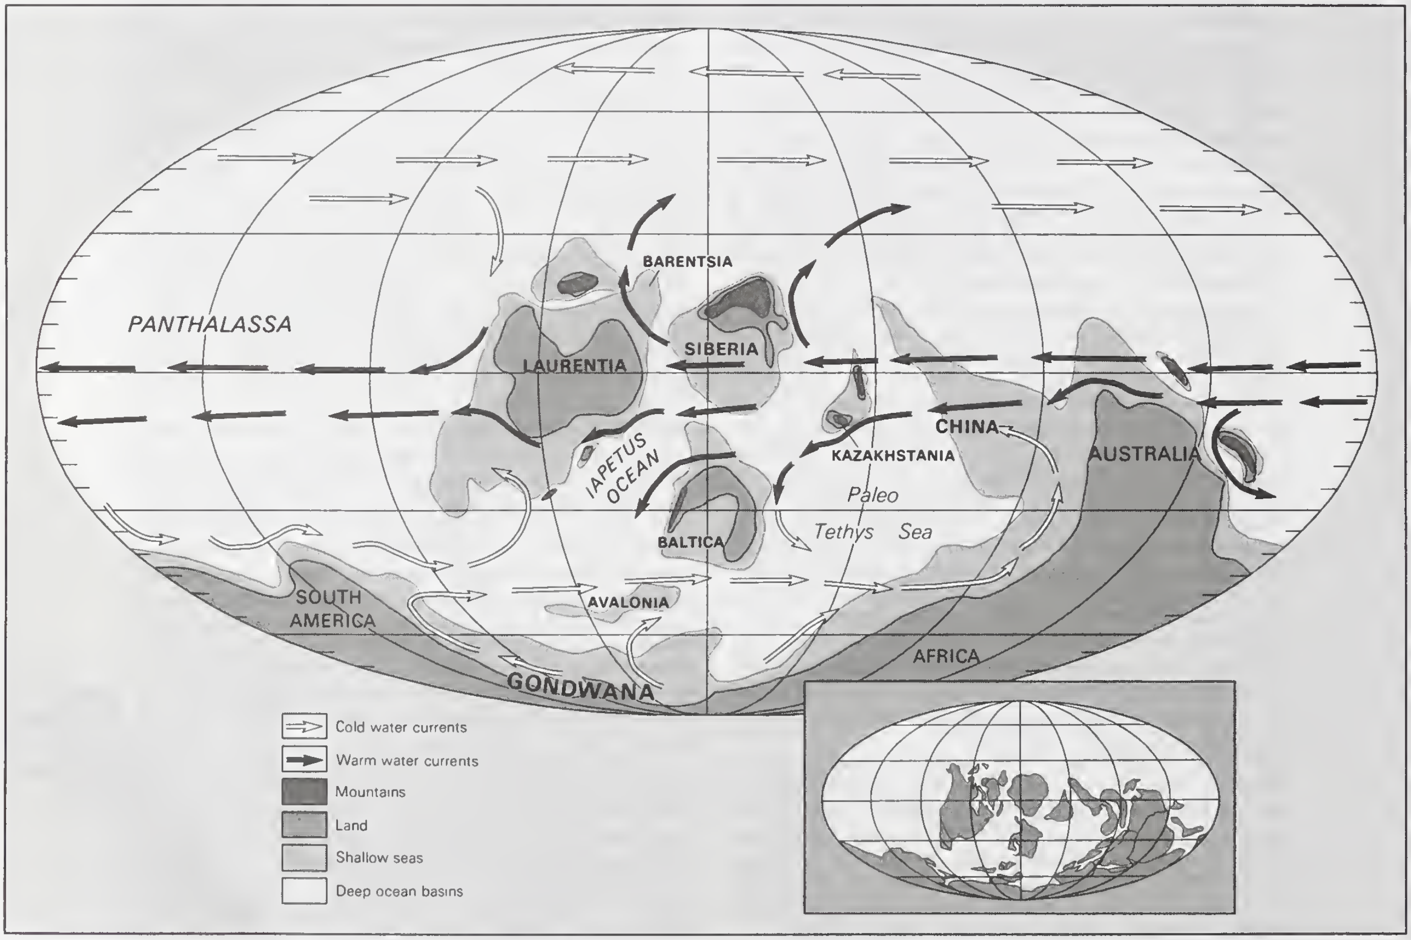

Figure 20: Distribution of landmasses, mountainous regions, shallow seas, and deep ocean basins during the Middle to Late Ordovician. Included in the paleogeographic reconstruction are cold and warm ocean currents. The present-day coastlines and tectonic boundaries of the configured continents are shown in the inset at the lower right.

colonies, the two branches were oriented in such a way that the zooids along them faced downward from the sea surface. In the later varieties, the zooids faced toward the sea surface. Zooids in the many-branched colonies faced downward from the sea surface.

The geologically oldest remains of nearly complete fish skeletons occur in Early Ordovician strata in Australia. These fish fossils are imprints on sandstones formed in nearshore marine environments. The remains are of ostracoderms, jawless armoured fish. Other, but disarticulated, ostracoderm remains are known from rocks of slightly younger Ordovician age in the western United States. The Ordovician ostracoderms occur in nearshore tropical marine settings.

Impact of prolonged continental glaciation

All marine animals suffered mass mortalities during the Late Ordovician. Presumably, these large-scale die-offs, observed among both shelly-fossil organisms and graptolites, were the result of environmental changes associated with the prolonged continental glaciation in the Southern Hemisphere. Mass mortalities at the close of the Cambrian and late in the Ordovician resulted in the unique aspects of the Ordovician fauna. The Late Ordovician mortalities created new opportunities for benthic and planktonic marine organisms. Reradiation during post-Ordovician glaciation led to many new taxa—those characteristic of the Silurian (see below *Silurian life*).

Some form of terrestrial plant life may have developed during the mid-Ordovician. Spores suggestive of land, but not vascular, plants occur in siliclastic Ordovician rocks on those lithospheric plates that were in the tropics at the time.

Distribution patterns of Ordovician marine organisms are consistent with plate distributions deduced from studies of remanent magnetism. The Ordovician tropical shelf seas were sites of a warmwater fauna distinct from that found in the nontropical shelf-sea rock suites. Studies of both benthic and planktonic organisms suggest that the several tropical plates were separated from one another. Faunas suggestive of distinct provinces may be found in rock suites on each plate. Faunal provincialism was marked during the Early Ordovician. As the plate bearing what is now the Baltic region and Scandinavia moved into the tropics during the mid-Ordovician, many new taxa were introduced to tropical environments. A marked incursion of such new taxa, seen in both planktonic and benthic faunas, typifies the basal part of the Caradoc Series. The ancestors of some of these taxa are found in the Balto-Scanian rock suites of Early Ordovician age. Ordovician faunal distribution patterns appear to reflect plate positions and relative plate motions, documenting the influence of plate tectonics on the distributions of organisms. (W.B.N.B.)

SILURIAN PERIOD

General considerations. The Silurian, the third period of the Paleozoic Era, occurred between 438 and 408 million years ago (see Table 4). As previously explained, absolute figures like these are calculated on the basis of radioactive isotopes, which must be analyzed geochemically from igneous samples. The radioisotopes decay at an exponential rate starting with the crystallization of the host rock from a magmatic source. Reheating of the host rock due to metamorphism, however, has the effect of resetting the radioisotope clock. Igneous rocks associated with sedimentary layers bearing fossils defined as Silurian are the desired targets for geochemical analysis, but few have remained untouched by metamorphism during their long existence. Typically, no more than four or five igneous localities are selected by teams of geochronologists to establish Silurian dates. Because igneous bodies are seldom found near the defined boundaries between geologic systems, the boundary ages for the Silurian Period must be extrapolated, taking into account a limited number of data points from older Ordovician and younger Devonian rocks. Competing groups of geochronologists disagree on precisely when and for how long the Silurian Period occurred. The oldest suggested age is 445 million years; the youngest is 395 million years. Some researchers believe the Silurian was as brief as 18 million years, while others argue for a span of 40 million years. In any case, the Silurian qualifies as one of the shortest geologic time periods, with many others approximately twice as long.

In 1835 R.I. Murchison named a sequence of rocks in Wales and its borderland with England "Silurian" in honour of a native people called the Silures, who had resisted Roman conquest. Murchison's classic contribution, *The Silurian System* (1839), illustrated 656 fossils, most of which were defined as characteristic of Silurian time. In this way, the formal groundwork was laid for recognition of Silurian rocks elsewhere around the world. Some years earlier (1822), William Buckland of Oxford University observed that fossil brachiopods and corals collected by British army officers stationed on Drummond Island (Michigan Upper Peninsula) and by fur traders working at Cumberland House (east-central Saskatchewan) in North America were equivalent to fossils from Dudley, Eng., as well as to those from the Swedish island of Gotland and the Baltic countryside (Estonia) neighbouring St. Petersburg. Each of these sites rests on Silurian bedrock, as now strictly delimited. Murchison's original concept grew in his lifetime to embrace what is now differentiated into the Cambrian, Ordovician, and Silurian systems. Claims for a monolithic system began to weaken in 1854 with discovery of the famous Onny River unconformity in Shropshire, Eng., which indicates a natural break within the classic Silurian on its own home territory. Major unconformities exhibiting a sustained pause in sedimentation subsequently were recognized between the Ordovician and Silurian systems in many other places around the world where the boundary beds are exposed.

Murchison's genius for military-style organization promoted the rapid adoption of his Silurian System throughout the British Isles, Scandinavia, and Europe. He was an active traveler who conceived of his field studies in terms of "campaigns." Local guides and fossil collectors were considered "aides-de-camp" in his service. Contemporaries who undertook research on Silurian strata and fossils with equal vigour were the French paleontologist Joachim Barrande in the Prague Basin and the American geologist and paleontologist James Hall in the states of New York, Michigan, Wisconsin, and Iowa. Other investigators who circulated to the distant territories of the British empire lost little time in recording the worldwide distribution of Silurian fossils. The first report of Silurian fossils in Australia, for example, was made (erroneously) in 1838, prior to the publication of *The Silurian System.* While the absolute limits of Silurian time remained imprecise, Murchison's triumph was the identification of successive fossil types with broad geographic distributions that always follow in the same relative stratigraphic order wherever they occur.

Boundaries and subdivisions. Continuing research has been preoccupied with decisions as to exactly where Silurian life may be defined stratigraphically as starting and ending and how the Silurian System may be broken into smaller chronostratigraphic units. The International Commission on Stratigraphy and its committees or working groups are charged by the International Union of Geological Sciences (IUGS) to reach such decisions based on the informed knowledge of members with broad geographic representation. The results of lengthy deliberations by the working group on the Silurian-Devonian Boundary were published in 1977, fixing the base of the *Monograptus uniformis* biozone (a single graptolite taxon but reinforced by associated conodont and trilobite taxa) as the base of the Devonian System. The top of the Silurian System is constrained by this marker (the so-called golden spike), which has its stratotype at a designated horizon in a cliff section near Klonk in the Czech Republic. Thus, the Silurian-Devonian boundary is anchored to the first occurrence of specific index fossils. The Klonk section acts as a kind of standard reference section with which other stratigraphic sections, potentially involving the Silurian-Devonian boundary beds, may be compared. This agreement arrived at by a committee of specialists represents the first time that the concept of the golden spike was put into effect internationally.

Boundary stratotype

In 1985 the working group on the Ordovician-Silurian Boundary ratified its decision to use the base of the

Parakidograptus acuminatus biozone (a group of concurrent graptolites) as the base of the Silurian System. The stratotype was fixed at a horizon in Dob's Linn near Moffat in the Southern Uplands of Scotland. The golden spike marking the Silurian–Devonian boundary is not associated with any unusual climatic changes or other physical phenomena that might have left a stratigraphic signature. In the case of the Ordovician–Silurian boundary, however, the effect on sea level of Late Ordovician glaciation and deglaciation with increasing deglaciation during the early Silurian accounts for widespread stratigraphic unconformities that usually omit the *P. acuminatus* biozone. In earliest Silurian time, the Dob's Linn locality was situated environmentally in marine waters deep enough to remain unaffected by these changes.

Silurian series

The IUGS's Subcommission on Silurian Stratigraphy has exercised its authority to codify chronostratigraphic subunits within the Silurian System. These include definitions of four series (see Table 8). The Llandovery, Wenlock, and Ludlow series bear names corresponding to historical units originally proposed by Murchison, but these are now rigorously defined in terms of basal stratotypes. The Wenlock Series, for example, derives its name from the Wenlock Edge (a prominent 25-kilometre-long ridge of limestone running southwestward from near the town of Much Wenlock in Shropshire). Its basal stratotype is now fixed at a locality called The Leasows section in Hughley Brook. The occurrence of specific microfossils (conodonts and acritarchs) signifies the beginning of Wenlock life and time as recorded at the base of the Wenlock series. Wenlock life and time may be said to reach an end when Ludlow life takes over (also represented by specific index fossils in a fixed stratotype). The last of the four series, the Přídolí, takes its name from an area outside Prague where a basal stratotype is defined by the first occurrence of a graptolite species (*Monograptus parultimus*) fixed at a horizon in exposures leading to the Pozary Quarries.

Silurian stages

Just as the Silurian System is composed of all rocks formed or deposited during the Silurian Period, the various series include all rocks formed or deposited during their respective time units called epochs. Series may be further divided into stages. The Llandovery Series consists of three stages (Table 7), whose names are derived from place-names for Welsh farms. The Wenlock and Ludlow series are each divided into two stages, but the Přídolí awaits further subdivision. All are defined by basal stratotypes, some of which are shared in common with larger units. The basal stratotype for the Rhuddanian Stage, for example, is the same as for the Llandovery Series and the Silurian System itself (located at Dob's Linn as discussed above). The various stages include all rocks formed or deposited during their respective time units called ages.

Table 7: Chronostratigraphic Units of the Silurian System

chronostratigraphy global standard stratigraphy				location of basal boundary stratotype
Silurian System	Upper Silurian	Přídolí Series	(division into stages to await necessity)	Barrandian (Pozary Section)
		Ludlow Series	Ludfordian Stage	Ludlow District (Sunnyhill Quarry)
			Gorstian Stage	Ludlow District (Pitch Coppice)
	Lower Silurian	Wenlock Series	Homerian Stage	Wenlock District (Whitwell Coppice)
			Sheinwoodian Stage	Wenlock District (Hughley Brook)
		Llandovery Series	Telychian Stage	Llandovery District (Cefn Cerig Section)
			Aeronian Stage	Llandovery District (Cefn Coed-Aeron Farm)
			Rhuddanian Stage	Southern Uplands of Scotland (Dob's Linn)

By permission of the National Museum of Wales

Regardless of their lithology, exposed fossiliferous strata, for instance, in the upper Mississippi River valley of the United States, may be classified as belonging to the Silurian System, the Llandovery Series, or the Telychian Stage, so long as they agree with fossils known to be restricted to those units as demarcated by their respective stratotypes in the United Kingdom and the Czech Republic. Correspondingly, the strata bearing particular index fossils in the upper Mississippi River valley may be described as having accumulated during the Silurian Period, Llandovery Epoch, or the Telychian Age.

Distinctive features. This hierarchy of stratigraphic nomenclature does little justice to the wealth of natural scenery shown by Silurian formations widely scattered around the world. Niagara Falls and the 11-kilometre-long Niagara Gorge on the Canadian–U.S. border were eroded and continue to be sculpted by rushing waters undercutting the soft Rochester Shale beneath a ledge of more resistant Lockport Dolomite. The Niagaran Escarpment is an arcuate ridge of resistant dolomite stretching more than 1,000 kilometres from the Niagara Falls area through the Bruce Peninsula and across Manitoulin Island (fringing the eastern and northern sides of Lake Huron in Ontario) to the Michigan Upper Peninsula and beyond to Wisconsin's Door Peninsula (fringing the northern and western sides of Lake Michigan). This resistant feature stands as much as 125 metres above the Great Lakes, which were shaped by the excavation of soft shales during the glaciations of the Pleistocene (see below *Pleistocene Epoch*).

Other notable manifestations of Silurian rock include the rolling hills of eastern Iowa and the similar rounded hills, called klintar, that dot the island landscape of Gotland, Swed., where Silurian mound reefs reach the surface. The renowned naturalist Linnaeus sketched in his field notebook the bizarre shapes of "stone giants"—large limestone sea stacks—8 to 10 metres high, which still stand in ranks along the shores of Gotland at Kyllej.

Some of Norway's beautiful inland (or isolated) fjords, such as Tyrifjorden northwest of Oslo, are lined by Silurian shales and limestones. Long graceful curves made by the Dniester River in Ukraine and the Moiero (or Moyyero) River in Siberia carve through high bluffs of Silurian limestone and marl. Picturesque sea cliffs formed by Silurian clastics guard the coasts of Ireland's Dingle Peninsula. Australia's Kalbarri National Park features river gorges winding their way to bold sea cliffs on the Indian Ocean, which are all set in Silurian Tumblagooda Sandstone. The partly Silurian Tabuk Formation forms vast desert stretches in Saudi Arabia. At an elevation of 6,000 metres, the Spiti River valley in India's Himalayan region is lined partly by limestone and quartzite belonging to the Muth Formation. Beneath the present varied scenery lies a totally different Silurian world, one which must be reconstructed from environmental clues in the rocks.

Elevated sea level

The most unusual features of the Silurian that distinguish it from the present-day physical environment relate to conditions of low continental elevations in conjunction with a much higher global stand in sea level. During Llandovery and Wenlock times, more than 65 percent of North America's craton (a somewhat smaller continent named Laurentia) was flooded by shallow seas ranging in water depth from a few to little more than 100 metres. These seas were tropical to subtropical in climate, and coral mound reefs with associated carbonate sediments were very common. During Ludlow and Přídolí times, deposition of evaporites (salts) was periodically set in motion as a result of reduced circulation. This general scenario had its counterparts in northern Europe (a separate continent named Baltica) and in Siberia (also a separate continent).

To a lesser degree, some of these elements are found in South China on the Yangtze platform (a separate continent) and Australia (part of the much larger continent Gondwana).

Seafloor topography was muted over large areas of these particular platforms, and faunas of shelly invertebrates were remarkably consistent with one another. Eastern Australia sustained a more varied seafloor topography due to extensive volcanism but shared many of the same faunal elements because of its tropical latitude. Much of remaining Gondwana (including Antarctica, India, Arabia, Africa, and South America) was centred over the south geographic pole, where a substantial landmass was heavily glaciated during late Ordovician time but much less so during early to mid-Silurian time. Early Silurian marine faunas recovered from a major extinction brought on by climatic change and lowered sea level resulting from late Ordovician glaciation. Except for primitive vascular plants restricted to coastal areas, the relatively small land areas were essentially barren.

Economic significance. Silurian rocks embrace a normal range of types that assert some role on local economies. A minor amount of petroleum is associated with Silurian reef structures; a substantial quantity of Silurian salt is mined; Silurian limestone and dolomite are widely quarried for crushed rock. The economic significance of Silurian raw materials, however, is mostly of historical relevance. Development of the Severn River valley in Shropshire, Eng., brought together for the first time the mineral ore, coal, and limestone necessary to fuel industrial iron production. The construction in 1779 of an iron bridge across the Severn River may be regarded as the starting point of the Industrial Revolution. Local quarrying of the Wenlock Limestone provided the fluxing agent necessary for the manufacture of iron. The English iron industry later shifted to the Birmingham area, where the Wenlock Limestone continued to be exploited for this purpose. A major underground canal system was built at Dudley in order to facilitate limestone mining. A similar juxtaposition of raw materials led to the industrial development of Birmingham, Ala., in the southeastern United States. Again, Silurian rocks provided one of the key ingredients. This time it was hematite ore from the Llandovery Red Mountain Formation, which was mined from 1862 to 1971. A third unusual site in this regard is the ghost town of Fayette in Michigan's Upper Peninsula. It was founded as a company town in 1867 because local resources offered an abundance of Silurian dolomite for use in iron smelting. At the opposite end of the Michigan Upper Peninsula on Drummond Island, dolomite from the Wenlock Engadine Group is still quarried on a large scale for this special industrial use.

Sedimentary rocks

Silurian rocks. *Types and distribution.* Excluding peat and coal, the same kinds of strata in the process of forming today were also deposited during Silurian time. Owing to the heightened state of sea level, coupled with the low relief of many continents, production of certain Silurian sediments was proportionately different than that observed in the present world, however. Chief among these are limestones, which form primarily from the carbonate detritus of coral skeletons, shells, and calcified algae. Unless such detritus is produced in great quantities or rapidly buried, it tends to dissolve in cold (temperate to polar) waters. In shallow warm (tropical to subtropical) waters, carbonates may collect more gradually to form continuous layers of limestone. The geographic locations of Laurentia, Baltica, and in part Siberia within 30° latitude on either side of the Silurian equator ensured the development of extensive platform carbonates. In North America, Silurian limestones or dolomites (altered from limestone by partial secondary substitution of magnesium for calcium) are found across an enormous territory stretching along one axis from northern Greenland to West Texas and along another axis from Quebec's Anticosti Island to the Great Basin of Utah and Nevada. Formation names and their stratigraphic ranges are shown in Table 8 for some typical carbonate sequences preserved in Canada (Quebec and Manitoba) and in the United States (northern Michigan, eastern Iowa, and the Great Basin of Utah and Nevada). Parts of Baltica where carbonate deposition was prevalent include Sweden's Gotland, Estonia, and the Ukrainian region of Podolia; carbonate deposition was also prevalent over much of Siberia (Table 8). Platform carbonates of this kind rarely exceed 200–300 metres in thickness. Important limestone units more restricted in Silurian time and space include the Wenlock Limestone (Shropshire, Eng.), the Ryterraker Formation (southern Norway), the Xiangshuyuan Formation and lateral equivalents (South China), and the Hume Limestone (New South Wales, Australia).

Evaporites, including salt (halite), anhydrite, and gypsum, are chemical precipitates that usually accumulate as layers through evaporation of marine waters isolated in shallow bays. This process is most effective under a warm, arid climate commonly found at latitudes of about 30° or less. Distributed through parts of Michigan, Ohio, and New York state, the Upper Silurian (Ludlow–Pridoli) Salina Group is one of the world's most famous evaporite deposits. A maximum aggregate thickness of 600 metres occurs in Michigan, where one individual halite bed reaches a thickness of 165 metres. A 2-metre halite bed occurs in the Interlake Formation (Wenlock) of North Dakota. Gypsiferous beds occur in parts of the Upper Silurian Yangadin and Holuhan formations of Siberia, as well as in comparable formations in Latvia and Lithuania. Upper Silurian (Pridoli) evaporites are characteristic of three different basins in Western Australia. Minor amounts of halite and anhydrite occur in the Dirk Hartog Formation in the Carnarvon Basin; more extensive halite or anhydrite beds or those of both have been discovered in comparable formations from the Canning and Bonaparte Gulf basins.

Clastic wedges

Clastic rocks, including conglomerates, sandstones, and shales, generally occur in wedge-shaped deposits adjacent to land areas from which terrigenous materials erode under conditions of moderate to high annual rainfall. Owing to steady accumulation over protracted periods of time, such deposits tend to become very thick and subside under their own weight, forming troughlike structures parallel to their sediment source. In contrast to thin platform deposits, clastic wedges may be thousands of metres or more than one kilometre thick. Taconica was a long narrow highland roughly corresponding to the present position of the Appalachian Mountains in North America. During early Silurian (Llandovery) time, these highlands shed the Shawangunk Conglomerate (500 metres thick) near its front in southeastern New York state and distributed the Tuscarora–Clinch sandstones (150–250 metres thick) throughout central Pennsylvania and western Virginia from more than 80 kilometres beyond its front. These deposits accrued from sediments carried by braided streams crossing coastal plains to a wave-swept shore. *Arthrophycus* trails (those made by annelids tolerant of low salinity) are recorded in the more seaward portions of the Tuscarora Sandstone. Collectively attributed to the Clinton Group, a variety of Upper Llandovery rocks with high iron content subsequently were deposited from New York to Alabama. These strata often contain marine fossils, but their iron was derived from Taconica. Tiny pellets, or oolites, coated with hematite occur in seams up to 2 metres thick in New York; massive ferruginous sandstones are found in Pennsylvania; and oolitic ironstone beds up to 15 metres thick occur in Alabama (in the Red Mountain Formation).

Evidence of another Laurentian highland called Pearya is found in the Canadian Arctic in the vicinity of northern Ellesmere Island. Clastic sediments eroded from this source were deposited in the Hazen Trough. One Lower Silurian (Llandovery) unit called the Danish River Formation is composed of interstratified conglomerates, sandstones, and shales one kilometre thick. The Caledonian highlands dominated depositional patterns on the paleocontinent of Baltica. Much of the highland front followed approximately the present spine of Norway and affected a broader area through generation of river-transported sandstones that gradually spread across Sweden to Poland in one direction and through northern England to southeastern Ireland in the other direction. Known traditionally as the Old Red Sandstone, these rocks are of late Silurian (Ludlow) age in southern Norway, mixed late Silurian (Pridoli) and early Devonian age in northern England, and

early Devonian age in southeastern Ireland and Poland. This variation in age reflects the growth of the Caledonian highlands and their ability to shed clastic debris farther and farther afield. In Western Australia, similar thick red sandstones belonging to the Upper Silurian Tumblagooda Sandstone were derived from a Precambrian massif called the Yilgarn Block. In contrast to sandstones that accumulated because of river transport, eolian sandstones are those deposited under desert conditions. The Mereenie Sandstone in central Australia (Amadeus Basin) is one of the few examples of a possible Silurian desert sandstone.

Outside clastic wedges closely linked to a land source, Silurian shales also formed on platform margins, as in the nearly 500 metres of strata belonging to the Road River Group in the Canadian Yukon. Based on sections in the Mackenzie Mountains, a distance of only one to a few kilometres separated the edge of a shallow water carbonate platform from the deepwater setting of basinal shales. Submarine avalanches (turbidity flows) brought the 1,200–1,500 metres of interbedded shales and fine sandstones constituting the Aberystwyth Grit Formation to a deepwater basinal setting in west-central Wales. Less commonly, Silurian shales passively accumulated in broad platform settings. The Lungmachi Formation in South China (Yangtze platform) is one such shale body, which makes up the basal Silurian throughout parts of the Yunnan, Szechwan, Shensi, Hupeh, Hunan, and Kweichow provinces. As much as 500 metres thick in places, these shales developed under anoxic conditions in quiet waters. Similar conditions prevailed during early Silurian times well within Baltica, including southern Sweden and Denmark.

Silurian sandstones and shales rest directly on Upper Ordovician tillites in Arabia (Tabuk Formation) and throughout large parts of North Africa. In South America (fused with Africa during the Silurian), glaciation persisted well into the period (Wenlock age). The Cancaniri Formation, including a prominent 60-metre-thick segment that bears the Zapla Tillite, extends 1,500 kilometres from northern Argentina over the Andes Mountains across Bolivia to Peru. Alpine glaciers descended to tidewater to deposit these layers, including faceted and glacially striated boulders 1.5 metres in diameter. Similarly, the widespread Trombetas Formation in the Amazon of Brazil may represent Silurian tillites filling submarine channels gouged by drifting ice blocks.

Volcanic rocks

Examples of rocks used to make absolute age determinations for the Silurian include a Llandovery volcanic breccia from the Descon Formation on Esquibel Island in Alaska, ash beds (bentonites) from the basal Wenlock Buildwas Formation and the Ludlow Elton Formation, both in Shropshire, Eng., and the Laidlaw Volcanics of Ludlow age near Canberra, Australia. Compared to other time periods, the Silurian was relatively quiet in terms of volcanic activity. Moderate activity occurred in those parts of the British Isles, the Canadian Maritimes, and coastal New England collectively attributed to Avalonia (as appended to Baltica). Approximately 1,000 metres of basalt flows belonging to the Skomer Volcanics in southwestern Wales are Llandovery in age. Rhyolite and andesite lavas were extruded in the area of the English Mendip Hills during Wenlock time. Basalts, rhyolites, and porphyritic andesites from the Newbery Volcanics in northeastern Massachusetts are Pridoli in age. Rhyolitic and andesitic flows of Silurian age also are known in the region of Passamaquoddy Bay in Maine, as are volcanic flows and breccias in adjacent New Brunswick. A Silurian chain of volcanic islands stood off the Laurentian craton, stretching from the Klamath Mountains of northern California to Alaska. Likewise, andesitic and basaltic sites of volcanism stretched along the edge of Baltica, as framed by the Ural Mountains.

The most extensive Silurian volcanism occurred in eastern Australia, principally in New South Wales but also in Victoria and Queensland. Activity was initiated during early Wenlock time with the Paddys River and Uriarra volcanics; expanded during Ludlow time with the Laidlaw, Mineral Hill, Bennetts Creek, Mullions Range, and Bells Creek volcanics; and concluded in Pridoli time with the Bombay Creek and Woodlawn volcanics in addition to the Currawan Basalt. Most of these were subaerial except for the basalt, which left submarine pillow structures. In New South Wales, more than 200 intrusive granitic bodies of the late Silurian or early Devonian are geochemically linked to these acid volcanics, but their precise age is difficult to establish.

Correlation. The most challenging goal in stratigraphy is to identify on a global basis all those rocks formed during the smallest possible interval of geologic time. Correlation of Silurian strata within limits more refined than a stage (or its corresponding age) is achieved through the recovery of fossils belonging to shaley and shelly facies.

Silurian index fossils

Shaley facies generally represent deeper-water environments, such as those under which the Road River Group (Yukon), Aberystwyth Grit Formation (Wales), and Lungmachi Formation (South China) accumulated. Fossils of graptolites are abundant in these dark Silurian shales. As explained above, graptolites were colonial hemichordates that secreted a protein exoskeleton commonly preserved as a carbon film in shales. An individual lived within a cuplike structure (theca); multiple cups were spaced along one or more branches (stipes); and the entire colony sometimes was connected by a threadlike structure (nema) to a central float. Some graptolites were bottom-dwellers, but the floating (or pelagic) species were geographically more cosmopolitan. They make excellent index fossils, because they underwent rapid evolution and attained a broad distribution. The genera *Pristiograptus* and *Cyrtograptus,* whose general features are illustrated in Figure 21, are pelagic graptolites characteristic of the Wenlock Series. As many as 42 graptolite biozones have been defined for the Silurian System (Table 9). Each biozone takes the name of one particular species but is usually based on several coeval species. The span of time represented by each graptolite biozone probably is not perfectly uniform, but the zonation facilitates correlation of strata in depositional units of 1 million years or less (provided of course that the Silurian Period lasted 30 million years). Superb as it is, this level of precision is restricted to regions rich in graptolitic shales. It is easier to correlate the deepwater shales of Wales and the Yukon with each other, for example, than it is to correlate either with nearby shallow-water shelf deposits.

In contrast to shaley facies, shelly facies are represented by relatively shallow platform carbonates and clastic wedges with a retinue of mostly bottom-dwelling invertebrates. Among these, Silurian brachiopods were especially

From E. Winson in W.S. McKerrow (ed), *The Ecology of Fossils*, Gerald Duckworth & Company Ltd

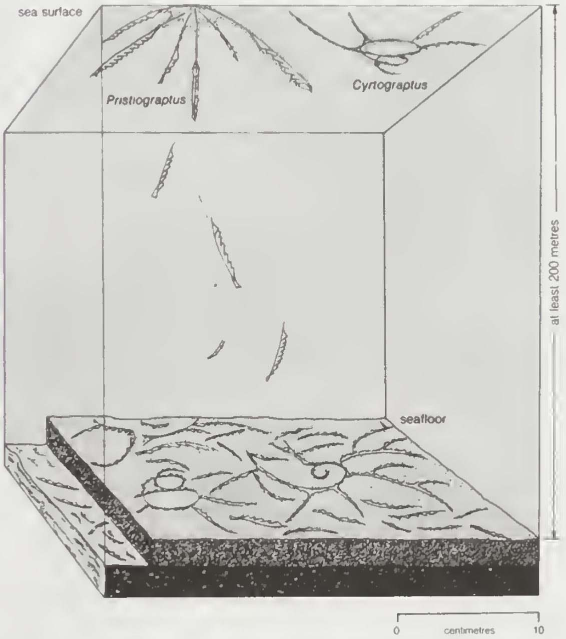

Figure 21: Pelagic graptolites belonging to the Wenlock genera *Pristiograptus* and *Cyrtograptus*.

abundant, diverse, and widely distributed, making them effective index fossils. A still extant group, the brachiopods possess a pair of bilaterally symmetrical shells and are tethered to the seafloor by a fleshy appendage usually protruding through one of the shells (thus the shells are typically unequal in shape). Biostratigraphic zonations based on brachiopod lineages are well suited to the correlation of Lower Silurian (Llandovery and Wenlock) strata. Those most frequently used are the *Stricklandia–Costistricklandia*, the *Borealis–Pentamerus–Pentameroides*, and the *Eocoelia* lineages (Table 9). Excluding most of Gondwana except eastern Australia, these brachiopods attained a broad tropical to subtropical distribution. Lineage members (including four subspecies of *Stricklandia*) may be employed independently but are more effective where it is possible to use them in combination as overlapping taxon zones. Thus, *Pentameroides subrectus* alone may indicate a late Llandovery (Telychian) age or an early Wenlock (Sheinwoodian) age. In association with *Stricklandia laevis* or *Eocoelia curtisi*, however, a Telychian age is certain. Single taxon zones also are helpful in the Upper Silurian (Ludlow and Pridoli). Only in unusual cases where brachipod-bearing layers are interbedded with graptolite-rich shales (at the narrow transition between shelly and shaley facies) may the temporal relationships between the two kinds of index fossils be established. Most of the projected correlations between graptolite and brachiopod biozones are approximate (Table 9).

Conodonts constitute a third group of index fossils important for Silurian correlation. These phosphatic microfossils with the shape of conelike teeth (as the name implies), are the remains of an apparatus from the mouth cavity of a small, bilaterally symmetrical, free-swimming (nektonic) animal extinct since Triassic time. Rare body fossils suggest some affinities with surviving cephalochordates, such as *Amphioxus*, or the chaetognaths (arrowworms). The individual elements comprising the conodont apparatus are very common in Silurian rocks that accumulated under a wide range of marine environments. Hydrochloric acid, which has no effect on phosphatic material, is used to dissolve limestone or lime-cemented sediments from which the conodonts may be recovered. Graptolite and brachiopod zonations have a long history of use in the Silurian, but the first conodont zonation based on material

collected at Mount Cellon in the Carnic Alps of Austria was not proposed until the early 1960s. Different kinds of conodont-bearing animals lived in shallow, nearshore environments (as opposed to deeper, more offshore environments), and some were more conservative in their evolutionary development than others. Global correlation is based on $12\frac{1}{2}$ conodont biozones for the complete Silurian (Table 9). The base of each zone is defined by the first occurrence of the taxon. All are characteristic of open marine environments; the zonation is not applicable to strata that accumulated in restricted nearshore or deep-basin facies.

Global correlation based on conodont biozones

Silurian environment. *Paleogeography.* The Silurian world consisted generally of a north polar ocean, a ring of at least six equatorial to middle-latitude continents, and one south polar supercontinent. A combination of paleomagnetic, paleoclimatic, and biogeographic data can be used to reconstruct the approximate orientations of the Silurian continents. The Earth's magnetic field leaves its signature on volcanic rocks and certain sedimentary rocks rich in such minerals as magnetite. As rocks capable of being magnetized were cooled or otherwise lithified, their component crystals or grains conformed to an alignment with the terrestrial magnetic field consistent with their latitudinal origin. Unless the rocks were reheated or reworked by erosion, they should retain this signature regardless of subsequent geographic displacement. The Earth's zonal climate also has an effect on global patterns of sedimentation (see above). Strata formed in arid regions, for example, differ from those formed in regions with high annual rainfall. Endemism provides an index sensitive to continental isolation. The geographic summary that follows is based on a global reconstruction specific to middle Silurian (Wenlock) time (Figure 22).

Much of North America, including Greenland, northwestern Ireland, Scotland, and the Chukotsk peninsula of northeastern Russia, belonged to the paleocontinent Laurentia. (The name is derived from Quebec's portion of the Canadian Precambrian shield.) With respect to the present-day Great Lakes and Hudson Bay, Laurentia was rotated clockwise during Wenlock time to fully fit within latitudes 30° N and S of the paleoequator. The present south shore of Hudson Bay was at the centre of Laurentia, with the Wenlock paleoequator crossing near Southampton Island. The microcontinent Barentsia (including Norway's island of Svalbard) probably was appended to Laurentia off eastern Greenland. Island arcs and highland areas, such as Taconica and Pearya (see above), rimmed the flooded continent.

Paleo-continents

The narrow, north–south Iapetus Ocean still separated Laurentia from Baltica during Wenlock time. (The continent's name is derived from the Baltic Sea and Baltic states—Estonia, Latvia, and Lithuania—at the core of northern Europe.) The Uralian and Variscan–Hercynian sutures marked the eastern and southern margins of this paleocontinent, respectively. The northern tip of Scandinavia was situated just below the Wenlock paleoequator, but the islands of Novaya Zemlya extended well above it. The most prominent features were the Caledonian highlands of Norway, although a lowland may have existed in the vicinity of Finland. The microcontinent of Avalonia—its name derived from the Avalon Peninsula of eastern Newfoundland—probably was appended to Baltica by the end of Ordovician time. It included what is now England, Wales, southeastern Ireland, the Belgian Ardennes, northern France, eastern Newfoundland, part of Nova Scotia, southern New Brunswick, and coastal New England.

Separated from Baltica by the Pleionic Ocean, the paleocontinent of Siberia assumed an orientation rotated 180° from its present alignment (as recognized by the inverted

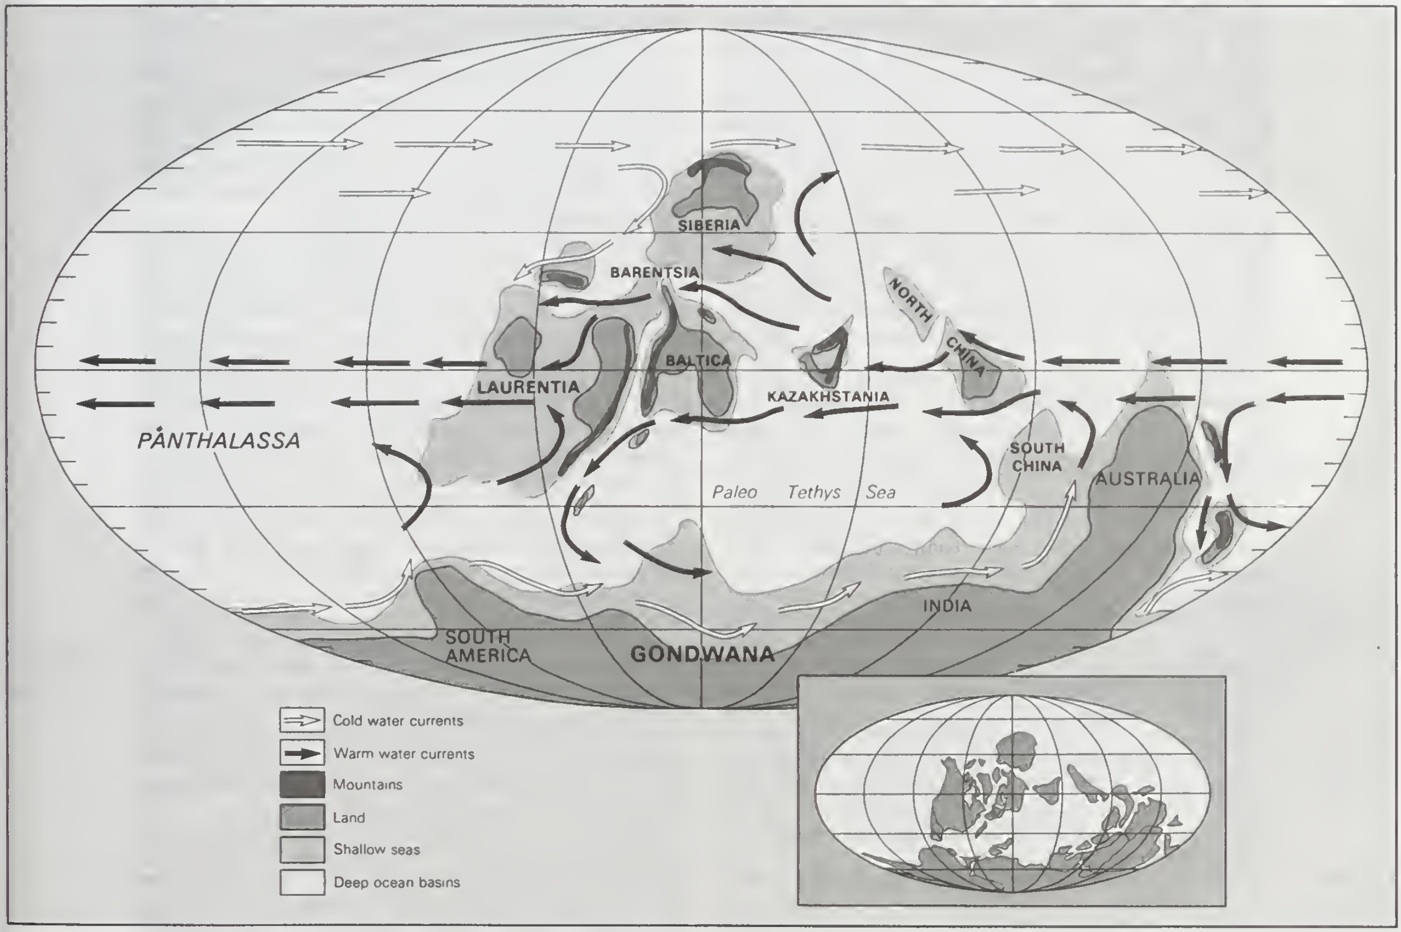

Figure 22: Distribution of landmasses, mountainous regions, shallow seas, and deep ocean basins during Early Silurian time. Included in the paleogeographic reconstruction are cold and warm ocean currents. The present-day coastlines and tectonic boundaries of the configured continents are shown in the inset at the lower right.

position of Lake Baikal). A huge Siberian platform sea was almost completely surrounded by lowlands. Kazakhstania was a neighbouring continent in the same middle northern latitudes. North China (including Manchuria and Korea) and South China (the Yangtze platform) were two separate continents situated in a more equatorial position. In contrast to the foregoing continents, most of North and South China were elevated above sea level during Wenlock time.

The vast supercontinent centred over the South Pole was Gondwana. In addition to Australia, Antarctica, India, Arabia, Africa, and South America, Silurian Gondwana also included smaller pieces of Florida, southern Europe, and the Cimmerian terranes—namely, Turkey, Iran, Afghanistan, Tibet, and the Malay Peninsula—on its outer fringes. The east–west ocean separating the southern European sector of Gondwana from northern Europe (Baltica) is called the Rheic Ocean. Present-day Brazil or contiguous West Africa was the locus of the South Pole, buried by an ice cap probably comparable in size to Antarctica. During Wenlock time, India, Tibet, the Malay Peninsula, and Australia projected into subtropical or tropical latitudes (see Figure 22).

Environmental conditions favourable to marine invertebrates

Significant geologic events. Resumption of environmental conditions favourable to faunal recovery from the late Ordovician extinctions was the most significant geologic event of the Silurian Period. It is estimated that these extinctions claimed 12 percent of all marine invertebrate families. Sixty percent of late Ordovician brachiopod genera survived the start of the Silurian Period, but only 20 out of 70 tabulate and heliolitoid coral genera and 14 out of 38 trilobite families made the same transition. Dramatic unconformities between the Silurian and Ordovician systems indicate how extreme the glacially induced drawdown in late Ordovician sea level had been. The maximum global fall in sea level was as much as 170 metres and drained immense areas of former marine habitat. River valleys up to 45 metres in relief were eroded into Upper Ordovician marine shales stretching across Iowa, Wisconsin, and Illinois on the Laurentian platform. On Baltica, marine carbonates in Norway and Sweden were transformed into karst surfaces through subareal exposure; a network of extensive tidal channels was developed across a formerly much deeper shelf in Wales. Close to the edge of the Gondwanan ice sheet in Saudi Arabia, the Jabal Sarah paleovalley was deeply incised by glacial outwash streams eroding through Ordovician shales and sandstones. These features and many others like them elsewhere were eventually filled and buried with the return of marine sedimentation in early Silurian time. Basal Silurian strata virtually everywhere record a rapid rise in the level of the sea, which reflooded vast continental platforms.

The few localities where marine sedimentation continued uninterrupted from late Ordovician to early Silurian time have been scrutinized for unusual trace elements. A major iridium spike of the sort widely found at the Cretaceous–Tertiary boundary has not been detected at the basal Silurian stratotype in Scotland nor at the parastratotype on Anticosti Island in Quebec. The introduction of high iridium levels in the environment requires unusual volcanic activity or the impact of a large asteroid. Neither of these agents seems to be linked with the Late Ordovician extinctions or subsequent Silurian developments. The small Lac Couture crater (eight kilometres in diameter) in Quebec is the only known impact structure of Silurian age, but no known iridium layer is associated with it. Large-scale reduction of marine habitat space in combination with global cooling probably were the primary agents of the Late Ordovician extinctions. Some Silurian continents recovered more rapidly than others. The niche of the large-shelled pentamerid and stricklandiid brachiopods on the Laurentian platform, for example, was filled belatedly by immigrants from Siberia and Baltica.

Recurrent fluctuations in sea level

Smaller fluctuations in sea level between 30 and 50 metres in magnitude continued to occur on a global basis throughout the Silurian. In contrast to the Late Ordovician event, these fluctuations did not strongly affect the shelly bottom-dwelling invertebrates perched on continental platforms. Benthic faunas accommodated by living conditions at particular bathymetric levels simply tracked changing sea level by sifting upslope or downslope. The amount of available habitat space was not drastically altered as a result of these maneuvers. Data from three or more different paleocontinents indicate that at least four globally coordinated highstands (*i.e.,* intervals during cycles of relative sea-level changes when the sea level lies above the continental shelf edge of a given area) took place during Llandovery time. The first event probably corresponds to the maximum rise in sea level achieved following recovery from the major drawdown in Late Ordovician sea level. This highstand occurred during the transition between the Rhuddanian and Aeronian ages near the boundary between the *Coronograptus cyphus* and *C. gregarius* graptolite biozones (Table 9). A second highstand of mid-Aeronian age corresponds to the basal parts of the *Stricklandia lens progressa* lineage zone and the *Monograptus sedgwickii* graptolite biozone. The third matches an early Telychian event linked to the *Stricklandia laevis* and *M. turriculatus* zones, and the fourth, a late Telychian event, is correlated with the lower range of the *Costistricklandia lirata* and *M. crenulata* zones. Standard geochronology suggests that these cycles of rising and falling sea level had an average duration of about 2.5 million years during the Llandovery.

Present data are not as complete for the rest of the Silurian, but a mid-Wenlock highstand in sea level is widely reported as coeval with the *Monograptus riccartonensis* to *Cyrtograptus ellesae* graptolite biozones. A mid-Ludlow lowstand in sea level also is commonly equated approximately with the *Saetograptus leintwardinensis* biozone, separating an early Ludlow highstand from at least one subsequent Ludlow highstand. Information on sea-level changes during Pridoli time is fragmentary and globally inconsistent. Late Silurian lowstands were sufficient to downgrade circulation patterns to a degree that stimulated widespread evaporite deposition in Laurentia, Baltica, Siberia, and the Australian sector of Gondwana. Some bathymetric changes clearly were local in effect, as brought about by submarine volcanism or by the tectonic elevation or subsidence of the seafloor. Those fluctuations recorded on different paleocontinents during the same interval of geologic time may have been coordinated by minor changes in the size of the surviving Gondwanan ice cap. South American tillites interpreted as Wenlock in age (see above) lend support to this model.

Several small extinction and radiation events in the evolution of nektonic and pelagic organisms appear to be linked to Silurian fluctuations in sea level. Five graptolite radiations are recorded in the Silurian System. Four of these sudden increases in diversity occurred, respectively, in early Aeronian, early Telychian, early Sheinwoodian, and early Gorstian times during or immediately after highstands in sea level. The basal Wenlock (Sheinwoodian) radiation, for example, involves distinct new genera such as *Cyrtograptus* (Figure 21) and as many as 20 new species. Among conodonts, a significant radiation is indicated by species within the *Pterospathodus amorphognathoides* biozone, which straddles the Llandovery–Wenlock boundary and includes the late Telychian highstand. Extinction of key species followed by the origination of several new species during early Sheinwoodian time was one of the most drastic changes in the Silurian conodont succession.

Acritarchs are microfossils that may represent the pelagically dispersed spore cases of benthic algae. Four major turnovers in Silurian acritarch species are recognized. Among those coinciding with highstands in sea level, the mid-Aeronian and early Gorstian turnovers are the most extensive. The various nektonic and pelagic organisms may have been affected by changes in water temperature related to minor episodes of glaciation.

Paleoclimate. If paleocontinental orientations are interpreted correctly and if the assumption is made that atmospheric circulation functioned according to the same basic principles in Silurian time as today, then it is possible to infer general Silurian climatic conditions. A zonally uniform climate is expected in the Northern Hemisphere during the Silurian due to the fact that it was dominated by a north polar ocean. Wind patterns must have included strong polar easterlies at high latitudes, prevailing westerlies at mid-latitudes, and northeast trade winds in the tropics. With the supercontinent of Gondwana centred over the South Pole, climate in the Southern Hemisphere must have been dominated by the interaction of cellular air masses over land and water. The resulting circulation pattern probably was more complex, involving seasonal monsoons.

The Silurian ITCZ

Atmospheric circulation patterns interpreted for an early Silurian summer in the Northern Hemisphere indicate high pressure over the polar ocean with a zone of low pressure around 60° N latitude. Distinct high-pressure cells formed above subtropical oceans, much like the persistent Bermuda high-pressure centre over the present subtropical North Atlantic. Another zone of low pressure formed above the thermal equator, or the region of most intense solar warming. This somewhat migratory zone was the Silurian intertropical convergence zone (ITCZ), where Northern and Southern hemispheric trade winds converged and rising tropical air produced regular cloud cover and precipitation. Mostly, the ITCZ remained near the equator, but it may have migrated slightly to the north in response to strong summer heating on Laurentia, Baltica, and possibly Kazakhstania. This tendency would have been strongest along the eastern margins of tropical continents, where anticyclonic circulation around subtropical highs pulled warm, moisture-laden air northwestward from equatorial oceans. Subtropical high pressure probably spread onto Gondwana, particularly the Australian and Antarctic sectors. A pressure ridge may have merged with these subtropical highs to form a massive cold cell penetrating to higher latitudes over the continental interior of Gondwana. Low-pressure systems over Gondwana's mid-latitude shelf were not unlike the Icelandic and Aleutian lows of today.

Pressure systems should have moved somewhat southward during the Northern Hemispheric winter, particularly the ITCZ, which generally tracks the thermal equator to the Southern Hemisphere during this season. A low-pressure system between Laurentia and Baltica is consistent with the erosion of thick clastics derived from the Taconic and Caledonian highlands. The most significant seasonal variation surely occurred in the eastern Australian and Antarctic sectors of Gondwana, where summer heating abolished winter high-pressure cells and pulled the ITCZ more poleward. This is comparable to today's monsoons, which pull the ITCZ in the opposite direction over the subcontinent of India during the Northern Hemispheric summer. Subtropical highs intensified over the ocean waters of the Southern Hemisphere and probably insulated the arid climate of Western Australia.

Silurian life. Marine benthic invertebrates of the Silurian Period belonged to persistent assemblages or communities that commonly conformed to ecological zonation. Ofle way in which zonation expresses itself is through bathymetric gradients. Paleoecologists studying in Wales, Norway, Estonia, Siberia, South China, and North America have used very similar models to explain the geographic distribution of Silurian communities. Some of these communities were adapted to life under conditions of stronger sunlight and more vigorous wave energy in shallow nearshore waters; others were restricted to darker, quieter environments in deeper offshore waters.

Pentamerid communities

The *Pentamerus* Community (Figure 23) was an early Silurian community dominated by the large-shelled brachiopod *Pentamerus oblongus.* The community often included from 5 to 20 associated species, although enormous monospecific populations sometimes are found preserved in growth position. The *Pentamerus* Community and its slightly older or younger equivalents dominated by similar pentamerid species in the genera *Virgiana, Borealis, Pentameroides,* and *Kirkidium* all occupied a bathymetric zone of medium water depth. These pentamerid communities are known to have lived in sunlit waters because they are associated with robust, calcareous green algae. The waters were not too shallow, however, because pentamerid brachiopods lost their pedicle (the fleshy appendage that tethers the shell to the seafloor) as they matured, and thus unsecured populations were vulnerable to disruption by steady wave activity. The pentamerid communities thrived within a depth range of perhaps 30 to 60 metres. This was below the level of normal (fair weather) wave activity but still in reach of storm waves. At their lower depth limit, the pentamerid communities were out of reach of all but the most intense and infrequent storms.

Figure 23: An early Silurian *Pentamerus* community.

In regions such as Wales that are characterized by clastic deposition, an onshore–offshore array of five brachiopod-dominated communities may be mapped in belts running parallel to the ancient shoreline. Listed in order from shallowest to deepest position, they are the *Lingula, Eocoelia, Pentamerus, Stricklandia,* and *Clorinda* communities. Below a relatively steep gradient, the centre of the Welsh basin was filled by graptolitic shales. Other areas, such as the Laurentian and Siberian platforms characterized by carbonate deposition, typically developed a continuum of stromatolite, coral-stromatoporoid, *Pentamerus,* and *Stricklandia* communities. *Clorinda* communities were rare in this setting. *Stricklandia* communities sometimes included smaller, less robust individuals of calcareous green algae, indicating a slightly deeper-water environment than that occupied by the *Pentamerus* Community. Coral-stromatoporoid communities (Figure 24), which sometimes formed reef mounds, preferred wave-agitated waters shallower than 30 metres. Much like the reef communities of today, they could not tolerate the more excessive rates of sedimentation typical of clastic settings. Bathymetric

relief on carbonate platforms was very gentle; the full spectrum of available communities usually was expressed over a gradient hundreds of kilometres long. In contrast, the bathymetric gradient on the Welsh shelf was no more than a few tens of kilometres long. Like the *Pentamerus* Community, the other early Silurian communities have ecological equivalents that took their place in later Silurian time. Sea-level fluctuations (see above) are reconstructed by studying community replacement patterns through well-exposed stratigraphic sequences and then comparing the timing of trends on an interregional to intercontinental basis.

Reef mounds (bioherms) provided the Silurian seafloor with an organically constructed microtopography featuring zonations of segregated brachiopods, gastropods, crinoids, and trilobites. The Thornton Reef Complex outside Chicago is an example of a well-zoned Wenlock complex more than one kilometre in diameter. Others are well known from the Silurian of Manitoulin Island (Ontario, Can.), northern Greenland, Shropshire (Eng.), Gotland (Swed.), Estonia, the central and southern Urals of Russia, and Siberia. The most spectacular complex is a 350-kilometre-long barrier reef of late Llandovery–early Wenlock age in northern Greenland. Reefs of all Silurian ages are known, but their development probably reached a climax during Wenlock time. Several thousand bioherms have been recognized from outcrop and subsurface evidence across a tract of 800,000 square kilometres surrounding the Great Lakes region of North America.

Silurian biozonation also is evident on a global scale. The rich benthic faunas just described were tropical to subtropical in distribution. A southern temperate zone, sometimes called the Malvinokaffric Realm, is represented by the low diversity *Clarkeia* (brachiopod) fauna from Gondwanan Africa and South America. A northern temperate zone is represented by the low-diversity *Tuvaella* (brachiopod) fauna mostly restricted to Mongolia and adjacent parts of Siberia. The *Tuvaella* fauna also has been discovered in northwestern China, which apparently represents a more southern extension.

Fish representative of all Silurian ages were widely distributed in marine environments (carbonate and clastic) in a broad belt within the latitudes 40° N and S of the paleoequator. They are known from individual scales as well as from rare body molds. A wide variety of Agnatha (jawless) fish are represented by species belonging to the orders Thelodonti, Heterostraci, Osteostraci, and Anaspida. Fishes with a primitive jaw apparatus are represented by members of the subclasses Acanthodii, Elasmobranchii, and Actinopterygii. Different endemic groups developed in Laurentia (known widely from sites in the Canadian Arctic, the Yukon, Pennsylvania, New York, and especially Scotland), Baltica (especially Norway and Estonia), and Siberia (including adjacent Mongolia).

Vascular land plants

Land colonization by vascular plants was under way during most of the Silurian Period, although activity clearly was restricted to coastal lowlands. Plant megafossils preserved as coalified impressions are fragmentary. Their known distribution includes most of the Silurian continents with limited representation on Laurentia (New York and northern Greenland), Baltica (Avalonian Wales and England, as well as Podolia), the Siberian corner of Sinkiang (northwestern China), and some Australian and North African sectors of Gondwana (Victoria and Libya, respectively). Latitudinal distribution apparently ranged from about 45° N (Siberia) to 30° S (Libya). Species belonging to the genus *Cooksonia* were among the first and most successful vascular land plants found in all the above-cited areas except for northern Greenland and Australia. These plants were small (about six centimetres in height) with smooth, simply branched stems bearing spore sacs at their tips. Photosynthesis took place entirely within the leafless stems. A distinctly endemic group is represented by the genus *Baragwanathia* (Ludlow age) in Victoria, Australia. (M.E.Jo.)

DEVONIAN PERIOD

General considerations. The Devonian Period is the interval of the Paleozoic Era that follows the Silurian and precedes the Carboniferous. It is thought to have covered the span of time between about 408 and 360 million years ago (see Table 4). The rocks that were formed or deposited during this interval make up the Devonian System. Rocks of this system are known on all continents both at outcrop and in the subsurface. Extensive areas of North America, South America, Europe, and the Soviet Union are underlain by Devonian rocks at depth. Subsequent folding has made such rocks common in many of the ancient fold belts.

Paleocontinents of the Devonian

Rocks of Devonian age were deposited after the fusion of the so-called Iapetus Suture had joined the paleocontinents of Laurentia and Baltica (see above) during the Caledonian orogeny. The combined landmass, known as Laurussia or Euramerica, gave rise to widespread areas of continental desert, playa, and alluvial plain depositions. This Old Red Sandstone continental area of what is now Spitsbergen, Greenland, some of Canada's Arctic Islands, Wales and Scotland, and the Baltic Shield forms one of the earliest documented large areas of nonmarine sedimentation. The Old Red Sandstone sectors of eastern and western North America, central and southern Europe, and parts of European Russia are fringed by marine deposits, however.

The present-day southern continents of South America, Africa, India, Australia, and Antarctica were joined together as the enormous continental mass called Gondwana during the Devonian. At this time Gondwana began impinging upon Laurussia. Also, large areas of Asia east of the Ural Mountains were divided into separate landmasses at this point in Earth history. Their distribution is poorly understood, but many of them may have been attached to the margins of Gondwana.

The name Devonian is derived from the county of Devon, Eng. Sedgwick and Murchison proposed the designation in 1839 for the marine rocks they encountered in southwestern England, following the recognition by another British geologist, William Lonsdale, that fossil corals from Torquay in Devon seemed intermediate in type between those of the Silurian System below and those of the Lower Carboniferous System above. This led to the conclusion that the fossil corals were marine equivalents of the terrestrial Old Red Sandstone rocks already known in Wales and Scotland. The recognition that such major paleogeographic differences existed was a great scientific advance, and it was soon confirmed when Sedgwick and Murchison visited Germany and again when Murchison discovered an intercalation of Devonian marine fossils and Old Red Sandstone fish near St. Petersburg in northwestern Russia. By 1843 James Hall of the United States was able to describe equivalent rocks in eastern North America, but precise correlation with European rocks was not achieved until some years later.

Boundaries and subdivisions. During the last half of the 20th century, the International Union of Geological Sciences (IUGS) defined the base of the Devonian System—*i.e.,* the Silurian–Devonian boundary—in a section of an outcrop of sedimentary rock near Klonk, Czech Republic (see above *Silurian Period: General considerations*). A point at La Serre in southern France has been identified as the Devonian–Carboniferous boundary. The base and top of the Devonian System mark the beginning and end of Devonian time.

Devonian series and stages

The characteristics of local sequences have given rise to many different names for subdivisions of Devonian rocks in various parts of the world. For international standardization, however, the IUGS now accepts division of the Devonian System into three series, which are in turn subdivided into stages (see Table 10).

The stage divisions given in the table were agreed upon only recently, so that different terminology may be found in older literature. Each of the stages listed either has been or soon will be defined by a type section or by what is termed a global stratotype section and point (GSSP).

Historically the early Devonian had been divided into the Gedinnian and Siegenian, which were stages based on clastic sections in Belgium and Germany. These sections were difficult to correlate globally, and highly fossiliferous calcareous rocks of similar age in the Czech Republic proved much more applicable. Thus the Czech terms have

Table 10: Subdivisions of the Devonian System

series	stages
Upper Devonian	Famennian (name derived from Famennes, Belg.) Frasnian (from Frasnes, Belg.)
Middle Devonian	Givetian (from Givet, Fr.) Eifelian (from Eifel Hills, Ger.)
Lower Devonian	Emsian (from Ems, Ger.) Pragian (from Prague, Czech Rep.) Lochkovian (from Lochkov, Czech Rep.)

been adopted for international definition. The designation Coblenzian was formerly employed and encompassed both the Siegenian and Emsian stages. Among French-speaking geologists the stage name Couvinian (from Couvin in Belgium) was used in a sense similar to the Eifelian. The new boundary between the Middle and Upper Devonian is somewhat higher than that formerly used in Germany and Belgium. The new definitions reflect the need to establish internationally useful marker levels.

Difficulty in correlating the Silurian–Devonian boundary

Stratigraphic boundaries within the Devonian System are correlated using various fossil groups. In Devonian marine deposits, the conodonts, ammonoids, spores, brachiopods, and corals are particularly useful. In nonmarine deposits such sea-living forms are not found, and freshwater fish and plant spores are employed for correlation. In the past, considerable difficulty was encountered in correlating the Silurian–Devonian boundary, and serious errors were made until recently. This situation resulted because of the misconception that graptolites became extinct at the boundary. It is now known that these invertebrates range almost to the Pragian–Emsian boundary. In areas where graptolites range so high, especially in mainland Europe and what was once the Soviet Union, much miscorrelation occurred. Today the base of the graptolite zone of *Monograptus uniformis* is regarded as the Silurian–Devonian boundary.

The Devonian–Carboniferous boundary similarly had been variously defined in different parts of the world. Although by 1935 it had been agreed to establish the boundary at the entry of the ammonoid *Gattendorfia* using a section in Hönnetal, Ger., French- and Russian-speaking geologists did not universally follow this approach, as they preferred an earlier level. It was subsequently discovered that a gap in the spore record occurs in Hönnetal below the entry of *Gattendorfia*, and the matter has been thoroughly investigated, resulting in a new IUGS definition based on the first appearance of the conodont *Siphonodella sulcata*.

Radiometric evidence has provided various estimates of the time interval represented by the Devonian System. Recent estimates for the base have ranged between 400 and 416 million years ago, and estimates for the top have ranged between 356 and 367 million years ago. (The different estimates carry method errors in excess of these figures.) In practice, it is the evolution of fossil groups that is used to subdivide and correlate rocks of the Devonian System, and at present the conodont and ammonoid scales give about 55 zonal divisions of the system, yielding a relative resolution of about 1 million years in most parts of the system, although in some parts it is considerably better.

Old Red Sandstone continent

Distinctive features. As previously noted, the Devonian System is well represented on all continents. The development of the Old Red Sandstone continent in the area of North America, Greenland, Scandinavia, and the northern British Isles, which were united during Devonian time, gives the first extensive evidence for nonmarine conditions. Because of this, the Devonian is remarkable for its evidence of the colonization of land as well as freshwater rivers and lakes by plants and fish. Both groups existed prior to this time, but they had their earliest extensive evolutionary radiation during the Devonian.

Economic significance. Devonian rocks are locally of economic importance. Marbles of Devonian age have been quarried in France and Belgium. German medieval castles are mostly clad with Devonian slates. In many countries Devonian rocks have provided building stone, refractory and building brick, glass sands, and abrasives. In areas of European Russia and in Saskatchewan, Can., evaporites, including anhydrite and halite, are commercially exploited. Lodes of tin, zinc, and copper occur in several areas where Devonian rocks have been subject to orogenic processes, as in Devon and Cornwall in England and in central Europe. Since the 19th century, oil and natural gas have been produced from Devonian rocks in New York and Pennsylvania. In the 1930s oil was found in Devonian sandstones in the Ural–Volga region and later in the Pechora area of northern European Russia. In 1947 oil was discovered in an Upper Devonian reef at Leduc, Alta.; this was followed by vigorous exploration, and oil production from the area remains significant today.

Devonian rocks. *Occurrence and distribution.* It generally is believed that Europe and North America were united approximately along the present continental slope margins during the Devonian Period. At the close of the Silurian and continuing in the Early Devonian, considerable igneous activity occurred in the belt including New England, Nova Scotia, Newfoundland, Scotland, Scandinavia, and eastern Greenland. Europe joined as described, the belt thus indicated formed a mountain tract of active uplift. This is the Caledonian mountain belt that resulted from the Caledonian orogeny. The deposits of the Old Red Sandstones appear to be the detritus produced by the erosion of these mountain areas. The marine Devonian rocks of western Canada and those in a belt from Montana to New York in North America, in Europe from Devon to the Holy Cross Mountains of Poland, on the Russian Platform and Novaya Zemlya, and, again, in the Arctic Islands of Canada appear to provide evidence that marine waters encircled the Old Red Sandstone continent.

The accompanying world map (Figure 25) shows the distribution of most of the major outcrops of Devonian rocks. In many areas the Devonian rocks have been much disturbed tectonically by subsequent deformation. These fold belts may be distinguished from cratonic areas where sediments remain much as they were when formed. The main fold belts in North America are the Cordillera (western mountain ranges, including the Rocky Mountains) and the Appalachian belts in the east. In contrast, the Devonian of the Midwest and adjoining areas is flat-lying. In South America, the main fold belt is the Andes and sub-Andes, and east of this line the Devonian rocks are little disturbed. In Australia the main fold belt is in the east from Queensland to Tasmania. In Europe the Armorican fold belt stretches eastward from Cornwall and Brittany. To the south of this line from the Pyrenees to Malaysia, Devonian rocks are caught up in the Alpine-Himalayan fold belt. Similarly, the Devonian of the Ural Mountains is disturbed, whereas to the west, on the Russian Platform, and to the east there is less deformation. In all these cases the folding occurred well after the Devonian, but there is evidence that Devonian sedimentation contributed to the oceanic belts that were sites of the mountain building that occurred later.

In the regions that have suffered severe deformation, the Devonian sediments are frequently metamorphosed into slates and schists and often lose all the characters by which they may be dated. In areas where little change has taken place, all rock lithologies occur, from those characteristic of continental and desert conditions to the varied lithologies associated with shelf and deep-sea accumulation. Contemporary igneous activity is widespread, both in the form of extrusive lavas, submarine pillow lavas, tuffs, agglomerates, and bentonites and also igneous intrusion. Extrusive activity is found in both continental and marine environments, whereas plutonic intrusions are usually linked with areas of uplift such as the Caledonian and Acadian belts of Europe and eastern North America.

For convenience in description this account will commence with a brief review of the European and North African sequences and then pass eastward to Russia, China, and Malaysia. Treatment of the southern continents from New Zealand to South America will follow, and North America will be considered last. Occurrences of various units are presented in Tables 11 and 12.

Europe

A line passing from the Bristol Channel eastward to northern Belgium and Germany roughly demarcates the Devonian marine area south of the Old Red Sandstone continental deposits, which characteristically are red-stained with iron oxide. The continental deposits extend also to Greenland, Spitsbergen, Bear Island, and Norway. The British geologist Robert Jameson coined the term "Old Red Sandstone" in 1808, mistakenly thinking it to be A.G. Werner's "Aelter Rother Sandstein," now known to be of Permian age. The rocks of this wide area have a remarkable affinity in both fauna and rock type and are usually considered to have been united in Devonian times. The relations with the underlying Silurian system are seen in the classic Welsh Borderlands, where the Ludlow Bone Bed was taken as the boundary until international agreement placed it somewhat higher. In Wales, southern Ireland, and the Scottish Lowlands, thicknesses of detritus, chiefly sandstones, accumulated to as much as 6,100 metres in places, and widespread volcanics occur in Scotland. These sediments are rich in fish and plants, as are the eastern Greenland and Norwegian deposits.

Devonian rocks in Devon and Cornwall are mostly marine, but there are intercalations of terrestrial deposits from the north. In northern Devon at least 3,660 metres of shales, thin limestones, sandstones, and conglomerates occur, the latter two lithologies typical of the Hangman Grits and Pickwell Down Sandstones, which are the main terrestrial intercalations. However, in southern Devon reef limestones are in the Middle Devonian, and the Upper Devonian locally shows very thin sequences formed on submarine rises and contemporary pillow lavas in basinal areas. In northern Cornwall both the Middle and Upper Devonian are primarily in slate facies. Fossils found in these rocks have permitted detailed correlations with the Belgian and German sequences.

Devonian rocks of mixed terrestrial and marine type are known from boreholes under London, and these form a link with the Pas de Calais outcrops and to the classic areas of the Ardennes. There, between the Dinant Basin and Namur Basin to the north is evidence of a northward landmass, as in Devon. Both the Lower and Upper Devonian consist of near-shore and terrigenous sediments that reach thicknesses of 2,740 metres and 460 metres, respectively. The Middle Devonian and lower Upper Devonian (*i.e.,* the Eifelian, Givetian, and Frasnian stages, whose type sections are here) consist mainly of limestones and shales and reach at least 1,500 metres in the south. Reefs are especially well developed in the Frasnian and occur as isolated masses, usually less than about 800 metres in length, separated by shales. Equivalents to the north show red and green silts and shales of marginal continental marine type. Because the Belgian Devonian rocks are well exposed along a north–south line, their changes in thickness, lithology, and fauna have been well-documented.

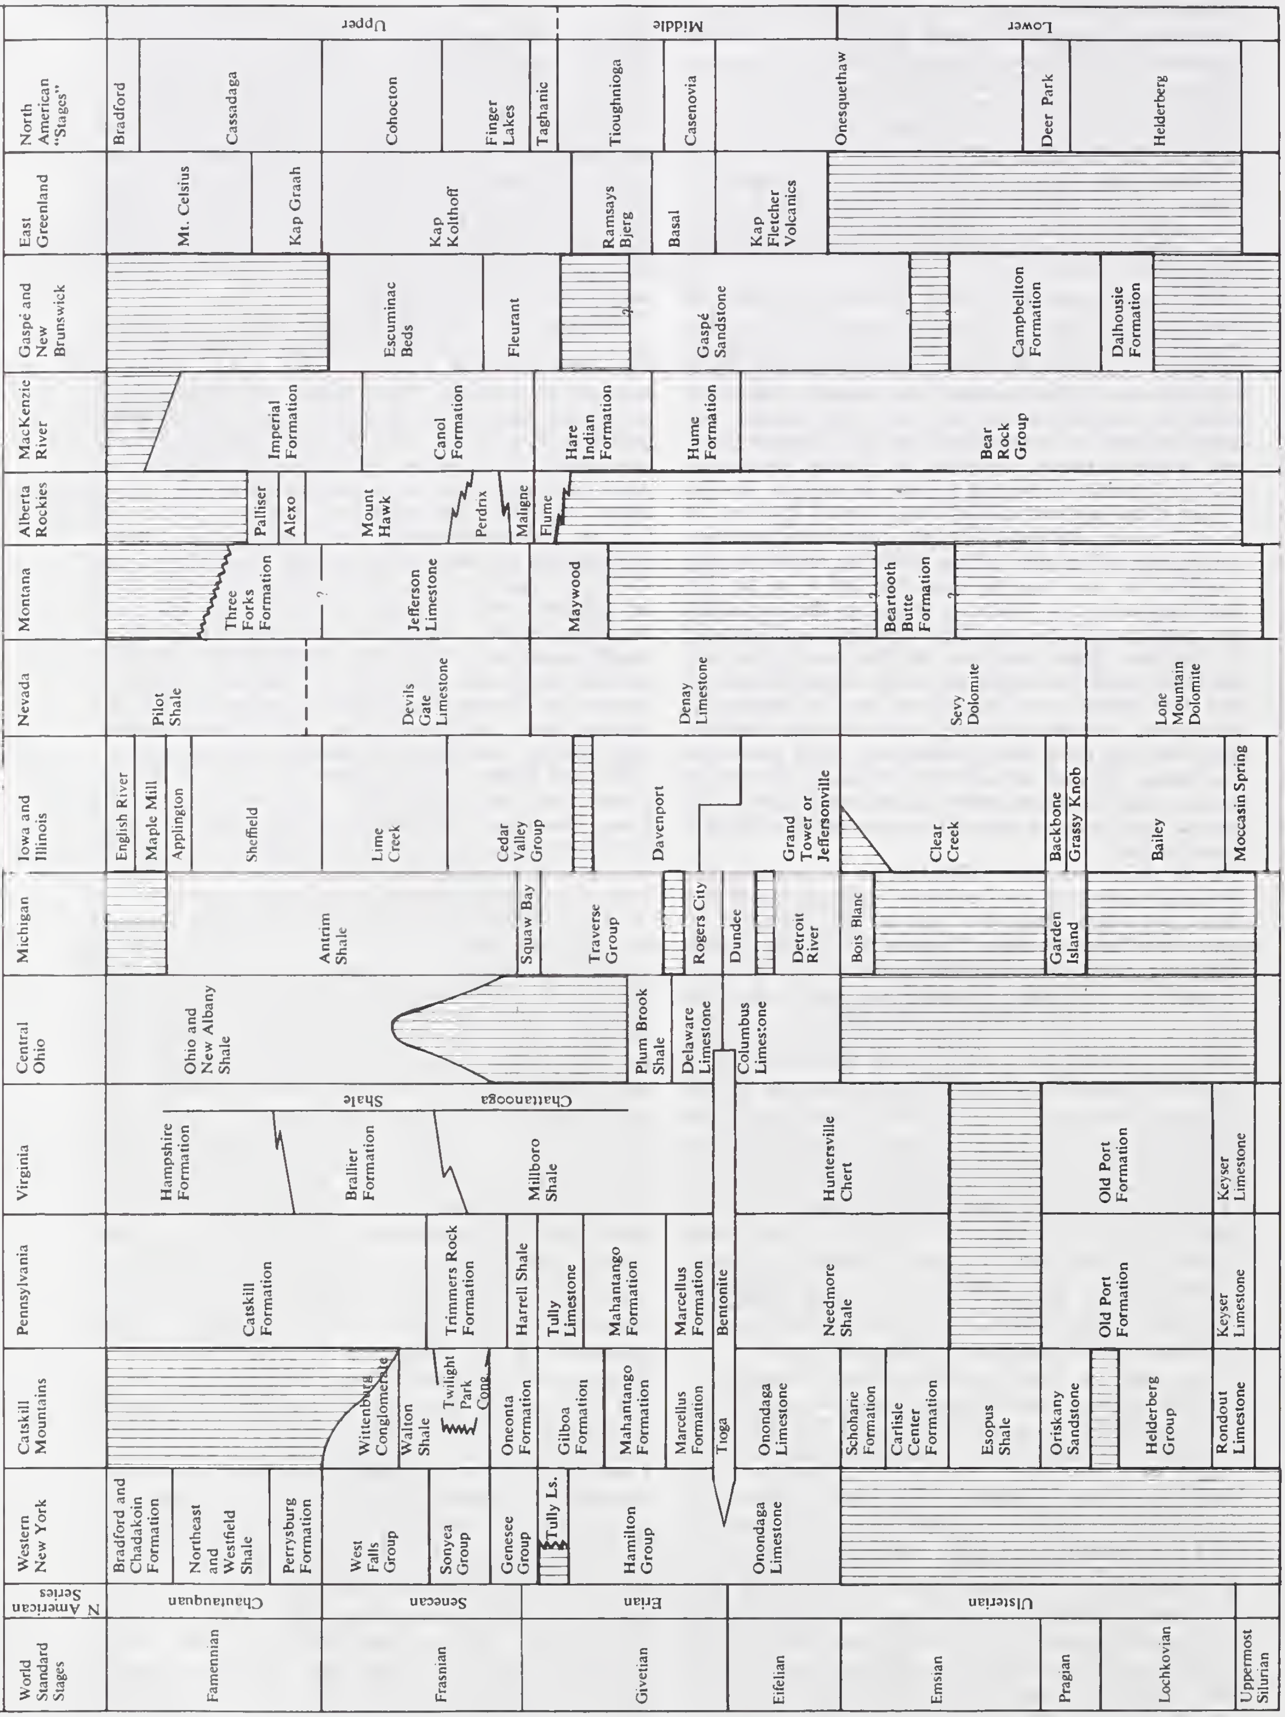
The Eifel forms a natural eastern extension of the Ardennes, and a somewhat similar succession is known. The Lower Devonian is nonmarine, and the Middle Devonian and Frasnian have a poor reef development, but the calcareous shales and limestones carry a rich and famous fauna. The uppermost Devonian is not preserved.

The Rhine valley, along with the Rheinisches Schiefergebirge to the east, has been, since the early days of geology, the subject of extensive study by the numerous German universities that surround it. Again, a northern sediment source generally is indicated, but a borehole near Münster, well to the north, has encountered Middle and lower Upper Devonian marine limestones. To the south also, approaching the Hunsrück-Taunus mountains, there is evidence of a landmass. Between these areas a rich Devonian sequence is exposed in folded terrain. The maximum thickness is 9,140 metres. The Lower Devonian consists of slates and sandstones. The slate has been much worked to clad houses and castles. A ledge of Emsian sandstone in the Rhine gorge is the setting for the Lorelei legend. Limestones are common in the Givetian and are termed Massenkalk. Middle and Upper Devonian areas of thin sedimentation, as in Devon, are interpreted as deposits on submarine ridges. These are commonly nodular limestones rich in cephalopods that occur between thick shale sequences. Evidence of volcanic activity is common, and this has been invoked to explain the concentrations of sedimentary hematite iron ores in the Givetian and Frasnian. The Harz Mountains show a more calcareous Lower Devonian section. Here copper, lead, and zinc are exploited from lodes in the famous Wissenbach Slate.

A calcareous Lower Devonian succession, the Bohemian facies, occurs in the Prague Basin of eastern Europe. A continuous marine succession formed from the Silurian into the Devonian, and the boundary is drawn at the top of the Přídolí Formation with the crinoid genus *Scyphocrinites.* The overlying Lochkovian and Pragian formations include the Koneprusy Limestone with substantial reefs. The Upper Devonian is not preserved. In Moravia complete successions of calcareous and basinal volcanic sediments occur.

Devonian rocks of a type analogous to those of southern England and the Ardennes crop out in Brittany. Farther south outcrops occur in Spain and Portugal. The successions of the Pyrenees, Montagne Noire, and Carnic Alps include deepwater limestones; and marine deposits are known in the Balkan Peninsula, including Macedonia,

Table 12: Devonian Stages of North America



and Romania. The southern Polish outcrops of the Holy Cross Mountains are especially famous and include a lower marine and continental series with a calcareous Middle Devonian and an Upper Devonian of reefs and shales rich in ammonoids and trilobites.

In Podolia, along the Dniester (Dnestr) River, are fine marine sections going well up into the Lower Devonian and overlain by the Dniester Series of the Old Red Sandstone type. During the entire Devonian the Ural Mountains formed a depressional trough linked northward to Novaya Zemlya and southward to the Crimean–Caucasian geosyncline that, with the southern European outcrops already mentioned, formed part of the original Tethyan sediments of the Alpine–Himalayan fold system

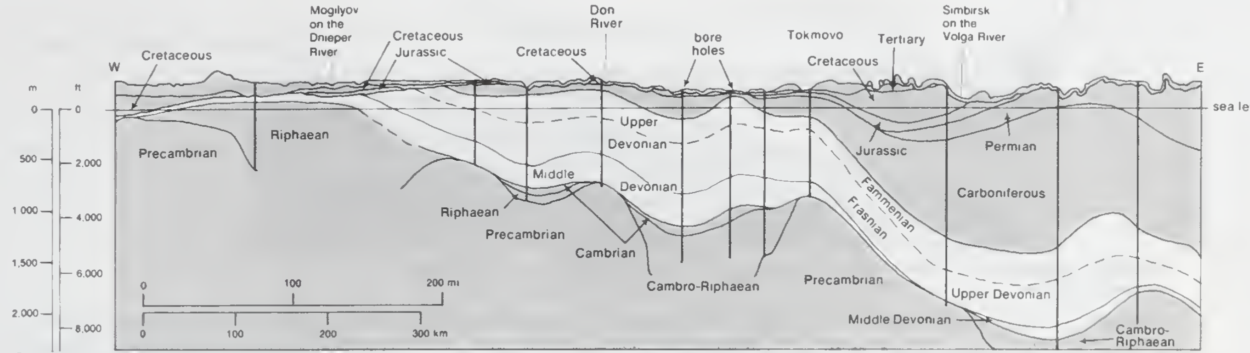


Figure 26: Geologic cross section from near the Polish frontier eastward to the foothills of the Ural Mountains showing subsurface distribution of Devonian rocks.

of the present day. In European Russia, Old Red Sandstone conditions were general, but marine tongues stretched westward from the Urals to reach Moscow in the Middle Devonian and St. Petersburg in the lower Upper Devonian. A remarkable series of boreholes revealed this in great detail (Figure 26), and there is widespread evidence for salt lakes. Apart from the St. Petersburg outcrop and those along the Don River south of Moscow, the salt lakes are known from subsurface data only. Of economic importance here are the Timan-Pechora oil and gas field and the oil and potash of the Pripet Marshes. The North African areas of Algeria and especially Morocco are noted for their wealth of fossils.

Asia

Devonian rocks are widespread in Asia east of the Ural Mountains; however, in Devonian time Asia was composed of separated microcratons or terranes, which appear to have been attached, or adjacent, to the northern margin of Gondwana (see below *Paleogeography*). The coalescence into present-day Asia took place after the Devonian. Devonian rocks are well known fringing the central Siberian craton (a Devonian microcontinent), especially in some of the northern coastal islands, in the Kolyma River basin, and even farther east in Siberia. A particularly good record has been found in Kazakhstan. Devonian rocks occur in the Caucasus and Tien Shan mountains along the southern border of Kyrgyzstan, and there is an excellent carbonate sequence in the Salair and a full marine sequence in the Altai. The Altai–Sayan area contains a wealth of Old Red Sandstone fish and plants.

Scattered Devonian sequences occur in Turkey, Iran, and Afghanistan, but the Himalayan records need revision, as it has now been determined that reported significant fossils are spurious and come from quite different areas. Isolated Devonian rocks are known in Vietnam and Malaysia.

The Greater Khingan Range has a good record of Middle and Upper Devonian marine deposits. China is especially noted for its Devonian rocks; both marine and nonmarine facies occur. Reefs and carbonate deposits also are well developed, and the photographically spectacular sugar-loaf hills near Kuei-lin are of Devonian age. Much research by Chinese geologists since the early 1980s has led to great advances in knowledge of the Devonian in the many outcrops in the People's Republic of China. Devonian rocks in Japan contain the plant genus *Leptophloeum*, which is also widespread in China.

Southern Hemisphere

In New Zealand the Lower Devonian is known in the Reefton and Baton River areas. The brachiopods in the fauna include European elements and have few typical austral types.

Devonian rocks are known in eastern Australia in a belt from Queensland to Tasmania as part of the Tasman geosyncline. Fluviatile sediments are found to the west. Thicknesses of 6,100 metres are known. *Leptophloeum* is found in the Upper Devonian portion. Devonian rocks occur in central Australia in Lake Amadeus and along the western coast in the Carnarvon, Canning, and Bonaparte Gulf basins. Complex facies changes are known, and the Canning Basin reef complexes show every detail of forereef, reef, and backreef structures exposed by modern erosion.

In the Antarctic both marine and continental Devonian occur, the latter rich in fossil fishes of European genera. The marine Lower Devonian shows some affinity with the Bokkeveld in South Africa, which, in turn, has strong links with South America. No Devonian is known in Africa between Bokkeveld and sections in Ghana and northwestern Africa.

Early Devonian marine rocks are well developed in South America, but the Late Devonian is poorly documented. In the western mountains of the Andes and sub-Andes, Devonian remnants are preserved from southern Chile north to Peru, Ecuador, Venezuela, and Colombia. The Devonian rocks of Uruguay, Argentina, and Brazil are thought to represent marine transgression from the west. Both continental and marine faunas have been documented. The fauna of the Falkland Islands as well as of the Paraná and Parnaíba basins includes many genera of brachiopods and trilobites that are common within the circum-Antarctic region but unknown in the Northern Hemisphere. In Venezuela and Colombia, however, faunas of Appalachian type dominate, although austral elements, such as *Australospirifer*, linger.

North America

The Appalachian area of eastern North America shows spectacular and historically famous Devonian rocks first described by James Hall in New York state. A source of sand and other clastics in the east provided a flood of sediment from an eastern land area, which formed the Devonian Catskill Delta that filled a broad sedimentary trough (Figure 27). In the area encompassing Ontario, Michigan, and Indiana, early thin calcareous sequences give way to deeper-water marine black shales, which were formed especially in the area of the Great Lakes and south beyond Indiana. The central area of the United States formed a mid-continental rise during the Devonian, and the Devonian rock record there is thin and incomplete. Devonian rocks are well developed in New Mexico, Utah, Nevada, and north to Montana, where evaporites in the subsurface are known to extend into Saskatchewan. In the mountainous area of the eastern United States, Devonian rocks are scattered and may have coalesced from separate microcratons or microplates over a long period of time. Very thick sequences of Devonian volcanics are known, for example, in the Sierra Nevada of California. In western Canada flat-lying Devonian rocks are well known in the

Light gray areas represent red and green shales, sandstones, and conglomerates deposited in fresh or brackish water. Darker gray area represents dark gray or black shales and limestones with marine fossils. White areas indicate gray shales and siltstones with shallow-water marine organisms.

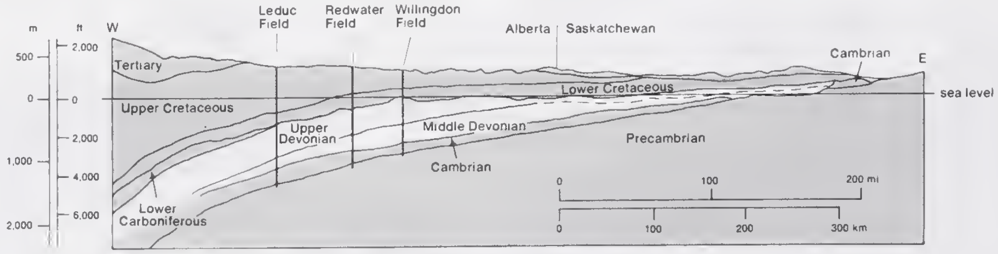

Figure 28: Geologic cross section from the foothills of the Rocky Mountains eastward across the interior plains of Canada showing location of oil fields in the Devonian subsurface rocks.

subsurface of Saskatchewan, and in Alberta they include oil-bearing Devonian reefs (Figure 28). Devonian reef complexes also occur along the Canadian Rocky Mountains. Involved in the thrusting of the Rockies, they can be seen in Alberta's Banff and Jasper national parks. In more scattered outcrops to the east, it would appear that deeper-water facies are represented. Following the discovery of oil in a Devonian reef at Leduc, Alta., much detailed exploration was undertaken. Rocks of Devonian age are widespread from there northward to the Canadian Arctic islands and Alaska. Their faunas show many similarities with those of Europe.

Types. A wide range of terrestrial and marine sediments of Devonian age are known internationally, and there is a corresponding variety of sedimentary rock types. Devonian igneous activity was considerable, albeit localized. The Old Red Sandstone continent is thought to have been near-tropical and sometimes arid. Playa facies, eolian dunes, and fan breccias are known. Fluviatile sediments, deposited by water under flash-flood conditions, have been identified, and these link to alluvial sediments of broad coastal flats. There are lacustrine deposits of freshwater or supersaline type. Similar facies are known in other continental areas of the Devonian. Similarly, nearshore clastic, delta sandstones and prodelta and offshore mud facies compare with those known in other periods.

Special features

Devonian sedimentary rocks include the spectacular carbonate reef deposits of Western Australia, Europe, and western Canada, where the reefs are largely formed of stromatoporoids. These marine invertebrates suddenly vanished almost entirely by the end of the Frasnian Age, after which reefs were formed locally of cyanobacterian stromatolites. Also distinctively Devonian is the development of locally extensive black shale deposits. The Upper Devonian Antrim, New Albany, and Chattanooga shales are of this variety, and in Europe the German Hunsrückschiefer and Wissenbacherschiefer are similar. The latter are frequently characterized by distinctive fossils, but rarely of the benthic variety, indicating that they were formed when seafloor oxygen levels were very low. Distinctive condensed pelagic limestones rich in fossil cephalopods occur locally in Europe and the Urals; these form the facies termed "cephalopodenkalk" or "knollenkalk" in Germany and "griotte" in France. In former times, the latter was worked for marble. Evaporite deposits are widespread, but coals are rare. There is no firm evidence for glacial deposits. Various types of volcanic rocks have been observed in the areas that were converging island-arc regimes. Some volcanic-ash horizons, such as the Tioga Metabentonite of the eastern United States, represent short-term events that are useful for correlation.

Correlation. Most groups of fossil forms contribute to the establishment of a faunal and floral chronology that enables Devonian rocks to be correlated. For the continental deposits, fish and plant spores are most important. The fish give a very precise zonation in parts of the system. The Baltic Frasnian, for example, can be divided into at least five time zones using psammosteids (Agnatha), thus probably equaling the precision possible for the better-known marine Frasnian sequences. Many problems remain, however, in the correlation of the continental and the marine deposits.

The faunal succession in marine strata has been established for many groups, but only those of significance for international correlations are mentioned here. Traditionally the goniatites and clymenids (ammonoid Cephalopoda) form the standard. The succession established first in Germany by the paleontologist Rudolf Wedekind in 1917 has been found to hold for all continents where representatives have been discovered. The index genera are shown in Table 13. All these genus zones (or *Stufen*) are subdivisible into species zones.

Rivaling the ammonoids in most parts of the Devonian and useful for defining the base of the system are the conodonts. The Late Devonian was characterized by a spectacular evolutionary radiation of *Palmatolepis* and its relatives.

The brachiopods, although more restricted, are also important. This is particularly true of the spiriferids of the Early Devonian and of the entry and evolution of the cyrtospiriferid types in the Late Devonian. The rhynchonellids also are of great value in the subdivision of the Late Devonian. Some brachiopods, however, show diverse distribution patterns. *Stringocephalus,* a well-known Middle Devonian guide fossil in the western United States, Canada, Europe, and Asia, is entirely absent from the rich New York succession; yet *Tropidoleptus,* elsewhere confined to the Lower and Middle Devonian, ranges high in the Devonian of New York. Corals also have been used for correlation, but further work suggests they were particularly sensitive to changing local environments and thus are poor time indicators.

Tables 11 and 12 show rock sequences in many parts of the world and how they are thought to be correlated.

Devonian environment. Rock types of the Devonian System indicate that most environments of the present day were represented but that they were very differently distributed. During Devonian times the equator is thought to have passed across Laurussia, and so the Old Red Sandstone continent was essentially tropical or subtropical. Paleomagnetic evidence, however, is not clear, and various positions for the equator have been proposed. Furthermore, paleomagnetic evidence can suggest former magnetic latitudes, but it does not indicate longitudinal position. For Gondwana, the evidence suggests a pole probably in the South African area during the Devonian.

Paleogeography. A description of the physical geography of the Devonian can be attempted using evidence from paleomagnetism, paleoclimate, paleobiogeography, and tectonic reconstruction. Because the paleomagnetic data for the Devonian remains problematic, recent efforts to elucidate paleogeographic position have concentrated on the rock types associated with particular environments and to a lesser extent on faunal distributional data. Such methods use the distribution of evaporites, shelf carbonates, and hermatypic corals, since the present-day aspects of these deposits have specific climatic constraints.

The reconstruction for the later part of the Early Devonian (shown in Figure 29) reflects one interpretation of continental distribution. There is general agreement that the equator crossed the northern part of the Old Red Sandstone continent during the Devonian but that it migrated southward over the course of the period. This is indicated by the reduction in evaporitic environments in western Canada and the onset of humid and moist conditions in the area of New York. Evidence of nonmarine fish and marine invertebrates provides links across the northern area between Europe, Siberia, and the Canadian Arctic islands. Positioning in relation to Gondwana is more difficult. Some interpretations favour a wide ocean separating Gondwana from Laurussia. This arrangement is thought unlikely because of the remarkable occurrences

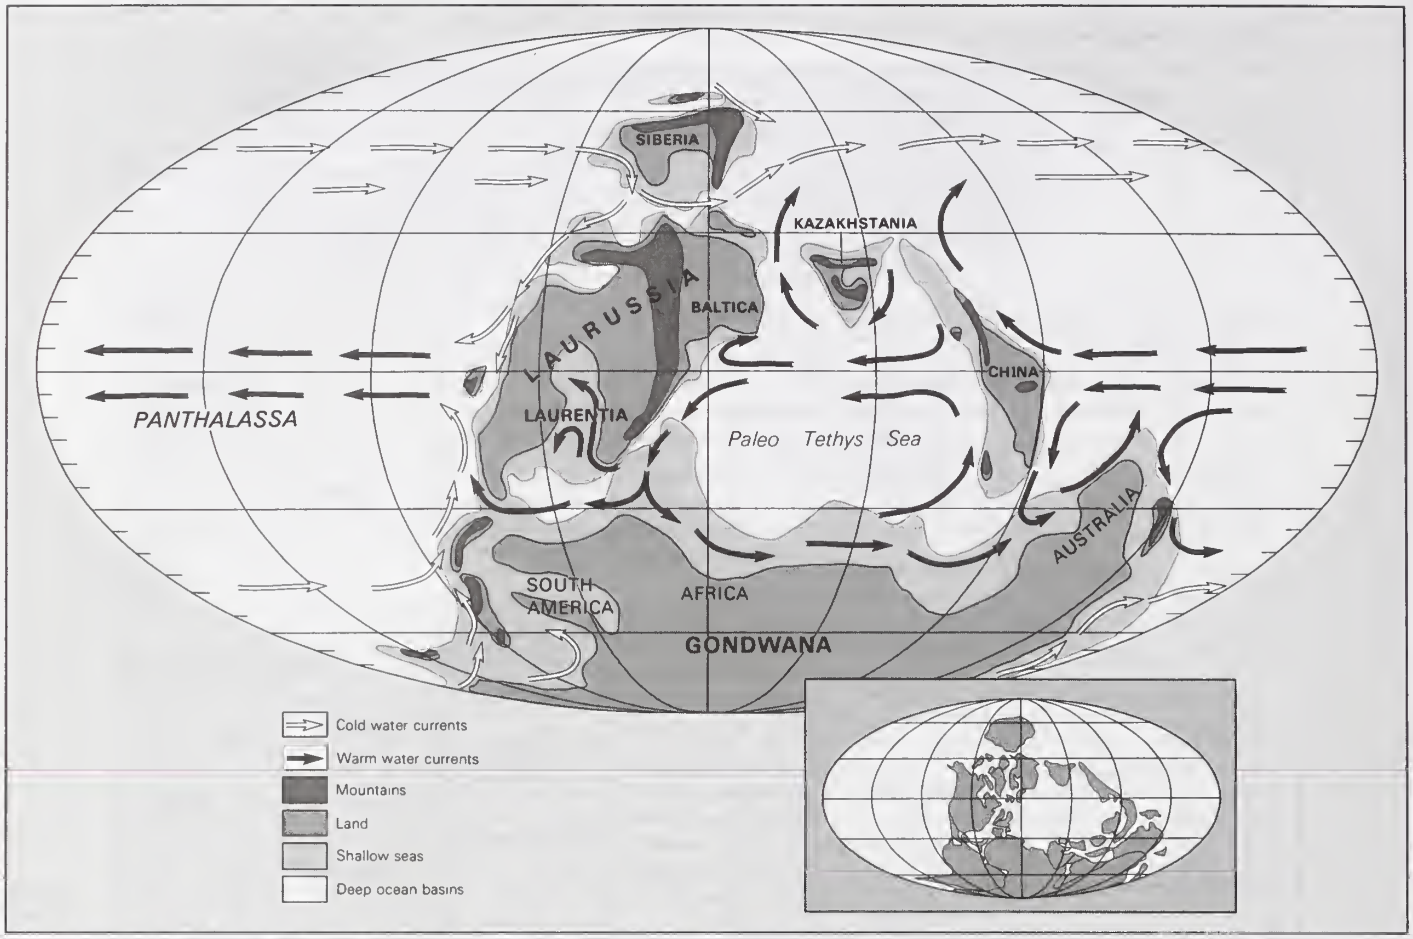

Figure 29: Distribution of landmasses, mountainous regions, shallow seas, and deep ocean basins during Early Devonian time. Included in the paleogeographic reconstruction are cold and warm ocean currents. The present-day coastlines and tectonic boundaries of the configured continents are shown in the inset at the lower right.

Adapted from C.R. Scotese, The University of Texas at Arlington

of similar corals, brachiopods, and ammonoids between eastern North America, Morocco, and Spain. Yet, even if they were close together, precise positioning is a matter for dispute, and using the preceding argument some would have North Africa adjacent to the eastern North American seaboard.

There is general agreement that the southern continents of today were united during the Devonian along the lines of their present-day continental slopes. Paleomagnetic evidence is, however, inconsistent on the position of the South Pole; some suggestions favour central South America, while others advance positions in South Africa or sites off the southeast coast. The late Devonian reef developments in Western Australia suggest a near tropical site.

During the Devonian, Asia was composed of many separate microplates that are now joined together. Of these, Siberia and Kazakhstania began fusing during the late Devonian and later joined Laurussia, forming the Ural Mountains along the junction. The positions of the other microcontinents are rather uncertain, but many of them were probably either attached or adjacent to the northern margin of Gondwana and migrated north to fuse with growing Asia at several junctures during the later Phanerozoic.

Tectonic events

Significant geologic events. The union of Laurentia and Europe during the Caledonian orogeny near the beginning of the Devonian Period established a mountain chain that traversed at least from Greenland and western Scandinavia, through Scotland, Ireland, and northern England, including eastern North America especially east of the Hudson River, and continued south to the fringes of western North Africa. Radiometric dating of granitic intrusions yields ages in this belt of between about 430 and 380 million years. The igneous activity that produced such intrusions constituted the final stages of subduction and obduction (*i.e.,* overthrusting of the edge of one lithospheric plate over another at a convergent boundary), leading to the union of the constituent parts of the Old Red Sandstone continent. Considerable extrusive and intrusive volcanic activity would have been associated with the Caledonian orogenic belt. Clastic material from the belt dominated the European Lower Devonian but was local and limited after that point. In eastern North America similar activity near the Silurian–Devonian boundary was followed by renewed activity during the Middle Devonian that was associated with the Acadian orogeny and the commencement of the Catskill Delta. The easterly derived fan clastics of the latter are increasingly dominant eastward across New York state, and its mostly nonmarine alluvial rocks are best seen in the Catskill Mountains near Albany.

It is clear that there was probably easterly directed subduction in western North America during the Devonian. Relics of this process are to be sought in the Cordilleran Mountain chain as discrete terranes that were accreted to the continent during or after the Devonian. The clearest evidence is from the mid-Famennian Antler orogeny, during which a tectonic event that resulted in clastic material spreading eastward is well documented, especially in Nevada.

Sedimentary events

In recent years it has become increasingly apparent that there were specific periods of sedimentary perturbation during the Devonian Period. A dozen or so such "events" have been identified (Table 14). An associated transgression, regression, or transgression/regression "couplet" of brief duration is often involved. Some of these were accompanied by short-term deposition of anoxic (*i.e.,* oxygen-depleted) black shales or limestones. Many are quite widespread internationally, and while eustatic sea-level changes were usually involved, none of the sedimentary indicators appear to be global. Some are associated

with the extinction of important groups of fossil organisms. Two are especially important in this regard, the double Kellwasser event and the Hangenberg event.

All the so-called events listed in Table 14 are associated with the loss of certain fossil groups. The pair of Kellwasser events in the late Frasnian show a staged extinction of many groups, especially colonial rugose corals, stromatoporoids, and numerous varieties associated with carbonate environments, including orthid, pentamerid, and atrypid brachiopods, and a large number of trilobite groups. This extinction event has been interpreted as having resulted from one of the following phenomena: a global deepening of the sea by transgression leading to the destruction of reefs and hence of many of their associated fauna; a widespread development of anoxia following transgression and regression; or a meteoroidal or cometary impact and resultant dust clouds. The extinctions of the Hangenberg event at the close of the Devonian show the loss of the clymenid ammonoids and of the phacopid trilobites. Again, there is a link with anoxic conditions, as attested to by the Hangenberg Shale in Europe and by the Exshaw Shale and its equivalents in the western United States and similar lithologies recognized in China.

Paleoclimate. There is evidence for most of the expected climatic belts during the Devonian. Evidence of glacial deposits in the Devonian is questionable, however, and it is clear that, if polar ice caps did exist, they were very much smaller than they are today. It follows that the Earth was warmer during Devonian time than at present.

Prevalence of warm and equable climates

The wide distribution of evaporite basins in the Northern Hemisphere, of coals in Arctic Canada and Spitsbergen, of desert conditions, and of widespread marine faunas and carbonate reefs suggests that warm and equable climates covered large areas. Nevertheless, from New York, where rich forests grew, *Callixylon* trunks with annual rings typical of the seasonal growth of higher latitudes are known. Studies of growth lines on Devonian corals indicate that the number of days in the Devonian year was on the order of 400 and that the lunar cycle was about 30½ days. The wide distribution of salt deposits suggests high evaporation and warm climates in many areas from western Canada to Ukraine and Siberia and, again, locally in Australia.

Devonian life. A highly varied invertebrate fauna derived from that of the Silurian continued in the Devonian, and most ecological niches of shallow and deep marine water were exploited. The remarkable proliferation of primitive fish, which has given the period the name the "Age of Fishes," occurred in both fresh and marine waters. Derivation of carnivorous fish from mud-eating forms occurred early in the period, and the tetrapods were derived from the fish near the close of the period. Also remarkable is the rise to dominance of the vascular plants. By the mid-Devonian the first tree forests are known in place, but rich groves must have occurred earlier to provide the widespread plant debris.

Invertebrates

The Devonian invertebrate faunas are essentially of the type established by the Ordovician. In nearshore sandy and silty environments bivalves, burrowing organisms, brachiopods, and simple corals abounded. In offshore reefs, free from land detritus, biostromes and bioherms flourished, rich in corals, stromatoporoids, crinoids, brachiopods, trilobites, gastropods, and other forms. In deeper waters the cephalopod goniatites, one of the few new groups to appear, were abundant; and there is evidence that the surface levels of these deep waters were occupied by small dacryoconarids of uncertain affinity and by ostracods (arthropods) later in the period.

Both Foraminifera and Radiolaria among the Protozoa are well known, and sponges were locally abundant; the famous dictyospongoids of New York are an example.

The corals and stromatoporoids among the coelenterate Hydrozoa were extremely important in the reef facies. Elsewhere, only simple corals are frequently found. The limestone-reef and forereef facies and biostromal limestones are known in many areas of the world. The corals include tabulate corals, such as *Favosites* and *Alveolites,* but especially rugose corals, which have been used to establish correlations. *Amphipora* is a common rock-building type in the mid-Devonian of the Northern Hemisphere, and its twiglike form produces a "spaghetti" or "vermicelli" rock.

Bryozoa were especially common in shallow shelf seas of the period, and rich faunas are known from North America. Both stony (trepostomatous) and netted forms occurred, but the latter, the fenestellids, became important during the period.

The brachiopods of the Devonian show great diversity. The spire-bearing spiriferoids were perhaps the most common and have been used for zonation. Two groups of importance emerged during the Devonian: the loop-bearing terebratulids and the spiny, mud-dwelling productids. At the same time, a number of groups became extinct, including various orthids and the pentamerids.

Molluscan groups were well represented. The marine clams (Bivalvia) increased greatly during the period, especially in the nearshore environments. The earliest freshwater bivalves appeared in the Late Devonian. The gastropods were well diversified, particularly in calcareous environments, but much less than in later periods. The Scaphopoda first appeared here. A significant Devonian event was the origin of the ammonoids from their continuing nautiloid ancestors. In the chambered shell of the ammonoids, the siphuncle is ventral or outermost in position (except in Late Devonian clymenids), and the septa commence the elaborate folded patterns that culminate in the ammonites of the Mesozoic. From their appearance, probably in the Emsian, the evolution of the goniatites and later ammonites allows a detailed zonal subdivision to be established through the end of the Cretaceous. Devonian goniatites have been found on all continents except Antarctica.

Among the Arthropoda the giant Eurypterida are found in the Old Red Sandstone facies. Some were predacious carnivores and probably lived on fish. The first insect, a supposed collembolan, has been recorded from the Devonian of Russia and other areas of the former Soviet Union. Ostracods were locally very abundant; benthic forms occur in shelf-sea deposits and planktonic forms in the Upper Devonian, where their remains form the widespread ostracod-slate facies or cypridinenschiefer. The trilobites were well developed in terms of size (some up to 61 centimetres long), variety, and distribution. Nearly all have clearly established Silurian ancestors. The most common were the phacopids, which exhibit a curious trend toward blindness in the Late Devonian. Almost all the diverse Lower Paleozoic trilobite stocks that entered the period were extinct before the close, and only the proetaceans survived into the Early Carboniferous.

Among the Echinodermata, holothureans, asteroids, and ophiuroids are known, but they are rare. Crinoids were abundant, including free-living types with grapnel-shaped anchors. The blastoids diversified considerably, but the cystoids did not survive the period.

Conodonts had perhaps their greatest diversification during the Late Devonian and have proved of major importance for correlation.

Vertebrates

Many groups of Devonian fish were heavily armoured, and this has led to their good representation in the fossil record. Fish remains are widespread in the Old Red Sandstone rocks of Europe, especially in the Welsh Borderland and Scottish areas; these are mostly associated with freshwater or estuarine deposits. In other areas marine fish are known, and some of these, such as *Dunkleosteus* (*Dinichthys*) from the Upper Devonian of Ohio, may have reached nine metres in length.

The earliest fish, comprising the Agnatha, were without jaws and presumably were mud-eaters and scavengers. These are usually called ostracoderms. Some, such as the osteostracan cephalaspids, had broad, platelike armour of varied form; and the brain and nerve structures in some of these are well known. The anaspids also were covered with armour in the form of scales. The heterostracans, which include the oldest known fish, have an anterior armour basically of upper (dorsal) and lower (ventral) plates; *Pteraspis* is an example. The Early Devonian saw the entry of jawed forms or gnathostomes, and the armoured forms of these, the Placodermi, characterize the period. The arthrodires with a hinged frontal armour in two portions, and the grotesque antiarchs belong here. The close of the Devonian saw the diminution and extinction of most of these groups, but several other groups continued and have a significant later history. Sharklike fish, the Chondrichthyes, have been found in the Middle Devonian. The bony fish, or Osteichthyes of current classification, include the climatioid acanthodeans, which had appeared before the period began, but the lungfish (Dipnoi), the coelacanths, and the rhipidistians made their first appearance during this time. The last group is thought to have given rise to the four-footed amphibians as well as to all other higher groups of vertebrates.

Plants

In the history of vascular plants, Devonian evidence is of fundamental importance because there was a remarkable initiation of vascular plants of diverse type. Their colonization gave rise to the first forests, such as the rich Gilboa forest of New York, of late Middle Devonian age. Much new information on spores is being provided by palynologists, and this situation may enable the antecedents of the Devonian flora to be established. Evidence of algae is common in the period, Bryophyta are first known here, and Charophyta are locally common. Freshwater algae and fungi are known in the Rhynie Chert of Scotland.

Some supposedly Silurian floras, such as that at Baragwanath, Vic., Australia, are now known to be Early Devonian. The *Cooksonia* Late Silurian record of what is now the Czech Republic seems to be the earliest unquestionable evidence of vascular plants. By the Early Devonian a varied flora was established.

The Psylotophytopsida is the most primitive group of the Pteridophyta; they did not survive the Late Devonian. *Cooksonia, Rhynia,* and others possessing a naked stem with terminal sporangia belong here. In other members, sporangia were borne laterally, but no true leaves were developed, and the branching was often of a primitive dichotomous type. The Psylotophytopsida forms a basic stock from which other groups apparently evolved. *Asteroxylon,* known with *Rhynia* in the Lower Old Red Sandstone Rhynie Chert of Scotland, forms a link with the Lycopsida by having lateral sporangia and a dense leafy stem. This group soon gave rise to treelike forms and later to the important lepidodendrids of the Carboniferous flora. Another apparent derivative, the Sphenopsida, with jointed branches, is represented by *Hyenia* and *Pseudobornia.* The Pteropsida also appeared in the Devonian. Primitive gymnosperms are known and drifted trunks of *Callixylon,* up to 1.8 metres in diameter, occur in Upper Devonian deposits of the eastern United States and the Donets Basin of Russia and Ukraine.

The rich record of land plants may be related to the fact that the Old Red Sandstone represents the first widespread record of continental conditions. However, the primitive nature of the stocks seen and the absence of a long earlier record, even of drifted fragments of vascular plants, suggest that the colonization and exploitation of this environment was a real Devonian event. Fortuitous finds, such as the silicified flora of the Rhynie Chert and the pyritized tissue from the Upper Devonian of New York, have enabled the intimate anatomy of many of these forms to be elucidated in detail equivalent to that of modern forms.

Faunal realms and migrations

There is a marked similarity in the faunas and floras of the continental facies the world over. Recent records from such deposits in China containing Early Devonian genera of the armoured fish *Cephalaspis* and *Pterichthys* or the widespread Australian records of *Bothriolepis,* a Late Devonian antiarch, link closely with the Old Red Sandstone faunas of Europe. Yet when studied in more detail, specific differences become apparent. It has been suggested that the Baltic fish succession is so rich that it must have formed a migration centre. This may be so, but the wide distribution of supposed estuarine and freshwater fish raises many problems. Many of these can be resolved if the continents were closer together during the Devonian than at present.

The marine faunas of the Devonian give little evidence of faunal provinces. It is true that in the Lower Devonian the brachiopod *Australocoelia* has been recognized only in the Antarctic, the Falkland Islands, South America, South Africa, and Tasmania and that *Australospirifer, Scaphiocoelia,* and *Pleurothyrella* share parts of this distribution. These genera are not known in the marine Lower Devonian of northern continents, and this seems to establish an "Austral" fauna of limited circum-Antarctic distribution at this time (if the southern continents were then united as Gondwana). Elements of this fauna are often called "Malvinokaffric" after the Falkland (Malvinas) Islands and the South African Bokkeveld Beds. At other levels in the Devonian, however, provincial distinctions are not apparent, with the exception of local coral provinces that are distinguishable in the areas that once constituted the Soviet Union. (M.R.H.)

CARBONIFEROUS PERIOD

General considerations. The Carboniferous Period is the interval of the Paleozoic Era that succeeds the Devonian and precedes the Permian. In terms of absolute time, the Carboniferous began approximately 360 million years ago and ended 286 million years ago (see Table 4). Its duration of roughly 74 million years makes it the longest period of the Paleozoic and the second longest of the entire Phanerozoic time scale. The rocks that were formed or deposited during the period constitute the Carboniferous System. The name Carboniferous is derived from coal deposits typical of strata in the upper portion of the system throughout the world.

Boundaries and subdivisions. In the early organization and subdivision of Britain's geologic record, coal-bearing strata were combined with a portion of the underlying rock record to be distinguished as the Carboniferous "Order." The Carboniferous initially included the following rock units (listed in ascending order): Old Red Sandstone; Carboniferous, or Mountain, Limestone; Millstone Grit and Shale; and the Coal Measures. The Old Red Sandstone was subsequently placed in the Devonian System, and with time the Upper and Lower subdivisions of the Carboniferous served to differentiate the productive Coal Measures from the barren, predominantly limestone strata below. A similar subdivision was recognizable in North America, and the names Mississippian and Pennsylvanian were proposed as series-rank subdivisions to formalize the same separation of coal-bearing strata from underlying limestones of the Carboniferous System. With the emphasis on the use of unconformities (widespread surfaces of erosion) as a basis for period or system recognition, it was argued that the Mississippian and Pennsylvanian should be separate systems, comparable to the others of

the Paleozoic, because of their unconformable contact. That proposal has been accepted in North America since about 1915, although the U.S. Geological Survey treated the Mississippian and Pennsylvanian as subsystems of the Carboniferous until the 1950s.

The Mississippian and Pennsylvanian have rarely been used outside of North America as systems or lower-ranking subdivisions of the Carboniferous. It has been recognized, at least since 1937, that the Lower–Upper Carboniferous boundary of Europe falls well below the Mississippian–Pennsylvanian boundary in North America. Consequently, neither boundary or subdivision has much stratigraphic significance to the other geographic region. Recently, the Lower–Upper subdivisions of the European Carboniferous were formalized as subsystems with the names Dinantian and Silesian, respectively. In Russia, Ukraine, and other former Soviet republics, a threefold division of the Carboniferous has been employed, with the Lower–Middle boundary approximating the Mississippian–Pennsylvanian boundary and the Middle–Upper boundary falling in the upper portion of the Pennsylvanian.

Carboniferous series and stages

The Carboniferous System has been broken down into series-level subdivisions throughout the world. In Europe the Dinantian, or Lower Carboniferous, is divided into the Tournaisian and succeeding Visean series. The Silesian, or Upper Carboniferous, is divided into the Namurian, Westphalian, and Stephanian series. The British Dinantian has been subdivided further into six stages (in ascending order): the Courceyan, Chadian, Arundian, Holkerian, Asbian, and Brigantian. These stages have for the most part replaced the use of Tournaisian and Visean in Britain, but the Dinantian is still employed as a subsystem. Stages also have been recognized in the Silesian throughout Europe. In the Namurian Series, these stages were originally named for their characteristic ammonoid genus (*e.g., Eumorphoceras* = E stage), with further subdivisions identified by numbered subscripts and letters. This practice has been replaced by the use of geographically named stages, but their letter designations are still commonly given. Currently, the Namurian is divided into the Pendleian (E_1), Arnsbergian (E_2), Chokierian (H_1), Alportian (H_2), Kinderscoutian (R_1), Marsdenian (R_2), and Yeadonian (G_1) stages. Westphalian stages have been lettered A–D. Geographic names adopted for these stages are Langsettian (A), Duckmantian (B), and Bolsovian (C). Westphalian D remains unnamed. The Stephanian is divided into the Cantabrian Stage succeeded by three stages lettered A–C. Barruelian has been adopted recently for Stephanian A. Representative rock exposures, or type sections, have been proposed in Europe for most of these series or stage divisions from which fossils may be collected to fix the time concepts they represent and to provide an objective base for their correlation.

In North America, the Mississippian is divided into the Kinderhookian, Osagian, Meramecan, and Chesterian series. The Pennsylvanian for most of the continent is divided into the Morrowan, Atokan, Desmoinesian, Missourian, and Virgilian series (see Table 15). In contrast, the Pennsylvanian of the Appalachian region, particularly its coal basins, is divided into the Pottsville, Allegheny, Conemaugh, and Monongahela series. In the former Soviet republics the Lower Carboniferous is divided into the Tournaisian, Visean, and Serpukhovian series. The Middle Carboniferous is subdivided into the Bashkirian and Moscovian series, and the Upper Carboniferous is broken down into the Kasimovian and Gzhelian. In China the Lower Carboniferous consists of the Aikuanian and Tatangian series, while the Upper Carboniferous is composed of the Weiningian and Mapingian. Correlation of the boundaries of these various divisions of the Carboniferous is unsettled and is the focus of international research. A suggested correlation chart is given in Table 15.

A proposal for an international classification of the Carboniferous System was presented at the Eighth International Congress on Carboniferous Stratigraphy and Geology held in Moscow in 1975. This proposal, shown in Table 16, represents a significant advance toward standardization of international Carboniferous nomenclature. While final agreement on the names used to designate the various levels of the classification scheme lies well in the future, it has been agreed internationally that the bipartite division of the system would make use of subsystems and that their boundary would fall at a level approximating the appearance of the ammonoid genus *Homoceras,* the conodont species *Declinognathodus noduliferus,* and the foraminifers *Millerella pressa* and *M. marblensis.* A date of 320 million years is generally assigned to this horizon. At the same time, international agreement has been reached on a working definition of the Devonian–Carboniferous boundary. Operationally, this horizon is placed at the base of the appearance of the conodont *Siphonodella sulcata* (in an evolutionary lineage derived from *S. praesulcata*). An international effort is under way to find reference stratotype sections for both the Devonian–Carboniferous and mid-Carboniferous boundaries.

Varied depositional settings

Distinctive features. The Carboniferous was a time of highly variable depositional settings, exhibiting both shallow-marine and continental environments. In the Northern Hemisphere, the Lower Carboniferous is characterized by shallow-water limestones, while the Upper Carboniferous has cyclic sedimentary deposits, reflecting an alternation of marine and nonmarine conditions and a frequent occurrence of coal swamps. In contrast, the Southern Hemisphere experienced widespread continental glaciations during much of the same interval.

Plants and animals were diverse and had a decisive effect on the accumulation of the Carboniferous sedimentary record. Most Lower Carboniferous limestones are composed of the disarticulated remains of stalked echinoderms known as crinoids. Bryozoans and brachiopods were also common and diverse in the Lower Carboniferous. Coals and associated strata in the Upper Carboniferous contain abundant remains of unusual vascular plants, such as the sphenopsids, lycopods (or lycopsids), and seed ferns. More coal was formed during the Upper Carboniferous than at any other time in the entire geologic record. In the Southern Hemisphere a cold-climate flora, typified by seed ferns, dominated upland environments and became the source of coal deposits as well. Amphibians, which appeared in the Devonian, were joined on land by a great variety of insects. In addition, the first reptiles appeared in the late portion of the Upper Carboniferous.

Pulses of mountain building occurred in the Cordilleran (Rocky Mountain) region of North America, the Hercynides and Ural Mountains of Europe, and in Asia and Africa. The preservation of these physical and biological events is one of the most extensive in the entire Phanerozoic record, and Carboniferous strata are well exposed on all continents.

Economic significance. Much of the recoverable bituminous coal of eastern North America and Europe occurs in large sedimentary basins of the Upper Carboniferous. Smaller coal basins of Carboniferous age are found in North Africa (Algeria and Morocco), northern China, and Korea. Also of considerable economic importance are limestone deposits of Lower Carboniferous age. Such limestones are extensively quarried for building stone, lime, cement, and fertilizer. Other commercially valuable materials derived from Carboniferous rocks include refractory clays and gypsum.

Carboniferous rocks. *Occurrence and distribution—Lower Carboniferous.* The Carboniferous is traditionally broken down into lower and upper divisions that reflect major differences in depositional regimes and biota as well as in age and correlation. The Lower Carboniferous, or Mississippian, is characterized by shallow-water limestones deposited on broad shelves occupying most continental interiors, but particularly in the Northern Hemisphere. By contrast, geosynclinal facies, especially turbidites, formed in deeper troughs along continental margins. Shallow terrigenous clastic facies, such as sandstone and shale, are more poorly developed, and coals are rare.

Types—Lower Carboniferous. Limestones of the Lower Carboniferous are for the most part composed of the disarticulated remains of crinoids. These echinoderms attached themselves to the seafloor by means of a long stalk. The stalk and the flowerlike crown of such animals are composed of plates consisting of single crystals of calcite (calcium carbonate). The crinoids grew in great profusion, forming "meadows" of thousands of individuals. Calcite is extremely stable in warm, shallow marine conditions, and so when individual crinoids died their plates would accumulate on the seafloor as sand-sized sediments, which were subsequently cemented together by calcium carbonate. The crinoid fragments were frequently reworked by currents, and the deposits exhibit both cross-bedding and ripple marks. Deposits of crinoidal limestone approaching 160 metres in thickness are not uncommon for certain intervals of Lower Carboniferous time, particularly in North America. Limestone of this kind is exploited as quarry stone.

Crinoidal limestone deposits

In addition to the crinoidal limestones, oolitic limestones and lime mudstones formed in shallow-water marine environments of the Lower Carboniferous. Ooliths are concentric spheres of calcium carbonate that were inorganically precipitated around a nucleus on warm, marine-shelf margins subject to high wave energy (such as the Bahama Shelf and northern Red Sea today). These deposits also exhibit cross-bedding and ripple marks, which testify to the high-energy conditions. Mixtures of ooliths and abraded fossil fragments, particularly foraminifers, are common in the Lower Carboniferous. Lime mudstones reflect quiet, shallow-water environments, such as are found in Florida Bay and on the west side of Andros Island in the Bahamas, which may have been exposed by tidal change. The carbonate mud is produced through the life cycle of green algae, but fossils are not particularly common in these lithologies. Deposits of these Lower Carboniferous limestones are frequently used as quarry stones as well.

In the upper portion of the Lower Carboniferous, marine cycles are developed, probably reflecting the beginning of mountain building in the Appalachian region of eastern North America. Quartz sandstones typically appeared at the outset of each of these cycles as the seas transgressed across the continental interiors. Shales may succeed the sandstones, followed by limestone development, which suggests the clearing of the water and the establishment of carbonate production by animals and plants.

Limestones of Lower Carboniferous age are typically as-

Chert lenses and beds

sociated with lenses and beds of chert (silicon dioxide). The origin of this chert is somewhat problematic, but it appears to be of either primary or secondary origin. Chert of both origins may occur within a single limestone unit but reflect different times of silicification. Primary cherts form penecontemporaneously with the deposition of the limestones in slightly deeper water settings. Secondary chert forms as a later replacement by groundwater usually involving shallower water deposits. Primary cherts are frequently dark-coloured (flint) and disrupt the bedding rather than follow it. They usually lack fossils. Secondary chert is light-coloured, follows the bedding, and is usually fossiliferous.

In deeper-water carbonate regimes on the margins of the continents, limestones become finer-grained and the biotic component less readily recognizable; crinoids and bryozoans are only a minor component. These deposits are termed the Waulsortian facies, and mounds cored by carbonate mud formed on ramps that extended from the shelf areas into deeper water. Famous exposures of such mounds occur in the Franco-Belgian Basin near Namur in south-central Belgium; southwestern Ireland, particularly County Galway; the Craven basin in northern England; and the Sacramento Mountains of southern New Mexico in the United States. The Waulsortian mounds lack an obvious baffling or framework-building organism that would have formed these cores, although cryptostomous bryozoans have been observed in mounds in New Mexico and crinoid "halos" are associated with mounds in both Europe and North America.

In contrast to the shallow-shelf areas that received carbonate sediments, the deeper intracontinental basins and geosynclines are characterized by terrigenous clastics. In Europe these clastics are termed the Culm facies, and they may also contain volcanic units. In North America the eastern continental margin received thick sequences of coarse clastics derived from the highlands to the east that were formed during the late Devonian. Turbidites of Lower Carboniferous age were deposited in both the Ouachita–Marathon and Cordilleran geosynclines. Turbidites, as well as marine and terrestrial clastics of Lower Carboniferous age, have been reported from South America, Australia, and both North and South Africa. Coal-bearing deposits occur in portions of Scotland, Belgium, China, Russia (Siberia), and Kazakhstan. Evaporite deposits and red beds were formed as part of the Lower Carboniferous record of the Maritime Provinces of Canada. Igneous activity, particularly volcanism and granitoid intrusions, characterizes the Lower Carboniferous record of Australia. The Clyde Plateau lavas of Scotland also are of Lower Carboniferous age.

Type region for the Mississippian subsystem

Correlation—Lower Carboniferous. The type region for the Mississippian subsystem lies in the central Mississippi River valley of the United States. Most of the formations representing the type sequence are found in Missouri, Iowa, and Illinois. The Kinderhookian Series includes the Hannibal Formation and the Chouteau Group. The succeeding Osagian Series includes the Burlington Limestone and overlying Keokuk Limestone. The Meramecan Series includes (in ascending order) the Warsaw Formation, Salem Formation, St. Louis Limestone, Sainte Genevieve Formation, Aux Vases Sandstone, and a portion of the Renault Formation. The Chesterian Series includes (in ascending order) the following formations: upper Renault, Yankeetown, Downeys Bluff, Bethel, Ridenhower, Cypress, Beech Creek, Fraileys, Haney, Hardinsburg, Glen Dean, Tar Springs, Vienna, Waltersburg, Menard, Palestine, Clore, Degonia, Kinkaid, and Grove Church. Other well-known Lower Carboniferous units in North America include the Pocono Group and Mauch Chunk Shale of the Appalachian region; the Fort Payne Chert of Tennessee and Alabama; the Caney and Goddard shales of the Arbuckle region in Oklahoma; the Stanley Shale of the Ouachita Mountains in Arkansas and Oklahoma; the Madison Group and Big Snowy Groups of the northern Rocky Mountains; the Redwall Limestone of the Grand Canyon region; and the Lisburne Group of the Brooks Range in northern Alaska.

Lower Carboniferous units exposed at the famous Avon Gorge section at Bristol, Eng. (in ascending order) include the Shirehampton beds, Lower Limestone Shale, Black Rock Limestone, Gully Oolite, Clifton Down Mudstone, Goblin Combe Oolite, Clifton Down Limestone, Hotwells Limestone, and the Upper Cromhall Sandstone. Other notable Lower Carboniferous formations outside of North America include the limestones at Waulsort and the Black Marble of Dinant in Belgium; the Montagne Noire of the French Massif Central; and limestones in Spain and in the Ural Mountains and the Moscow and Donets basins in Russia and Ukraine.

Occurrence and distribution—Upper Carboniferous. The Upper Carboniferous of the Northern Hemisphere is characterized by deposits reflecting an alternating transgression and regression of the continental interiors by shallow seas. These cyclic sequences of distinct strata known as cyclothems include both terrigenous clastics and limestones. Nonmarine strata typically develop coal beds, and Upper Carboniferous (or Pennsylvanian) cyclothems contain the major portion of world coal reserves. Coal cyclothems are interpreted as having resulted from the widespread continental glaciation reflected in coeval deposits of the Southern Hemisphere. Geosynclinal areas continued to receive clastic facies, particularly turbidites, and brief episodes of mountain building began to markedly affect depositional sequences and their thicknesses.

Coal cyclothems

Types—Upper Carboniferous. Cyclothems occur on a worldwide basis throughout the Upper Carboniferous strata, but they have been most widely studied in North America. The cyclothems display one of two types of development. In the eastern interior of North America, where they were first studied, a single cyclothem might consist of as many as 10 separate beds reflective of a single transgression-regression by shallow seas. The lower portion of the cyclothem is predominantly nonmarine and consists of (in ascending order) sandstone, shale, "freshwater" limestone, underclay (buried soil), and a coal bed. Its upper portion shows evidence of marine conditions and is composed of alternating shale and limestone beds, both of which usually contain fossils. The nonmarine sequence probably represents deltaic conditions associated with the regression that allowed swamp conditions to develop on a delta plain. Transgression began with the shale beds overlying the coal. Rapid regression ends each cycle, which is capped by an unconformity. Most cyclothems are incomplete; they do not exhibit the full sequence of beds.

Cyclothems of the Appalachian Basin coalfields in Ohio, Pennsylvania, and West Virgina typically have a good representation of the nonmarine portion of the sequence with thick coals. These coals formed from the carbonization of plant debris, and it is generally held that 30 centimetres of coal equals the compaction of approximately 1.5 metres of plant material. Some coal beds are remarkably thick. The Mammouth coal bed of the Anthracite Belt (also called the Southern Anthracite field) in eastern Pennsylvania has an average thickness of 11–12 metres throughout its extent. The Pittsburgh seam in western Pennsylvania averages 4 metres thick and is reported workable over 15,500 square kilometres. More than 60 coal seams have been identified in Pennsylvania, although only about 10 have ever been exploited. Coeval cyclothems in the western mid-continent exhibit better development of the marine portion of the sequence and have fewer and thinner coals.

In contrast to the coal cyclothems, predominantly marine intervals of Upper Carboniferous age in the western mid-continent, particularly Kansas, Iowa, and Missouri, feature cylothems with alternating beds of limestone and shale. These cyclothems also reflect transgression and regression by shallow seas, but the lower portion of the cycle is the transgressive event, followed by regression in the upper part. Such a cyclothem begins with a sandy shale containing marine fossils. It is succeeded by dark, carbonate mudstones, which are in turn overlain by black shale. The black shale marks the maximum marine transgression. Above the black shale occur marine carbonate mudstones and grainstones, followed by a return to sandy shale. One striking feature of both coal and marine cyclothems is the tremendous lateral persistency of beds within the sequence. Tracing a single bed from outcrop to outcrop over a distance of hundreds of kilometres would not be uncommon in the mid-continent.

Depositional cycles similar to those of eastern North America can be recognized in Europe, but the distribution of sediments is confined to small isolated basins rather than to a broad cratonic shelf. Nonmarine sequences predominate, and indeed some sequences exhibit no marine influence at all. The positioning of the basins is the result of the folding and faulting associated with the Hercynian orogeny. The Middle and Upper Carboniferous record of eastern Russia is similar to that of North America.

In the Southern Hemisphere, there is a marked cooling event beginning in the Namurian (approximating the mid-Carboniferous boundary), and faunas and floras after that time are highly provincial, impoverished, and adapted to cold climates that persisted into the Permian Period. A single continental mass, Gondwana, existed in the Southern Hemisphere at this time, while several continents, notably Laurussia, Siberia, Kazakhstania, and China (including Southeast Asia), occupied the Northern Hemisphere (see below *Carboniferous environment*). Upper Carboniferous glacial deposits of the Gondwana Realm are characterized by tillites resting on polished and striated bedrock surfaces. Striated cobbles, glaciofluvial deposits, and varved lacustrine (lake) sediments occur over large areas of South America, Africa, India, Australia, and Antarctica. The extensive occurrence of these unusual deposits has been used as an argument for continental drift. Timing of the glacial episodes is still uncertain, and they may have actually begun in the Lower Carboniferous. Furthermore, many glacial advances and retreats occurred, and they were not necessarily simultaneous over the whole of Gondwana.

Gondwanan glacial deposits

Areas marginal to continental masses continued to receive turbidites, particularly in the Ouachita–Marathon region of Arkansas, Oklahoma, and Texas, and the Cordilleran geosyncline in the western United States. Evaporites formed in restricted basins, such as those in Montana–North Dakota (Williston) and the Four Corners area (Paradox), which lay near the Upper Carboniferous equator. Igneous and metamorphic rocks of Upper Carboniferous age reflect the Hercynian orogeny and its equivalents in North America, Europe, and North Africa.

Correlation—Upper Carboniferous: The type region for the Pennsylvanian subsystem is located in central West Virginia. There, the interval is represented by the following groups or formations (in ascending order): Pocahontas, New River, Kanawha, Charleston Sandstone, Conemaugh, Monongahela, and basal Dunkard. Other well-known Upper Carboniferous units in North America include the Jackfork and Johns Valley shales of Oklahoma and Arkansas; the Atoka Formation of Arkansas and Oklahoma; the Supai Group of the Grand Canyon region; the Amsden and Tensleep formations of the northern Rocky Mountains; the Fountain Formation of the central Rocky Mountains; and the Haymond and Gaptank formations of the Marathon region in West Texas. Major coalfields in the United States include the Appalachian region (Pennsylvania, West Virginia, Ohio), Illinois Basin, Mid-continent region (Iowa, Missouri, Kansas), Arkoma Basin (Arkansas and Oklahoma), and north-central Texas.

Type region for the Pennsylvanian subsystem

The type region for the upper part of the Carboniferous in Britain includes the Millstone Grit and the Coal Measures, designations that have been in use since the naming of the system. Local names are applied to specific intervals, and marine horizons, called bands, are named either for their characteristic fossil occurrence (*e.g., Listeri* Marine Band) or for a geographic locality (*e.g.,* Sutton Marine Band). This procedure is followed in most areas outside of North America. Major Upper Carboniferous coalfields occur throughout Europe, especially the central Pennines (Lancashire coal basin), the Scottish border, and southern Wales, in Great Britain; the Franco-Belgian Basin in Belgium; the Saar basin along the border of France and Germany; the French Massif Central (Saint Étienne and Gard coal basins); the Ruhr and Westphalian basins in Germany; the Silesian basin in Poland; and the Moscow and Donets basins in Russia and Ukraine.

Carboniferous environment. *Paleogeography.* Figure 30 shows the assumed positions of the continents during the Upper Carboniferous. As will be noted, the land-sea distribution at the time did not correspond to present-day geography. The bulk of the Earth's landmass was concentrated in the Southern Hemisphere. Relative lithospheric plate movements had brought the continents close together on one side of the globe. Only five major continental masses existed. Laurussia, formed by the joining of Laurentia (principally North America and Greenland) and Baltica (most of northern Europe and Scandinavia) in the Devonian, constituted the single largest landmass in the Northern Hemisphere during the Carboniferous Period. In addition to Laurussia, Siberia, Kazakhstania, and China, which included Southeast Asia, were each separate continents. The enormous continent of Gondwana occupied the Southern Hemisphere. Gondwana combined what are now Africa, India, South America, Australia, the Middle East, and Antarctica. The Tethys seaway separated the landmasses of the Northern and Southern hemispheres near the equator.

Laurussia

During the Lower (early) Carboniferous, Laurussia was apparently more fragmented than Gondwana. Siberia, Kazakhstania, and China occupied positions at high latitudes. Northern Europe and Scandinavia were joined to North America, with what is now northern Canada lying at a mid-latitude position and the United States, Poland, Ukraine, European Russia, Belarus, and adjacent areas near the equator. Gondwana lay entirely in the Southern Hemisphere, although little of the landmass was situated at the South Pole.

By the Upper (late) Carboniferous, plate movements had brought most of Laurussia into contact with Gondwana, thereby closing the Tethys. The two became fused by the Appalachian–Hercynian orogeny, which began in the Upper Carboniferous and continued into the Permian. The United States and northern Europe retained their equatorial position. China and Siberia remained at high latitudes in the Northern Hemisphere.

The distribution of land and sea followed fairly predictable limits. The continental interiors were terrestrial, and no major marine embayments apparently existed. Upland areas of the continental interiors underwent substantial erosion during the Carboniferous. Shallow seas occupied the shelf margins surrounding the continents. It must be remembered that areas that were marginal to the Carboniferous continents may very well have become continental interiors in the present geographic setting (as, for example, much of the United States). Deeper troughs (geosynclines) lay seaward of the continental masses, and their sedimentary record is now represented by mountains.

Significant geologic events. The Carboniferous marks a period of relatively stable crustal conditions between major mountain-building episodes in the Devonian and Permian. Nevertheless, the rocks of both the Lower and Upper Carboniferous show evidence of orogeny and isostatic adjustments in previously formed mountains. Among the major continental masses constituting present world geography, only Antarctica exhibits no recognizable trace of Carboniferous earth movements (tectonics).

Significant mountain building resulted from the collision of Laurussia and Gondwana. The movement of these continents toward each other began in the Lower Carboniferous and continued into the Permian. Their collision resulted in the formation of three mountain belts and ranges essentially at the same time. The Hercynides (occasionally called the Variscan Belt) were formed across southern Europe (including Britain). The Appalachians were formed along the eastern coast of North America, and their counterpart, the Mauritanides, emerged in North Africa. A fourth belt, the Ouachita (Marathon) Mountains, were formed along the southern border of North America. Usually viewed as an extension of the Appalachians, the Ouachita orogeny predates most movements in the Appalachians and is linked to the collision of the southern margin of North America with the South American portion of Gondwana rather than with North Africa.

Formation of the Hercynides, Appalachians, and Mauritanides

Less significant tectonism occurred in the Cordilleran (Rocky Mountain) region during a pulse of the Antler orogeny that elevated the Ancestral Rockies and produced thick clastic wedges, such as the Fountain Arkose. Precordilleran movements occurred in South America, and similar events took place in northern Asia (the Tien Shan, Kunlun, and Timan mountains), Australia, and New Zealand. The Ancestral Urals also were active during the Carboniferous.

Paleoclimate. Carboniferous deposits exhibit steep, latitude-controlled, climatic gradients, reflecting the elongate nature of the continental masses of Laurussia and Gondwana and their positions with respect to the equator, as seen in Figure 30. As would be expected, land areas occupying high latitudes were cold, while those near the equator were warm and moist. Widespread continental glaciation occurred in Gondwana in a manner similar to what took place much later during the Pleistocene Epoch in the Northern Hemisphere. Eustatic rise and fall of sea level resulting from glacial advance and retreat probably caused the cyclothems of the Upper Carboniferous coal swamps that developed in the equatorial region. At their maximum, continental glaciers extended from near the South Pole to nearly 30° S latitude, where subtropical conditions would have more likely prevailed. Coeval continental glaciations did not occur in the high latitudes of the Northern Hemisphere, probably because the landmasses were too small to sustain large ice fields. In addition to the glacial deposits, the floras of the Carboniferous reflect the same climatic gradients. Fossil plants of Carboniferous age found in high latitudes exhibit seasonal growth rings, while those of the presumed equatorial coal swamps lack such rings, just as do modern tropical trees.

Carboniferous life. The Late Devonian experienced major extinctions within some marine invertebrate groups, and Carboniferous faunas reflect a different composition than what had prevailed in the middle Paleozoic. Most notably, reef-forming organisms, such as tabulate corals and stromatoporoids, were limited, and this dearth of framework builders resulted in poorly developed reefs during the Carboniferous. Yet, this period was still one of diverse marine invertebrates. More striking, however, was the remarkable variety of terrestrial animals and plants associated with the coal swamps for which the period is noted. Arguably the most famous Carboniferous fossil occurrence is at Mazon Creek, Ill., in the north-central United States, where ironstone concretions formed around a multitude of different invertebrate and plant specimens. The concretions contain many soft-bodied forms, attesting to the rapid formation and burial of these structures.

Flora and fauna associated with coal swamps

Benthic marine communities in the Carboniferous included a variety of invertebrates. As discussed elsewhere, the crinoids grew in great profusion attached to the seafloor. These animals were solitary suspension-feeders. Their large numbers may have caused baffling of bottom currents, resulting in the deposition of carbonate mud around their bases that developed into mounds on the seafloor. The blastoids, a group of budlike stalked echinoderms related to the crinoids, are abundant in Carboniferous deposits as well. Areas favourable to the crinoids and blastoids were also occupied by the cryptostomous, or lacy, bryozoans. Their fanlike colonies were attached to the seafloor and may have aided in baffling fine sediment. Brachiopods, particularly the winged (or spiriferid) and the spiny (or productid) types, anchored their bivalved shells to the substratum by a fleshy stalk and pumped the water column with a ring of tentacles to recover food in much the same manner as the bryozoans. Brachiopods were particularly common during the Carboniferous, and all orders except the Atrypida and Pentamerida, which became extinct at the end of the Devonian, are found in rocks of the period. Both calcareous and agglutinate foraminifers are represented in Carboniferous deposits, especially limestones. An unusual group of these protozoans, called the fusulinids,

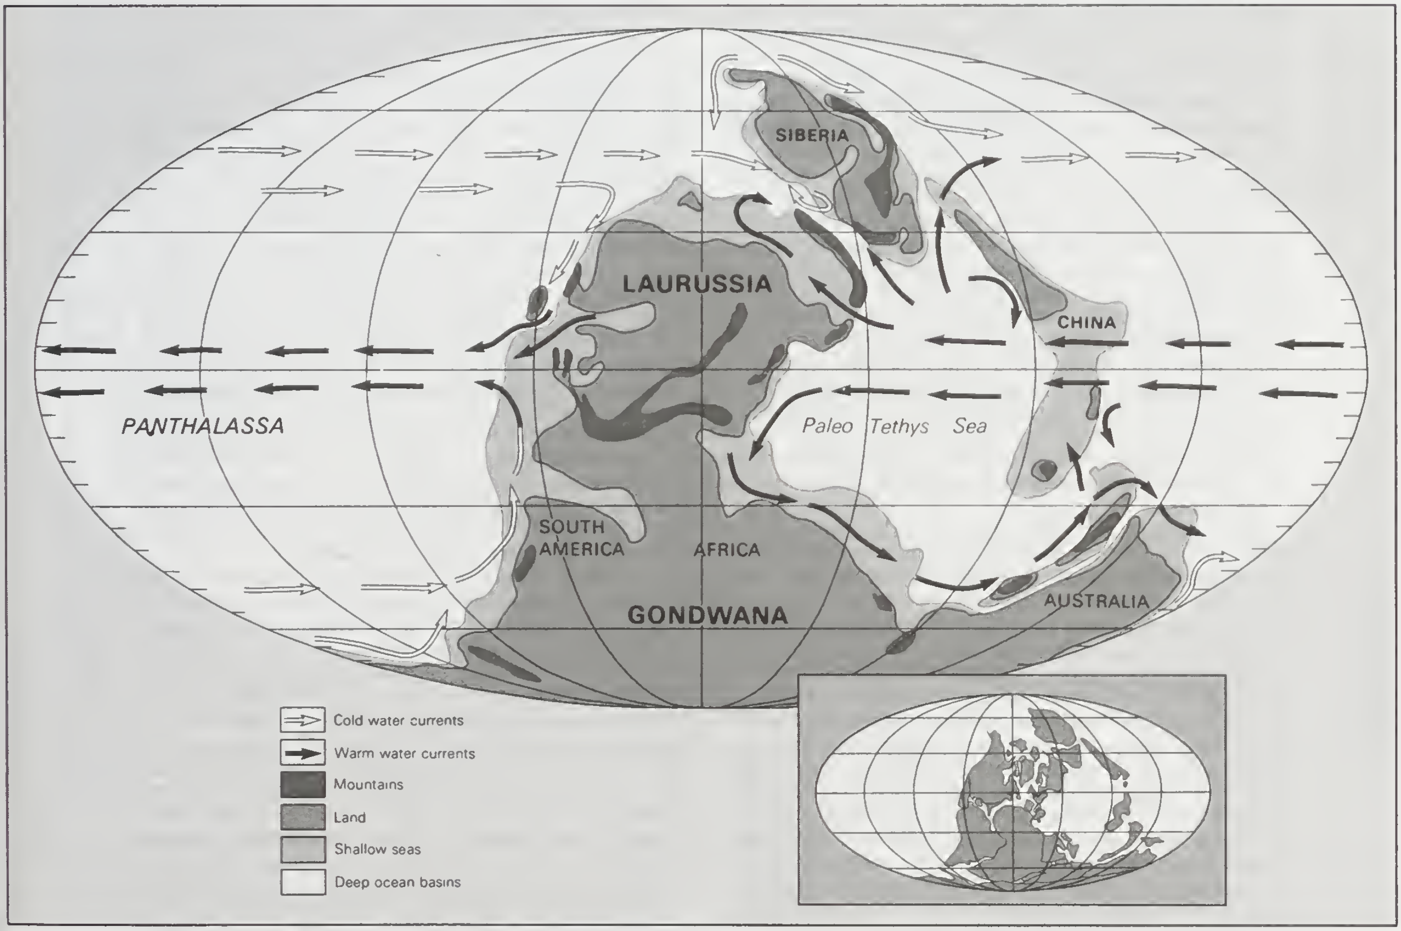

Figure 30: Distribution of landmasses, mountainous regions, shallow seas, and deep ocean basins during the Late Carboniferous. Included in the paleogeographic reconstruction are cold and warm ocean currents. The present-day coastlines and tectonic boundaries of the configured continents are shown in the inset.

appear in the rocks of the Upper Carboniferous and dominate the assemblages through the Permian, when they become extinct. The fusulinids secreted a tightly coiled, calcareous test that was chambered. They exhibited rapid evolutionary diversification, and the sequence of various morphologic features reflecting this diversification is used to subdivide and correlate the Upper Carboniferous on an intercontinental basis. In addition to marine invertebrates that inhabited the seafloor, the calcareous algae were well represented. Platelike red varieties were abundant enough to form mounds in the Upper Carboniferous. Benthic organisms on the decline during the Carboniferous were the trilobites, corals, and sponges.

The ammonoid cephalopods, extinct relatives of the chambered *Nautilus,* were common in deep marine waters. They swam by means of jet propulsion and either caught prey or were scavengers. The ammonoids, like the fusulinids, exhibited rapid evolution through the Carboniferous and serve as useful index fossils for correlation of the interval. True nautiloids also were represented in Carboniferous marine environments. While they are not as diverse as the ammonoids, both straight and coiled forms are common as fossils, and some straight forms grew exceedingly large (more than three metres) for invertebrates.

Dominance of vascular plants

Carboniferous terrestrial environments were dominated by plants, ranging from small, shrubby growths to tall trees reaching heights of more than 30 metres. The most important vascular plants were the lycopods, sphenopsids, cordaiteans, seed ferns, and true ferns. Lycopods are only represented in the modern world by the club mosses, but in the Carboniferous they included tall trees that had dense, spirally arranged leaves and spore-bearing organs on their leaves (cones might be present). *Lepidodendron,* with diamond-shaped leaf bases, and *Sigillaria,* with ribs and round leaf bases, were the dominant lycopod genera. They produced fossil logs that measure as much as one metre at their bases. Sphenopsids are trees and shrubs that have a distinctly jointed stem and leaves arranged in spirals from the joints. The horsetail rush (*Equisetum*) is the only living representative, while *Calamites* is the most common Carboniferous genus. Smaller than the lycopods, sphenopsids also occupied somewhat dry, more upland environments. The cordaiteans belong to the gymnosperms and are precursers of the conifers. They also favoured upland environments, grew tall, and had needles and cones like modern conifers, although the group itself has no living representatives. The genus *Walchia* probably formed forested areas much as modern pines do. Seed ferns, or pteridosperms, had fernlike foliage, but reproduced by seeds rather than by spores. They, too, are gymnosperms with no living representatives. The pteridosperms include such trees as *Glossopteris,* a genus that was characteristic of Permian floras from Gondwana; and such low shrubs (usually represented by fragments of their foliage) as *Neuropteris, Pecopteris,* and other forms from Mazon Creek (see above). The seed ferns and true ferns formed the "under" foliage associated with most Carboniferous coal swamps.

The diversity of fish from the Devonian continued into the Carboniferous in both marine and freshwater environments, although the arthodires (armoured, jawed fish) become extinct almost immediately in the Lower Carboniferous. Fully terrestrial environments were populated by a variety of animals. Pulmonate gastropods that respired by lungs arose from aquatic ancestors in the Upper Carboniferous. Insects evolved during the Devonian but diversified through the Carboniferous. No Devonian winged insects are known, and wings must have appeared in the Lower Carboniferous, although no fossil insects are known from that time. Dragonflies and mayflies, which lack the ability to fold their wings, were abundant and attained large sizes by the Upper Carboniferous. More advanced insects that could fold their wings, particularly the cockroaches, also appeared in the Upper Carboniferous, as did the ancestral forms of the grasshoppers and crickets. The earliest land-dwelling scorpions are of Carboniferous age.

While amphibians appeared in the Upper (Late) Devonian, their great radiation took place in the Lower Carboniferous, where they continued as the only terrestrial vertebrates. Although living a semiaquatic life similar to that of modern amphibians, Carboniferous varieties were generally larger by comparison and much more diverse in body plan, even including limbless forms. They may be classified as either labyrinthodonts (named for the infolding of dentine in their teeth), or lepospondyls (small, salamander-like or snakelike forms). The earliest reptiles have been found in Upper Carboniferous sediments filling the external molds of lycopod tree stumps in Nova Scotia. These small (less than 30 centimetres) animals are thought to have become entrapped in the cavities of the rotting trees. They differ only slightly from their amphibian ancestors, principally in the character of their backbone and the number and position of bones in their skulls. Once established, the reptiles diversified rapidly in the Upper Carboniferous, so much so that all the basic skull types except parapsid (*i.e.,* the pattern in which the postorbital and squamosal portions of the skull form a wide cheek) were developed by the end of the period. (W.L.Ma.)

Fossil remains of the earliest reptiles

PERMIAN PERIOD

General considerations. The Permian, the last period of the Paleozoic Era, began about 286 million years ago and ended 245 million years ago, extending from the close of the Carboniferous to the outset of the Triassic (see Table 4). The changes in the general distribution and types of sediments and fossils during these 41 million years suggest that the Permian was a time of progressive climatic shifts that resulted in major environmental challenges to marine and terrestrial life. The rocks that formed during this period make up the Permian System.

The history of the identification and acceptance of the Permian Period by geologists is in many ways the account of good deductive reasoning, a determined scientist, and an opportunity that was exploited to its fullest. R.I. Murchison, also known for his studies of the Devonian and Silurian (and Ordovician) periods (see above), had been aware that the Coal Measures, or Carboniferous System as these rocks became known, in northern England and in Germany were overlain by red beds and dolomitic, poorly fossiliferous limestones that had major rock intervals missing at their base and at their top (Figure 31). Murchison reasoned that somewhere, perhaps outside of northwestern Europe, a more complete stratigraphic succession would fill in these sedimentary gaps and would contain a more complete and better-preserved fossil assemblage. As was discussed earlier in the article, Murchison undertook expeditions in 1840 and 1841 to compile a preliminary synthesis of the geology of European Russia. He traveled extensively throughout the area and met with local geologists and paleontologists to discuss the geologic features of the various districts. Along the western flanks of the Ural Mountains, Murchison recognized that Carboniferous beds were overlain by a well-developed succession of rocks that included rocks equivalent in age to those problematic red beds and dolomitic limestones of northwestern Europe and filled the missing gaps below and above those sediments. He named these rocks the Permian System after the district of Perm, where the succession was particularly well developed.

Early investigations

In his 1845 publications Murchison included the red beds and evaporite beds now referred to as the Kungurian Stage in the lower part of his Permian System and also incorporated the nonmarine beds of the Tatarian Stage in its upper part. The upper portion of these nonmarine beds was subsequently shown to be of Early Triassic age. The Kazanian Stage in the middle is a close lithologic and age equivalent of the Zechstein of northwestern Europe.

Later work by other geologists on the Russian Platform and Ural foothills demonstrated that the clastic beds considered by Murchison to be equivalent to the Lower Carboniferous Millstone Grit were considerably younger and, at least in part, lateral facies of the lower beds of the Kungurian. These and some of the limestone-bearing beds at their base were called the Artinskian Stage. Later, the limestone-bearing lower part was studied in more detail and now has been divided into the Asselian and Sakmarian stages. The Permian succession in its type area as it is presently subdivided is shown in Figure 31.

The Permian was welcomed by many geologists as filling an obvious need for a system of rocks above the Carboniferous and below the Triassic. On the other hand, these latter two systems were well known, long studied, and established in what had become the fertile cradle of geologic thought in northwestern Europe. The type Permian System was distant, sketchily described, and poorly understood. There evolved a strange situation in which textbooks and most geologists widely accepted the Permian System after it was proposed; however, officially the U.S. Geological Survey did not adopt the system as such until 1941, and then only after a symposium organized by the American Association of Petroleum Geologists established North American standard reference sections for the Permian consisting of four series—namely, the Wolfcampian, Leonardian, Guadalupian, and Ochoan—on the basis of the succession in West Texas and New Mexico. The Wolfcampian Series was carried as "Permian?" until 1951 because of continuing controversies in defining the base of the Permian in what was then the Soviet Union.

Boundaries and subdivisions. During the 1960s attempts were made to unify the nomenclature within the Permian System. The system was subdivided into a Lower Permian Series and an Upper Permian Series, and to these were assigned stages with regional names (Table 17). The regional stages are necessary and important because they are based on strongly provincial faunal zonations in stratigraphic successions that differ markedly from one region to the next. This means that within a single region or faunal province the similarity of the succession of fossils and patterns of rock deposition permits ready age correlations. The age correlations from one region to the next are more difficult and open to more questions.

Permian series and stages

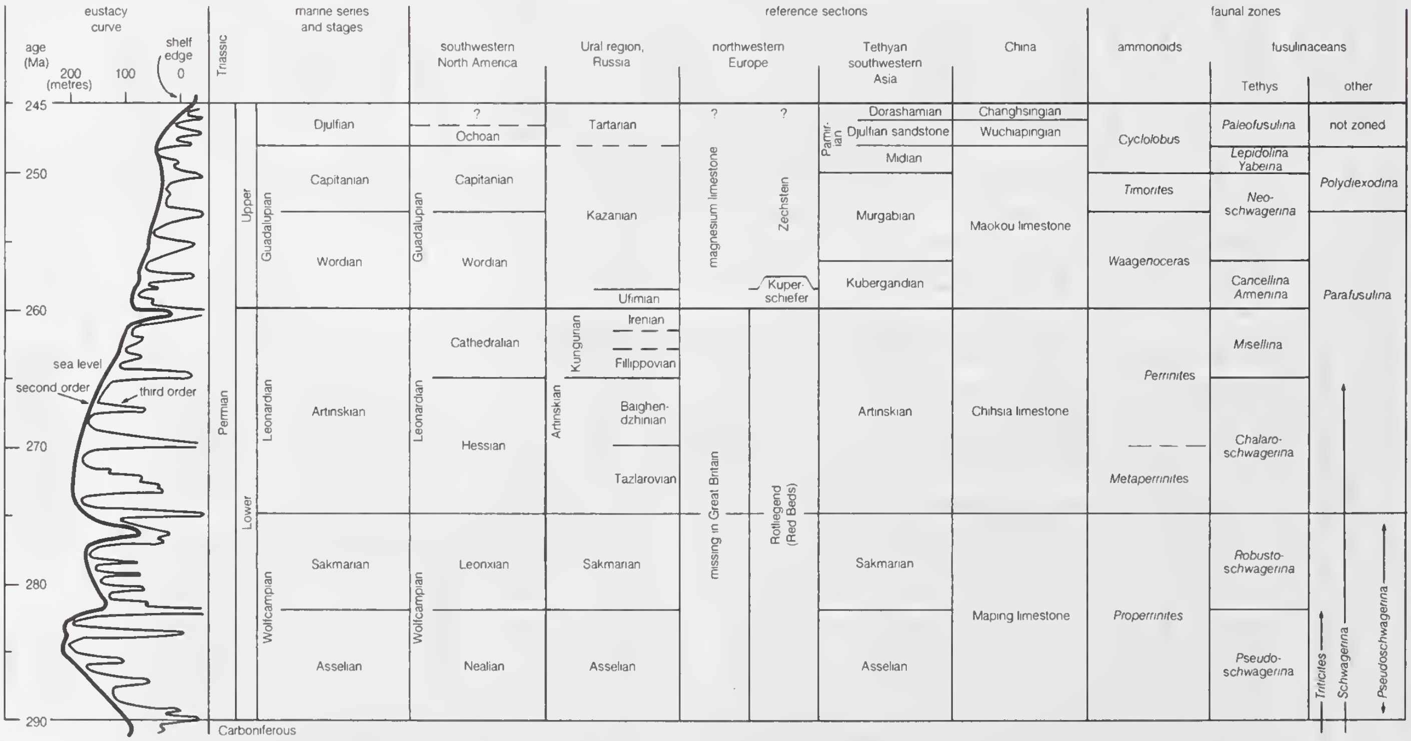
Problems of strongly differentiated faunal provinces during the Permian Period have plagued efforts to establish firm stratigraphic correlations between many regions. This differentiation of provincial faunas and their isolation from one another increases noticeably in the middle and later parts of the period. In the type area of the Permian, the Asselian, Sakmarian, and Artinskian stages are predominantly marine deposits with a reasonable number of cosmopolitan fossils. The Kungurian Stage is evaporitic and has locally limited and rare marine fossils. The Ufimian is largely nonmarine fluvial clastics, and the Kazanian is dolomitic and silty and has rare, restricted faunas that have been considered tolerant to wide swings in salinity—*i.e.,* from hyper- to hyposaline. The Tatarian is continental and has a well-described vertebrate, plant, insect, and freshwater ostracod fossil record.

In many other parts of the world, the equivalents of the Kungurian through Tatarian stages are marine deposits that have diverse and abundant normal marine faunas. Two predominantly carbonate provinces are recognized. One includes the southwestern United States and northwestern South America. The other, which is much larger and has a more diverse fauna, includes a belt of rocks from Tunisia and the Carnic Alps on the west through Turkey, Iran, southern China, Southeast Asia, and Japan, and central British Columbia and Washington, Oregon, and California in North America. This second carbonate province, called the Permian Tethys, was thoroughly disrupted by post-Permian orogenic deformation (as the result of seafloor spreading and plate tectonics) and is now found only as geographically dislocated fragments. These Permian Tethyan strata stand in sharp contrast to the Permian beds in the type area, and some geologists prefer to divide them into three series—Lower, Middle, and Upper. The two predominantly carbonate provinces are considered to have been tropical and subtropical and to have been centred near the equator but on opposite sides of the huge supercontinent of Pangaea.

Permian Tethyan strata

The boundary between the Permian System and the overlying Triassic System nearly everywhere constitutes a hiatus of one to several million years, except in the central Tethys region where local deposition was apparently continuous. There, the boundary between these two important systems—indeed, the boundary between the Paleozoic and Mesozoic—is not easily defined. The latest Permian faunas were reduced to only a few remnant species that were obviously sensitive to stressful new environments. Typical Triassic lineages were just starting out and also were few in number and species. The two sets of lineages appear to overlap in this part of the succession, and the exact placement of the boundary is still under study.

Economic significance. Permian rocks have long been important economic sources of evaporite minerals, such as halite (rock salt), sylvite (potash salts), gypsum and anhydrite, petroleum, and coal. The distribution of these



C A Ross and J R P Ross in C.A Ross and D Haman, (eds) Cushman Foundation for Foraminiteral Research, Special Publication 24, 1987

Figure 31: The marine series and stage names of the Permian, the correlation of regional reference sections, second and third order eustacy curves, and a broad, generic-level biostratigraphic zonation of ammonoids and fusulinaceans.

resources, in part, is related to the Permian paleolatitudes of the deposits (Figure 32). The evaporites were particularly common in subtropical and tropical Permian paleolatitudes in what is now West Texas, New Mexico, and Kansas in North America as well as in northwestern Europe and the European sector of Russia. Thick coals formed in cool temperate paleolatitudes, such as central and northern Siberia, Manchuria, Korea, peninsular India, eastern Australia, South Africa, Zimbabwe, and the Congo, which were all in high-paleolatitudes during the Permian (see Figure 32).

Many of the Permian intracratonic marine basins are productive sources of petroleum and have good reservoirs. The most famous are in West Texas, New Mexico, and Oklahoma in the United States and along the Ural fold belts in Russia.

Phosphorites are common in the deep-water sedimentary wedges next to the shelf margin in Montana, Idaho, Wyoming, Utah, and Nevada that marked the western edge of the North American craton in Permian time. In Europe, phosphorites occur along a deep-water trough marking the eastern edge of the Russian Platform.

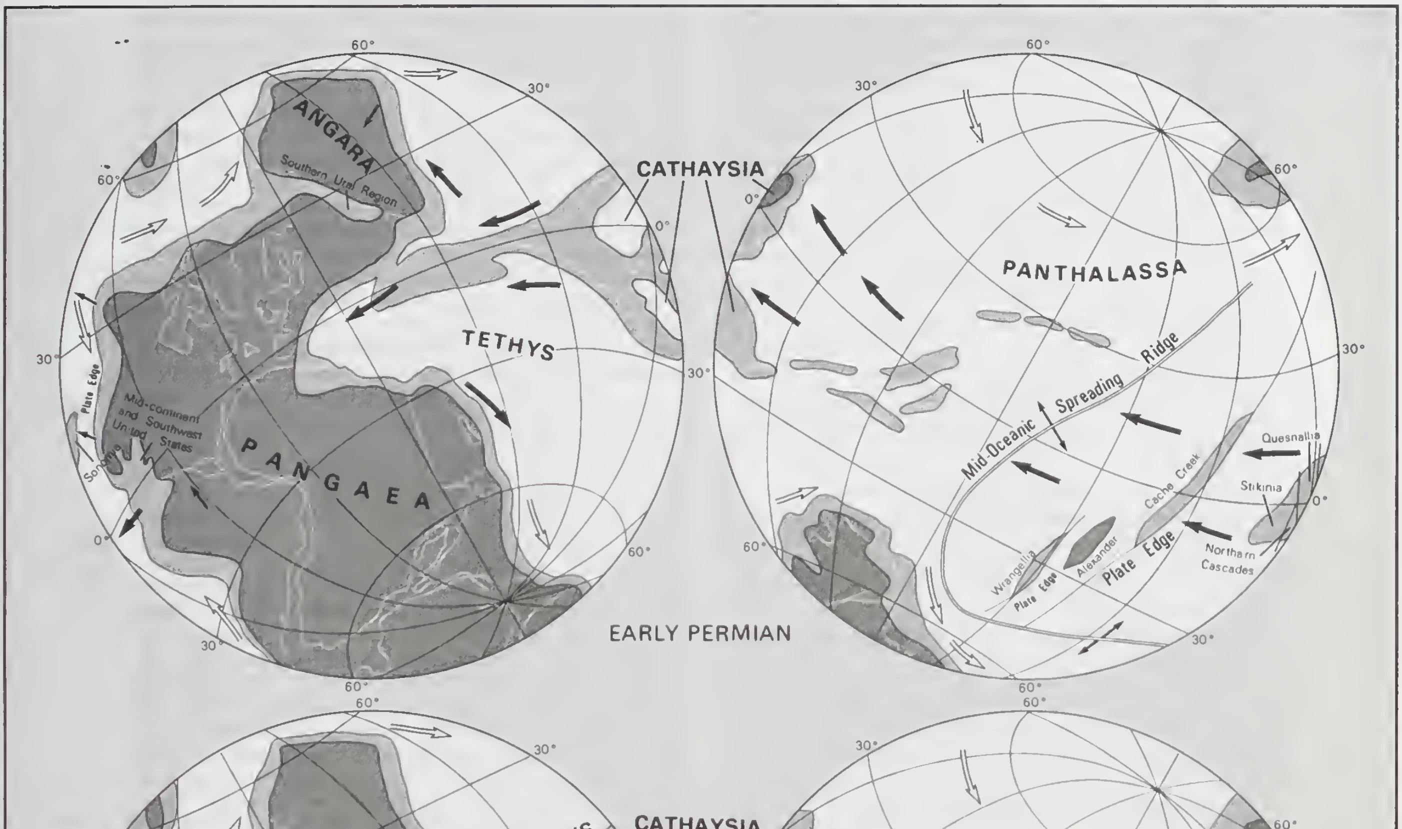

Figure 32: Paleogeography and paleoceanography of (top) the Early Permian and (bottom) the early Late Permian.

Of significance to European civilizations is the Permian Kupferschiefer, a copper-bearing shale that has been mined for hundreds, perhaps even thousands, of years. This rare type of copper ore was deposited in a marine basin that had no oxygen in its bottom waters.

Permian rocks. *Occurrence.* Permian rocks are found on all present-day continents; however, some have been displaced considerable distances, sometimes thousands of kilometres from their original site of deposition (Figure 32) by subsequent tectonic transport during the Mesozoic and Cenozoic eras. For example, Permian glacial and glacial marine deposits typical of the cold high latitudes of the Southern Hemisphere during the Permian are now found in Antarctica, southern Africa, India, Thailand, and Tibet, while Permian glacial deposits of the Northern Hemisphere are found in northeastern Siberia. By contrast, some Permian tropical and subtropical carbonate deposits, typical of deposition in low latitudes, have been relocated to high latitudes, and the present location of certain tropical provincial faunas suggests that other deposits have been moved considerable distances longitudinally to form tectonic belts of accretionary material added during Mesozoic and Cenozoic times to the former late Paleozoic continental margins. The commonly conflicting occurrences of different faunal provinces and tropical deposits in juxtaposition with temperate and cold (glacial) deposits became more readily explainable once the rates of motion that result from seafloor spreading and plate tectonics became established as 0.5 to 1.5 centimetres per year. When viewed on a Permian paleogeographic reconstruction (Figure 32), these apparent depositional conflicts disappear and a climatically compatible depositional pattern emerges.

Glacial and glacial marine deposits

The principal geographic features of the Permian world were the supercontinent Pangaea (which included all the then-existing major continents except North and South China) and a huge ocean basin called Panthalassa, with its branch, the Tethys (a large indentation in the tropical eastern side of Pangaea).

Panthalassa and Tethys encompassed scattered fragments of continental crust (microcontinents) and basaltic volcanic island arcs that featured extensive fringing limestone reefs and platforms. They are generally viewed as being analogous to the present-day Indian and Pacific ocean basins in terms of geologic construction. Cathyasia, comprising both the continents of North and South China, lay within western Panthalassa. The existence of several other, smaller (or now disrupted) microcontinents also has been proposed.

Pangaea contained extensive high mountain ranges along its orogenic suture between Euramerica (also known as Laurussia in Devonian and Carboniferous times) and the South American–Northwest African portion of Gondwana. These mountains influenced local climates and sedimentation during the early part of the Permian to a considerable extent. Later, during the middle Permian, the Angaran portion of western Siberia joined eastern Euramerica to form the Ural orogenic belt and mountains. Parts of Pangaea continued to be sheared and deformed by large linear zones of tear faults (steeply inclined faults along which movement has been largely horizontal and which include several failed rift structures) and by the vertical warping and faulting of the persistent North American transcontinental arch and similar tectonic activity in the northwestern segment of Europe.

Because these orogenic and related tectonic events progressively changed sedimentation conditions during the Permian Period, it is possible to consider shifts in depositional patterns in several phases. The Asselian and Sakmarian represent intervals of gradual transition from Late Carboniferous depositional facies typified by large sea-level fluctuations and strongly developed cyclical sediments (Figure 31). Less rapid and pronounced extremes in sea-level changes and more uniform sedimentation characterized the Artinskian. The Kungurian and later Permian deposition reflect increasing exposure and aridity on the cratonic shelves and well-developed intracratonic basins with more extensive evaporites. Marine deposits were primarily along the shelf margins. The latest phase, seen in Djulfian sedimentation, is not widely distributed and probably was restricted to the cratonic shelf margins or even to the upper shelf slopes.

Impact of tectonic activity on depositional patterns

Distribution and types. In terms of geologic setting, the Permian sediments that were deposited as thick sedimentary wedges along the tectonically active margins of the major cratons are the least understood in detail. Because there was one megacontinent, Pangaea, most of these wedges were facing into the huge active ocean basin of Panthalassa–Tethys. All these Permian sediments have subsequently been thrusted, metamorphosed, and involved in major geologic deformation. In many cases, it is difficult to determine the original thickness of these wedges, and much of the fossil evidence is from clastic material that was derived from shallow shelf environments or eroded from older rocks and deposited as deepwater debris fans. Great deposits—perhaps originally one to three kilometres thick—are known in central Nevada, Idaho, and northward into Canada. Similar deposits have been found in the Middle East, China, Japan, and eastern Siberia.

Interleaved with these thick clastic wedges are other thrust slices of ocean-floor deposits. These are thinner, about 0.5 kilometre thick or less, and are characterized by radiolarian-rich cherts, basaltic volcanic dikes, sills, and submarine lava flows, as well as silts and clays (commonly metamorphosed to slates) of the distal ends of turbidity flows (*i.e.,* those of density currents). Such completely deformed deposits are the only remaining record of Permian (and older) ocean-floor deposits, because only Jurassic and younger oceanic sediments survive in the present-day ocean basins. Most of the Permian (and older) ocean-floor deposits and thick sedimentary wedges have been caught up in subduction zones along the plate boundaries and lost to the Earth's mantle.

Associated with some oceanic basalts are thick accumulations of reef limestone that formed on seamounts and volcanic island arcs. These reefs were tropical and subtropical, as are modern oceanic limestone reefs. Because limestone is comparatively less dense than adjacent oceanic rocks, such as basalt or chert, many of the Permian reef limestones were not as easily subducted and are present in many modern mountain belts. Limestones of this kind are known from Tunisia, the Balkan Peninsula, Turkey, the Crimea (in Ukraine), the Middle East, northern India, Pakistan, Southeast Asia, New Zealand, China, Japan, eastern Siberia, Alaska, and the western Cordillera of Canada, the United States, and northwesternmost Mexico. These limestones commonly have complex structural relationships with adjacent rocks, usually of Triassic, Jurassic, or early Cretaceous age, suggesting that most such Permian limestones were incorporated into the mountain belts by those times.

Reef limestone

Cratonic shelf sedimentation in low paleolatitudes during the Permian was characterized by the gradual withdrawal of shorelines and the progressive increase in eolian sands, red beds, and evaporites. Many intracratonic basins, such as the Anadarko, Delaware, and Midland basins in the western United States, the Zechstein basin of northwestern Europe, and the Kazan Basin of eastern Europe, show similar general changes. In most cases, the inner parts of these basin systems became sites of red bed deposition during the Leonardian, followed within a short time by locally extensive evaporites. Sand sources along the Ancestral Rocky Mountains supplied eolian sand and silt in great quantities.

The outer portions of the intracratonic basin systems, as in the Delaware and Zechstein basins, were involved in some transform faulting and extensional tectonics and locally developed considerable depositional relief. Although some of this relief was from rotated fault blocks, most of it resulted from the very rapid growth of limestone reefs on upthrown blocks (*i.e.,* the sides of faults that appear to have moved upward) and the slower accumulation of clastic sediments on downthrown blocks. Striking examples of these reefs form the Guadalupe Mountains of West Texas and New Mexico. Such reefs also occur in the subsurface along the Central Basin Platform in West Texas, where they produce petroleum. Similar reefs are known from northern England, Germany, and the subsurface of the

North Sea. Lower Permian limestone reefs also are known from the western and southern Urals of eastern Europe.

At higher paleolatitudes, limestone is rare, and clastic rocks dominate the succession. Australia, Namibia, South Africa, peninsular India, southern Tibet, and southern Thailand all report Permo-Carboniferous tillite. These areas, as their paleogeographic reconstruction indicates, would have been in relatively high latitudes as parts of Gondwana during the Permian. Tillites are also known from the northern high paleolatitudes in northeastern Siberia. Some of the Gondwanan areas were tectonically very active during Permian time, as evidenced by extensive basaltic, andesitic, and other volcanic rocks in eastern Australia and by the development of intracratonic sedimentary marine basins, such as the Carnarvon Basin in Western Australia where nearly five kilometres of Permian sediments accumulated.

Continental rocks were widespread on all the cratons during the Permian. The Dunkard Group is a limnic coal-bearing succession that was deposited from latest Carboniferous into Early Permian time along the western side of the then-newly formed Appalachian Mountains. In what is now Kansas and areas of the western United States, coal-bearing cyclothems that formed along the margins of shallow seas in continental interiors persisted well into the Early Permian. Coal-bearing Lower and Upper Permian beds, up to three kilometres thick, are widely distributed in Australia, peninsular India (the lower part of the Gondwana System), southern Africa (the lower part of the Karoo [also spelled Karroo] System), the Kuznetsk Basin of southwestern Siberia, and the Paraná and Precordillera basins of southern Brazil and western Argentina in South America. Red beds were common in continental beds in tropical and subtropical paleolatitudes. During the Permian Period red beds became more abundant and widespread, suggesting that the climate became progressively warmer and tropical conditions became more widespread. This warming trend is also hinted at by a significant increase in the amount of dolomite in shelf sediments.

Permian environment. *Paleogeography.* The Permian constitutes an important crossroads both in the history of the Earth's continents and in the evolution of terrestrial life. During roughly the first half of the period, Gondwana collided with and joined western Euramerica, to which the Angaran sector of Siberia was subsequently fused (see Figure 32). Thus, the assembly of what is often referred to as Greater Pangaea was completed by mid-Permian time, giving rise to a single mountainous continental landmass that extended across all the climatic temperature zones without interruption virtually from one pole to the other. This megacontinent was surrounded by the immense world ocean Panthalassa, which, with the Tethys Sea, was the site of a small number of microcontinents, island arcs, oceanic plateaus, and trenches.

Formation of Pangaea

Paleoclimate. Extensive glaciation persisted in the Early Permian, largely in what is now India, Australia, and Antarctica but also in Siberia near the north paleopole. Hot, dry conditions prevailed elsewhere on Pangaea, and deserts became widespread in various tropical and subtropical areas of the continent by the Late Permian.

The gradual climatic warming that took place during the Permian at first encouraged evolutionary expansion among shallow-water marine faunas but later resulted in marked extinctions (see below *Permian life*). On the other hand, this warming trend, combined with climate diversity, provided an opportunity for broad adaptive radiation in terrestrial plants, insects, and reptiles, particularly among mammallike reptiles.

Permian life. Life during the Permian was very diverse, and the marine life of the period was perhaps more diverse than that of modern times. The previous period, the Carboniferous, had had two instances of significant marine faunal extinctions that had followed one another in relatively rapid succession. One was at the end of the Early Carboniferous (Mississippian subperiod in North America) and the other at the end of the Middle Carboniferous (the close of the Middle Pennsylvanian). Both may be attributed to global cooling during continental glaciations. The latest Carboniferous witnessed the establishment of new or highly modified marine lineages with relatively little ecological competition from the remnants of what had been highly successful earlier phylogenetic lineages. Most of these lineages are identified as new families or suborders among the foraminifers, ammonoids, brachiopods, bryozoans, bivalves, and some less-studied groups. In Wolfcampian, Leonardian, and Guadalupian times, these newly established lineages underwent rapid evolution and filled a remarkable number of specialized marine ecological niches. Some of this rapid diversification was probably the result of filling the ecological niches left vacant by the extinctions of the Carboniferous. Other factors undoubtedly included the gradual warming of oceans during the latest Carboniferous and the more rapid warming trends of the Early Permian. In paleotropical areas, a succession of carbonate bank, bioherm, and reef faunal associations evolved, which culminated in the late Guadalupian Capitan Reefs of the western United States and the more faunally diverse associations that formed even thicker fringing reefs in the Tethyan area. Because these two sets of tropical marine shallow-water faunal associations were separated by the large supercontinent Pangaea on the one hand and the deep oceanic basin of Panthalassa on the other, they tended to evolve independently of each other.

Near the end of the Guadalupian both of the these tropical faunal realms suffered major but incomplete extinctions, and the Djulfian saw a brief and relatively minor evolutionary re-expansion in some of the foraminifers and ammonoids. The trilobites were extinct by the end of the Leonardian. Only a few Permian bryozoan and brachiopod genera, and only one or two species of those genera, survived into the earliest Triassic. Although the magnitude of the extinctions among shallow-water marine organisms during the later parts of the Permian was great, the process took several million years and was accomplished in a series of steps followed by unsuccessful attempts by the surviving faunas to rediversify.

Permian extinctions

Terrestrial life in the Permian was closely keyed to the evolution of terrestrial plants, which of course were the primary food source for terrestrial animals. The fossil plant record for the Permian consists predominantly of ferns, seed ferns, and lycophytes, which is attributable to their adaptation to marshes and swampy environments. A less abundant fossil record of early coniferophytes and even some protoangiosperms suggests a broad adaptation of these plant groups to progressively drier areas. As discussed earlier, evidence seems to point to gradually warming and drier climates, which would have encouraged plant adaptations to drier conditions.

Another line of evidence suggesting broad plant diversification is found in the evolution of insects; these animals tend to be highly selective in choosing their plant hosts. Among the superclass Hexapoda of the phylum Arthropoda, at least 23 orders are known from the Permian, and of these orders 11 are extinct. By comparison, 250 million years later, there exist only 28 insect orders, and the new orders are mainly those that have adapted to living on the angiosperms or mammals that evolved after Permian time. Permian insects include a huge dragonfly-like creature that had a wingspan of 75 centimetres.

Terrestrial vertebrates of the Permian, in addition to freshwater sharks and fish and several orders of relatively large amphibians, are noted for the first appearance of several important reptile lineages. Although a few primitive and generalized reptile fossils are found in Middle Carboniferous deposits, Permian reptile fossils are locally common and include the protorosaurs, aquatic reptiles; the captorhinomorphs, the "stem reptiles" from which most other reptiles are thought to have evolved; the eosuchians, early ancestors of the snakes and lizards; early anapsids, ancestors of turtles; early archosaurs, ancestors of the large ruling reptiles of the Mesozoic; and the synapsids, a common and varied group of mammallike reptiles that eventually gave rise to mammals in the Mesozoic. Of these, the captorhinomorphs and synapsids are probably the best known.

Emergence of important reptiles

Captorhinomorphs are common in the Lower Permian beds of North America and Europe. Massively built and large for their day, they reached lengths of two to three metres. Captorhinomorphs are less common in Upper Permian beds, and only one small group survived into the Triassic.

Synapsids are divided into two orders: the pelycosaurs and the therapsids. The Early Permian pelycosaurs included a lineage containing both carnivorous and herbivorous members that developed long spines on their vertebrae, which seem to have supported a membrane, or "sail." The function of the sail is not fully understood; however, suggestions include its use in regulating body temperature. Pelycosaurs reached 3.5 metres in length and had large teeth. Their remains are commonly found in the Lower Permian red beds of central Texas but are rare in Europe.

The therapsids were advanced synapsids that are known from the Upper Permian Karoo beds of South Africa, South America, and India and equivalent beds in Scotland and what was formerly the Soviet Union. Therapsids range into the Triassic and show a great deal of diversification. Their dentition and bone structure are remarkably mammallike, and the point at which a mammallike reptile passes into an actual mammal has long been a point of controversy. The success of therapsids in the relatively high paleolatitudes of Gondwana has strengthened the view that they were able to maintain an elevated body temperature. (J.R.P.R./Ch.A.R.)

Mesozoic Era

The Mesozoic (from the Greek for middle life) began about 245 million years ago and ended 66.4 million years ago (see Table 4). The major divisions of the era, from oldest to youngest, are the Triassic, Jurassic, and Cretaceous periods. The Mesozoic was a time of heightened tectonic activity during which the supercontinent of Pangaea fragmented into separate continents that were gradually scattered across the Earth in a nearly modern geographic distribution. It also was a time marked by a distinct modernization of life-forms; the ancestors of the major plant and animal groups that exist today first made their appearance.

Redistribution of the landmasses

At the outset of the Mesozoic, all the continents were still joined together. Continental rifting, however, began in Late Triassic to Early Jurassic times. The separation of Laurasia and Gondwana and their constituent continents started by the Middle Jurassic, while much of Pangaea lay between 60° N and 60° S. (The paleoequator cut through the widening Tethys seaway between Laurasia and Gondwana.) Spreading centres and mid-oceanic rifts formed between several of the separating continents as well as between the segments of Gondwana. During the Jurassic, North America began pulling apart from Eurasia and Gondwana. By the Late Jurassic, Africa had started to split off from South America, and Australia and Antarctica had separated from India. Near the close of the Cretaceous, Madagascar separated from Africa, and South America drifted northwestward.

Thick sequences of marine sediments accumulated in large linear troughs called geosynclines along passive continental margins—namely, those formed by continental rifting and rupture. Geosynclinal deposits of Jurassic age formed in the present-day circum-Pacific region, along the coasts of eastern North America and the Gulf of Mexico, and on the margins of Eurasia and Gondwana (*i.e.*, along the northern and southern boundaries of the Tethys seaway). Thick deposits of this Tethyan Geosyncline were incorporated into the Alpine-Himalayan mountain system beginning in late Mesozoic time.

Major mountain building began on the western margin of both North America and South America and between the fragments of Gondwana. For example, the northwesterly movement of North America resulted in the collision of the western edge of the North American continental plate with a complex of island arcs in the Late Jurassic. During the ensuing mountain-building episode known as the Nevadan orogeny, so-called suspect, or exotic, terranes (geologic provinces that originated in the ocean crust and differ markedly in stratigraphy, paleomagnetism, and paleontology from the adjoining continental crust) were accreted to the margin of the North American Plate, huge granitic batholiths formed in what is now the Sierra Nevada range along the California-Nevada border, and thrusting occurred in an eastward direction. Other notable Mesozoic episodes of mountain building include the Sevier and Laramide orogenies that took place in western North America during Cretaceous time.

Episodic marine transgressions and regressions

At various times during the Mesozoic, shallow seas invaded continental interiors and then drained away. During mid-Triassic time, a marine incursion—the Muschelkalk Sea—covered the continental interior of Europe. Seas again transgressed between the Early and Late Jurassic and in the Early Cretaceous. Marine waters flooded large segments of all the continents during mid-Cretaceous time, marking the last transgression of a global scale. The sharp rise in sea level and resultant worldwide flooding are thought to have been caused chiefly by accelerated seafloor spreading and the attendant enlargement of the ocean ridges. This displaced enormous amounts of ocean water onto the landmasses. Transgression was so extensive that in North America, for example, a shallow sea spread all the way from the Arctic to the Gulf of Mexico.

Mesozoic rocks are distributed widely, appearing in various parts of the world. A large percentage of these rocks are of the sedimentary variety. Triassic limestone formed largely in the Tethyan (present-day Mediterranean) region and the western United States, while graywackes, sandstones, and shale of the same age predominate in the circum-Pacific geosynclines. Extensive beds of limestone, sandstone, ironstone, and clays were left in continental interiors by the shallow epicontinental seas of the Jurassic. Likewise, the large-scale marine inundation of Cretaceous time resulted in the widespread deposition of chalk, clay, and marl in the lower areas of several continents.

A substantial amount of igneous rock also formed during the Mesozoic. The initial rifting of Pangaea produced fault-block basins that were later filled with basaltic intrusions and pillow lavas, as well as with fluvial and lacustrine beds, between Late Triassic and Early Jurassic time. Subsequent rifting of the Gondwanan segments was accompanied by outpourings of flood basalt (*i.e.*, plateaus of basalt that extend many kilometres in flat, layered flows). The orogenies of the middle and late Mesozoic involved volcanism and plutonic intrusion, as with the emplacement of granitic and andesitic plutons in the Andes of South America during the Late Jurassic.

Mesozoic fauna and flora

Mesozoic biota had to recover from the major extinction episode at the end of the Paleozoic Era. Vertebrates, which appear to have been less severely affected by the event than invertebrates, diversified progressively through the Triassic. During this time, the seas became inhabited by such marine reptiles as the nothosaurs and ichthyosaurs. The Triassic terrestrial environment was dominated by the therapsids, mammallike reptiles, and the thecodonts, ancestors of the dinosaurs of the later Mesozoic. The first true mammals, small shrewlike omnivores, appeared in the Late Triassic, as did the primitive forebears of lizards, turtles, and crocodiles. A second major extinction event struck at the close of the Triassic, one that wiped out as many as 400 genera of ammonoids, along with about 80 percent of the reptiles. In all, 35 percent of the then-existing animal groups suffered extinction.

During the Jurassic, the ammonoids and brachiopods (lamp shells) recovered from the Late Triassic crisis, thriving in the warm epicontinental seas. The ammonoids, in fact, rapidly became the most prominent invertebrate marine form, and their remains proved to be the most important index fossil for worldwide correlation of Jurassic rock strata. Many other animal forms, including mollusks (notably the bivalves), sharks, and bony fish, flourished during the Jurassic, and new forms, such as frogs, toads, and salamanders, emerged. All these groups, however, were overshadowed by the giant reptiles that reigned throughout much of the Jurassic and Cretaceous. Such dinosaurs as the fierce predator *Tyrannosaurus* and the enormous vegetarian *Apatosaurus* dominated on land. Other reptile forms, like the plesiosaurs, ruled the seas, while the pterosaurs, creatures with batlike membranous wings, dominated the sky.

Birds evolved from reptilian ancestors during the Late Jurassic, and two important modern mammal groups—the placentals and the marsupials—made their appearance in the Late Cretaceous. Plant life also exhibited a gradual change toward more modern forms during the course of the Mesozoic. Whereas seed-fern flora had predominated in the Triassic, forests of palmlike gymnosperms known as cycads and conifers proliferated under the tropical and temperate conditions that prevailed during the Jurassic. The first flowering plants, or angiosperms, appeared by the Cretaceous. They radiated rapidly, supplanting many of the primitive plant groups to become the dominant flora form by the end of the Mesozoic.

Decimation of many animal forms

The Mesozoic closed with an extinction event that devastated many forms of life. The ammonoids, reef-building rudist bivalves, and numerous varieties of foraminiferans and coccolithophores died off, as did the dinosaurs and flying and marine reptiles. The Late Cretaceous extinctions have been variously attributed to such phenomena as global tectonics, draining of the epicontinental seas, northward migration of the continents into different climatic zones with much cooler conditions, intensified volcanic activity, and a catastrophic meteorite impact. The extinctions, however, were not sudden; they spanned millions of years, a fact that has led some researchers to believe that, after an era of dominance among various forms of life, decay of the Mesozoic ecosystem had set in. The Cretaceous extinction event may very well have had multiple causes. As the landmasses were uplifted by plate tectonism and migrated poleward, the climate of the Late Cretaceous began to change from warm/moist and warm/dry to cool. This favoured the angiosperms over tropical vegetation and provided habitats and food sources for the fur-covered mammals. In effect, conditions were right for the life-forms that were to replace the dinosaurs. (L.Si.)

TRIASSIC PERIOD

General considerations. The Triassic, the first period of the Mesozoic Era, began about 245 million years ago at the close of the Permian Period and ended approximately 208 million years ago when it was succeeded by the Jurassic Period (see Table 4). The rocks that originated during this time interval make up the Triassic System, which consists mostly of rocks of sedimentary type. Because there are relatively few igneous rocks to provide reliable radiometric dates, the time span and absolute ages cited by different investigators for the Triassic Period tend to vary (*e.g.,* some indicate that the period extended from about 240 million to 195 or 200 million years ago). Such dates are subject to revision as new and more accurate age determinations are made.

The name Trias (later modified to Triassic) was first proposed in 1834 by the paleontologist Friedrich August von Alberti for a sequence of strata in central Germany comprising three formations: the Bunter (or Buntsandstein), Muschelkalk, and Keuper. This so-called Germanic facies, typical of the Triassic in northern Europe, has many drawbacks as a standard by which to correlate rocks from other regions, because the Bunter and Keuper are mostly nonmarine, while the Muschelkalk, though marine, is not widespread geographically and contains an abnormal marine fauna. For many years the traditional Triassic stages were based mainly on type sections from the marine Triassic of the Alps, but now more complete marine sequences have been discovered in North America to serve as a standard for Triassic time in general. Also, seafloor spreading and plate tectonics have yielded important new information on the paleogeography and paleoclimatology of the Triassic, allowing for a better understanding of the evolution, extinction, paleoecology, and paleobiogeography of the biota. At the same time, the problems of defining the lower and upper boundaries of the Triassic System on a worldwide basis and understanding the reasons for mass extinctions at these boundaries continue to occupy the attention of paleontologists.

Major subdivisions. The Triassic Period is divided into three chronostratigraphic epochs: Early, Middle, and Late. In like manner, the Triassic System is broken down into three lithostratigraphic series: Lower, Middle, and Upper. Each of these series is further subdivided into stages and biochronological zones (or biozones), based mainly on the precise vertical ranges of marine pelagic cephalopod mollusks called ammonoids.

Series and stages

Early subdivision of the Triassic into epochs, stages, and biozones was based primarily on the extensive and highly fossiliferous Alpine (western Tethyan) sequence of marine strata exposed in Austria, Italy, Germany, and Switzerland. It was here that the type sections, or stratotypes, for the Middle Triassic stages Anisian and Ladinian and the Upper Triassic Stages Carnian, Norian, and Rhaetian were first established. The Scythian Stage of the Lower Triassic was based on occurrences in the Himalayas, the Salt Range of Pakistan, and what was once the Soviet Union but has now been replaced by three new stage names, which, in ascending order, are Griesbachian (with stratotypes in the Himalayas [substage Gangetian] and Arctic Canada [substage Ellesmerian]; Nammalian (with stratotypes in Arctic Canada [substages Dienerian and Smithian]); and Spathian (with stratotype in Arctic Canada). It should be noted, however, that the above stage and substage names have not been universally accepted; alternative names for part or all of the Triassic are used in Russia (as well as in the other former Soviet republics), Japan, and New Zealand. The complete sequence of epochs, series, stages, and biozones recognized by most authorities is shown in Table 18.

Distinctive features. The Triassic Period marked the beginning of the major changes that were to take place throughout the Mesozoic in the distribution of the continents and the impact of those changes on paleoclimates, paleobiogeography, and the evolution of Triassic biotas. Shallow shelf seas were reduced in extent toward the end of the Permian, probably contributing to the extinction of several marine invertebrate groups, such as trilobites, rugose and tabulate corals, productacean brachiopods, cryptostomate and fenestrate bryozoans, blastoid echinoderms, and fusulinid foraminiferans. The supercontinent of Pangaea comprised virtually all the major landmasses of the world at the beginning of the Triassic. Terrestrial environments with warm, dry climates predominated, which resulted in an increase in the relative importance of land animals, including the first mammals at the end of the Triassic. Reptiles increased in diversity and number, heralding the great radiation that would characterize this group during the Jurassic and Cretaceous periods. Some groups of marine invertebrates, such as the ammonoids, made a dramatic recovery from near-extinction in the Late Permian, although they were to suffer yet another crisis in the Late Triassic. Shelf seas, which gradually became more extensive during the Middle and Late Triassic, were also colonized for the first time by large marine reptiles and reef-building scleractinian corals of modern aspect, while holdovers from the late Paleozoic included bivalves, brachiopods, echinoids, and gastropods. In summary, the Triassic ushered in great changes not only in the distribution of the continents but also in the evolution of living forms on land and in the oceans.

Economic significance. Few deposits of major economic importance were formed during the Triassic. Workable coal deposits are known from Arctic Canada, Russia, Ukraine, China, Japan, Australia, and Antarctica. Oil and gas occurrences are rare, however. Halite (rock salt) is mined from Triassic evaporites in England, France, Germany, and Austria.

Development of geosynclines around Panthalassa

Triassic rocks. *Occurrence and distribution.* Major depositional troughs—*i.e.,* geosynclines—developed around Panthalassa, the ancestral Pacific Ocean, during the Early and Middle Triassic. Great quantities of marine sediments, mainly sandstones, shales, and graywackes, collected in these troughs, as indicated by deposits now found in the western Pacific geosynclinal belt (New Zealand and Japan) and the eastern geosynclinal belt (Alaska, Arctic Canada, British Columbia, western United States, and the west coast of South America). As an example, more than 3,000 metres of Triassic sediments accumulated in the Sverdrup Basin of Arctic Canada. A deep, narrow arm of Panthalassa, the Tethys Sea, stretched along an east–west belt separating what is now Africa from south-

ern Europe, and it also received geosynclinal deposits. In the northern Tethyan geosyncline, these deposits now outcrop in the Alps, Turkey, Iran, Pakistan, and the Himalayas, mainly as limestones, with deep-sea sediments such as radiolarian cherts that formed in troughs in the deeper parts of the Tethys Sea. To the south was the southern Tethyan geosyncline, bordering Gondwana and stretching from northern India through the Middle East to northern Africa. Shallow shelf-sea embayments of limited distribution occurred landward of these geosynclines and are represented mainly by limestones in low latitudes, as around the margins of the Tethys Sea. Such tropical and subtropical shelf seas were warm and often supported small reefs, the forerunners of the more extensive coral reefs of today. Although the Permo-Triassic extinction of rugose and tabulate corals resulted in an absence of Lower Triassic corals, small reeflike mounds of early Middle Triassic age were succeeded later in Middle Triassic times by more extensive reef complexes with some Permian biotic elements retained. Such reefs have been described from the Tirolian Alps of Austria and the Dolomites of Italy. Late Triassic reef complexes, more modern in aspect and dominated for the first time by scleractinian corals, occur as thick sequences in the Dachstein and Steinplatte regions of Austria and Germany, as well as in Iran and the Himalayas.

Reef complexes

In the circum-Pacific region some shelf-sea deposits, generally of clastic facies (sandstones and shales), occur in Western Australia, Siberia, and the circum-Arctic region, including Arctic Canada, Alaska, eastern Greenland, and Spitsbergen.

Continental sediments, dominated by red beds (*e.g.*, sandstones and shales of red colour) and evaporites, accumulated on land throughout the Triassic Period. The Bunter and Keuper Marl of Germany and the New Red Sandstone of Britain are examples of such red beds north of Tethys, while to the south are similar deposits in India, Australia, South Africa, and Antarctica. Although deposits of this kind usually indicate accumulation in arid regions, such as inland desert basins, sediments of fluvial or lacustrine origin may also be represented by these red beds. Large basins containing Triassic continental sediments occur in South America (Colombia, Venezuela, Brazil, Uruguay, Paraguay, and Argentina) and in western North America, particularly in Utah, Wyoming, Arizona, and Colorado. In eastern North America great thicknesses of sedimentary rocks of continental origin were deposited during the Late Triassic in a series of fault basins, of which the Newark Basin is probably the best known. Here sequences of continental red clastics with dinosaur tracks and mud cracks, along with black shales containing fossils of freshwater organisms, indicate a depositional environment of rivers draining into freshwater lakes in a generally arid or semiarid region, which from paleomagnetic evidence appears to have been located about 20° N of the paleoequator.

Triassic igneous rocks are not common, and reliable radiometric dates are available only from Upper Triassic rocks. Examples of extrusive basalt flows are known from Australia, South America, and eastern North America, while intrusive rocks include the well-known Palisades Sill of the Newark series. This 300-metre-thick diabase intru-

Igneous rocks of the Upper Triassic

sion has yielded a potassium-argon age of 193 million years. Lava flows in the Hartford Basin of Connecticut have been used to estimate the age of the Triassic-Jurassic boundary as between 184 and 195 million years, based on potassium-argon and argon-40-argon-39 geochronology.

Types. As a broad generalization, Triassic geosynclinal and shelf-sea deposits formed in low paleolatitudes are dominated by limestones, with minor amounts of clastics (*e.g.*, sandstone, shale, and graywacke), while high-paleolatitude depositional basins and the circum-Pacific geosyncline are dominated by clastics, with minor amounts of limestone. Volcanism is usually associated with faulting and is represented by basalt flows and diabase intrusions.

Correlation. The Triassic System is dominated by sedimentary rocks that generally do not yield reliable radiometric dates. Since Triassic igneous rocks are rare, relative ages of the sedimentary rocks, derived from superposition, lithology, and biochronology, must be used for correlation. Of these three tools, biochronology has proved to be the most accurate and reliable. Although palynology may prove to be useful for correlation of marine and nonmarine strata in the future, the most widely used fossils in biochronology are those of ammonoids. This is because pelagic swimming forms of this type fulfill the basic requirements for ideal zone fossils in being widespread geographically, rapidly evolving, and substrate-independent. Ammonoids thrived in Triassic seas, along with pelagic bivalves, such as *Claraia* and *Halobia.* While ammonoids have been used successfully to erect a series of biozones, each one probably representing no more than one million years, the problem has been to find complete sequences of undisturbed marine strata that represent all stages of Triassic time in any one general region. Since the Germanic facies is mostly continental, the marine Triassic of the Alps has traditionally been used as a standard for the period, with the two most important localities being Salzkammergut in the northern Austrian Alps and St. Cassian (now San Cassiano) in the Dolomites to the south. Unfortunately, there are very few ammonoids common to both the Salzkammergut and St. Cassian sections. Indeed, the Alpine succession in general is not without its drawbacks when an attempt is made to determine sequential faunal relationships. In the red Hallstatt limestone facies in the Alps and throughout the Tethyan region, ammonoids often occur in lenses (*i.e.*, deposits bounded by converging surfaces that are thick in the middle and thin out toward the edges) in areas of tectonic complexity. Furthermore, faunas are often condensed through possible postdepositional submarine solution, resulting in "cemeteries" of ammonoids of different ages in close association. Also, fracturing and solution occurring at nearly the same time during the Triassic apparently caused local mixing and inversion of zones as younger beds collapsed into solutional voids in older strata. Such condensed and mixed assemblages have led to difficulties for paleontologists attempting to use the Alpine zonal scheme as a standard with which to correlate marine Triassic sequences in other regions. Nevertheless, the importance of the Alpine Triassic should not be underestimated in the history of Triassic studies, because its fossils permitted initial correlations to be made with the Germanic Muschelkalk and marine sequences in the Arctic, Pacific, Himalayas, and Salt Range of Pakistan by the end of the 19th century.

Reliance on fossil ammonoids for correlation

Isolated occurrences of marine Triassic rocks were known from western North America by 1890, but discoveries of several hundred new localities from this region and Arctic Canada between about 1955 and 1970 added much information on the biochronology of the region. It also was recognized that more than half the world's known genera of ammonoids occur in North America, testifying to the cosmopolitan nature of the group. Dissatisfaction with the problems of using the Alpine succession as a standard for Triassic time led to the proposal of a new zonal scheme based on relatively complete and in-place sequences in Arctic Canada, northeastern British Columbia, and the western United States. This has been primarily the work of the Canadian paleontologist E. Timothy Tozer, who, with the American paleontologist Norman J. Silberling, has provided precisely defined stratotypes for all the recognized North American biozones. The North American zonal scheme, once defined, has since allowed Alpine (western Tethyan) zones to be placed in their proper chronological sequence. This scheme has been adopted here almost in its entirety and is shown in Table 18.

Controversy over boundaries

The exact position of both the Permian-Triassic and Triassic-Jurassic boundaries has been the subject of great controversy for many years. The transition from latest Permian to earliest Triassic is nowhere represented by a continuous (conformable) succession of marine strata containing fossils that are not open to ambiguous age interpretation. The Germanic facies is of little value in the dispute, for here the continental Bunter rests unconformably on Upper Permian Zechstein strata. The marine equivalent of the Bunter in the Alps is the Werfen Limestone that contains the distinctive Lower Triassic bivalve genus *Claraia* near its apparently conformable contact with the underlying Bellerophon Limestone, in which undisputed Permian faunas are found. Recent studies, however, suggest that the lowermost Werfen may contain Permian fossils. In the Himalayas, *Claraia* occurs with the ammonoid *Otoceras* in the so-called *Otoceras* beds, but are these beds Permian or Triassic? A Triassic age is suggested by the presence of *Claraia,* but otoceratids also occur in undisputed Permian strata in the Dzhulfa (Julfa) region in Armenia near the Iran border. It was agreed as long ago as the early 1900s that the Armenian otoceratids were not in the strictest sense identical with *Otoceras* and that the Himalayan *Otoceras* beds should define the basal Triassic. This issue, however, has been raised again by those who regard the *Otoceras* beds as Permian rather than Triassic.

At key localities where apparently conformable sequences occur, such as in Armenia, Pakistan, Kashmir, Arctic Canada, Greenland, Spitsbergen, Tibet, China, Siberia, and northern Alaska, the boundary beds—often of limited thickness—usually contain mixtures of Permian-type and Triassic-type faunas or show evidence of a disconformity or paraconformity (*i.e.*, the strata are parallel but the surface is nearly indistinguishable from a simple bedding plane since no effects of erosion are discernible). It is these transitional beds that are the crux of the boundary problem. In the Salt Range (of Pakistan), for instance, Permian brachiopods are found in close association with undisputed Triassic fossils, suggesting the possibility of Permian relics living in earliest Triassic time. Yet, recent studies suggest that both latest Permian and earliest Triassic strata are missing in this section. In East Greenland mixed faunas occur at the boundary, with Triassic ammonoids in association with Permian productacean brachiopods, but the latter appear to be derived, having been incorporated into Triassic sediments by reworking. A similar situation may prevail at the famous Guryul Ravine section in Kashmir. Studies on new sections in southern Tibet (Selong) and southern China (Mei Shan) have not yet led to agreement on whether there is continuous sedimentation between the Permian and Triassic or a well-disguised unconformity. Tozer supports the latter view and, furthermore, believes that there is evidence of a worldwide unconformity (often well-disguised) at the base of the *Otoceras* zone. He advocates that this level should once again define the Permian-Triassic boundary, since it clearly records a universal geologic event of great significance to marine biotas. Accordingly, he has proposed a stratotype for the boundary at the base of the Blind Fjord Formation of northwestern Axel Heiberg Island in Arctic Canada, where the *Otoceras concavum* zone (equivalent to the *O. woodwardi* zone of the Himalayas) rests disconformably on Permian strata.

The exact position of the boundary between the Triassic and Jurassic has been less contentious but not without its problems. Marine rocks stratigraphically above the Keuper Marl in Germany and the New Red Sandstone in Britain have traditionally been regarded as either uppermost Triassic or lowermost Jurassic. These rocks contain the distinctive bivalve species *Rhaetavicula contorta* but no ammonoids. Rocks of this *R. contorta* zone in northwestern Europe have been correlated with the stratotype of the Rhaetian, the marine Kössen beds in the Rhaetic Alps, mainly on the basis of the common occurrence of *R. contorta.* The Alpine Rhaetian contains a few ammonoids

Rhaetian stratotype

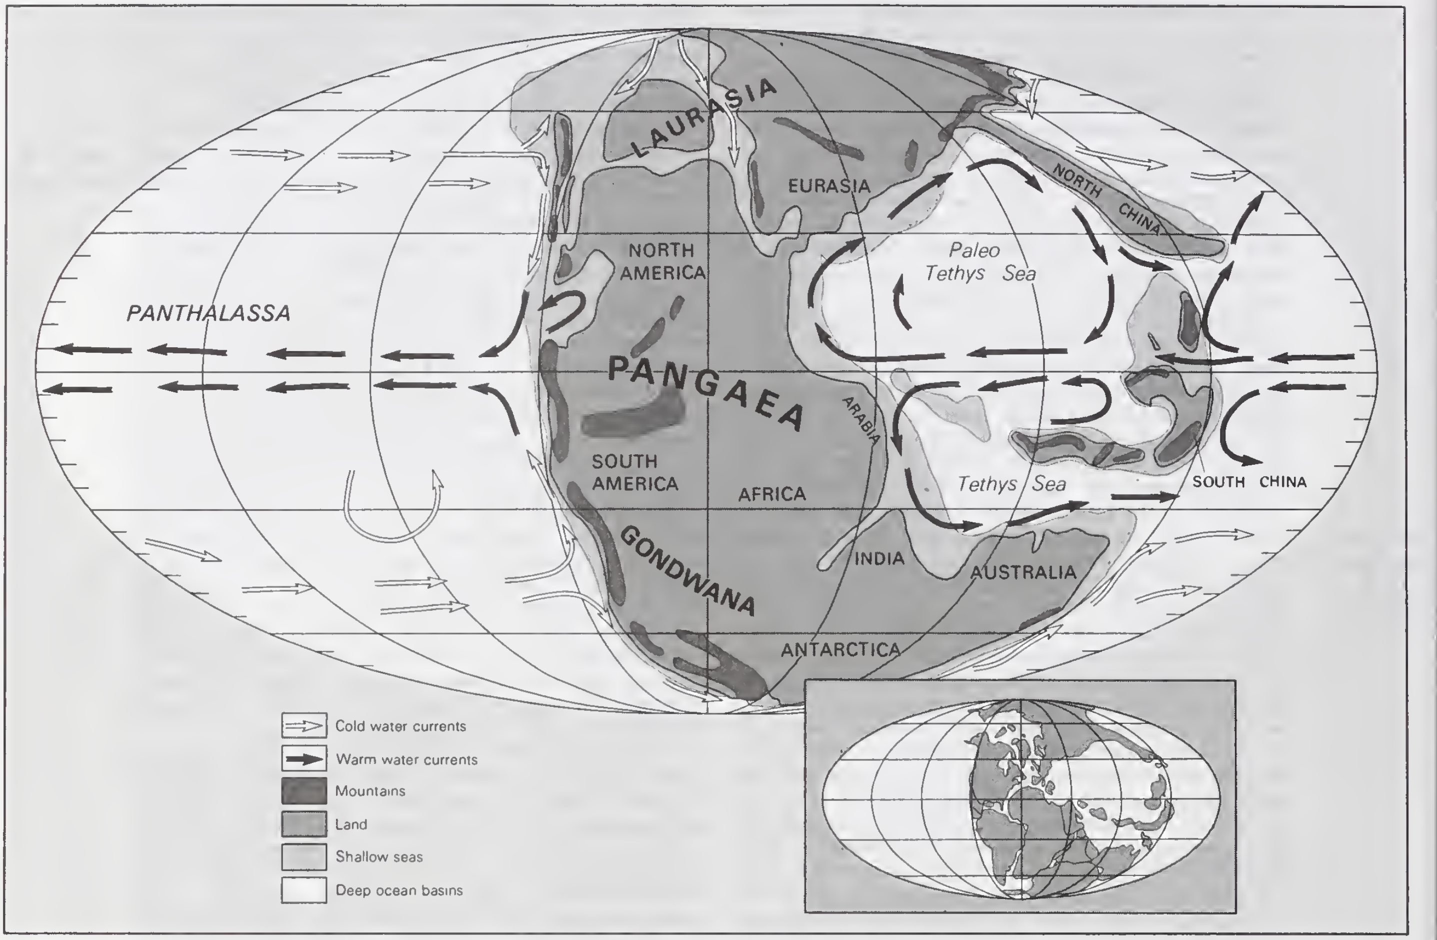

Figure 33: Paleogeography and paleoceanography of Early Triassic time. The present-day coastlines and tectonic boundaries of the configured continents are shown in the inset at the lower right.

Adapted from. C.R. Scotese, The University of Texas at Arlington

that are regarded as Late Triassic in affinity but not exclusively Rhaetian. The correlation of the Rhaetian of northwestern Europe with that of the Alps has been questioned, however, and it has been suggested that the former may be lowermost Jurassic in age, preceding the Hettangian *Psiloceras planorbis* zone. While all biostratigraphers would include at least the Alpine Rhaetian in the Triassic, Tozer advocates abandoning the term Rhaetian as a formal stage name and assigning Alpine Rhaetian rocks and their correlatives in North America and elsewhere to the uppermost Norian stage. Since the Rhaetian is so well known, the term has been retained here as a stage name, represented by a single zone, that of ammonite *Choristoceras marshi.*

Triassic environment. *Paleogeography.* As has been noted, at the beginning of the Triassic the present continents of the world were grouped together into one large supercontinent, Pangaea, which covered about one-quarter of the Earth's surface. Pangaea stretched from pole to pole in a narrow belt of about 60° of longitude and consisted of a group of northern continents, Laurasia, and a group of southern continents, Gondwana. The rest of the globe was covered by Panthalassa, the enormous world ocean that stretched from pole to pole and extended to about twice the width of the present-day Pacific Ocean at the equator (Figure 33). Scattered across Panthalassa, within 30° of the Triassic equator, were islands, seamounts, and volcanic archipelagoes, some associated with reef carbonates, which would later be driven into the lithospheric plates on either side of the Panthalassa spreading centre as displaced terranes.

A deep embayment of Panthalassa projected westward between Gondwana and Laurasia along an east–west axis approximately coincident with the present-day Mediterranean Sea. This ancient sea, the Tethys, was later to extend farther westward, as rifting between Laurasia and Gondwana began in Late Triassic time. This seaway would eventually link up with the eastern side of Panthalassa by Middle to Late Jurassic time when Gondwana proceeded to separate from Laurasia. The evidence for these paleogeographic reconstructions comes from many sources, of which paleomagnetic data and the matchups of continental margins, rock types, orogenic events, and distribution of fossil land vertebrates and plants prior to the breakup of Pangaea are the most important. In addition, the recalculated polar-wandering curves for Africa and North America converge between the Carboniferous and Triassic and then begin to diverge in the Late Triassic, indicating the exact time of the onset of separation of these two continents as the Tethys seaway began to open up.

Onset of rifting between Laurasia and Gondwana

Thick sequences of clastic sediments accumulated in marginal geosynclines bordering the present-day circum-Pacific region and the northern and southern margins of the Tethys, while shelf seas occupied parts of the Tethyan, circum-Pacific, and circum-Arctic regions but were otherwise restricted in distribution. Much of the circum-Pacific and the northeastern part of Tethys were active plate margins, as indicated by tectonic and igneous activity, but its northwestern and southern margins were passive during the Triassic.

Significant geologic events. The Triassic Period is characterized by few geologic events of major significance, in contrast to the Jurassic and Cretaceous when Pangaea fragmented and the new Atlantic and Indian oceans opened up. The beginning of continental rifting in the Late Triassic, however, caused stretching of the crust in eastern North America along the Appalachian Mountain belt from the Carolinas to Nova Scotia, resulting in normal faulting in this region. Here grabens received thick clastic sequences, which were later intruded by dikes and sills. In similar fault-controlled basins between Africa and Laurasia evaporites formed in arid or semiarid environments as seawater from the Tethys periodically spilled into these newly formed troughs. Evaporites of Late Triassic and Early Jurassic age in Morocco and off eastern Canada were apparently the result of such tectonism.

Limited orogeny

Mountain building was equally restricted during the Triassic, with relatively minor orogenic activity taking place along the Pacific coastal margin of North America and in China and Japan. The unmetamorphosed nature of the Triassic rocks of the Newark Group indicates that they were formed after the main phase of the Appalachian orogeny in the late Paleozoic.

Paleoclimate. The emergence of the supercontinent Pangaea and the reduction of shelf seas led to widespread aridity over most of the land areas beginning in the Late Permian and continuing throughout the Triassic. The relative paucity of shelf seas has been attributed to the reduced total shoreline of Pangaea and the lack of movement of the continents during this period of relative geologic quiescence. A single large landmass like Pangaea should experience an extreme continental climate, with widespread aridity. Paleoclimatic indicators for such aridity include poorly fossiliferous red sandstones and shales, lithified dune deposits with cross-bedding, salt pseudomorphs in marls, and evaporites, and these are found mainly in low and middle latitudes on the continents. Coal deposits may form in temperate and tropical climates, but their presence invariably indicates humid conditions, with relatively high rainfall responsible for both lush vegetational growth and poor drainage. The resultant large swamps act as depositional basins wherein the decomposing plant material can be gradually transformed into peat. Such humid conditions must have existed in high latitudes during the Triassic, based on the occurrence of coals in Arctic Canada, Russia, Ukraine, China, Japan, South America, South Africa, Australia, and Antarctica.

Homogeneous global climatic conditions

Worldwide climatic conditions during the Triassic seem to have been much more homogeneous than at present. It has been postulated that, because of the large size of Panthalassa, oceanic circulation patterns during the Triassic would have been very simple, consisting of enormous single gyres in each hemisphere (Figure 33). East–west paleotemperature extremes would have been great, with the western margin of Panthalassa much warmer than the eastern side. The permanent westerly equatorial current would have provided warm waters to Tethys, enabling reefs to develop there wherever substrates and depths were favourable. Temperature differences between the equator and the poles would have been less extreme than they are today, the result of which would have been reduced biotic provincialism.

The nature of Triassic fossils and their latitudinal distribution provide additional important evidence of paleoclimates. The biotas of the period are more modern in aspect, and so their life habits and environmental requirements can be reconstructed with relative confidence from comparisons with living relatives. As an example, the presence of colonial scleractinian corals as framework builders in Tethyan reefs of Late Triassic age suggests an environment of low-latitude, warm shelf seas. These seas must have been sufficiently shallow and clear to allow penetration of adequate light for photosynthesis by zooxanthellae (a form of dinoflagellate) inferred to be, perhaps for the first time in geologic history, symbiotically associated with reef-building corals.

Geographic distribution of modern-day animals indicates, with few exceptions, a faunal diversity gradient decreasing poleward in both hemispheres and apparently based on ambient temperature differences between high and low latitudes. Plots of the diversity of ectothermic (cold-blooded) amphibians and reptiles at the present time, for example, show a much higher diversity in low latitudes, reflecting the strong influence of ambient air temperatures on these animals that lack an internal temperature-regulatory system. The evidence from Triassic fossils is equivocal, however. Diversity–latitude plots of Triassic amphibians and reptiles appear to show only a weak diversity gradient, but plots of ammonoids from the upper part of the Lower Triassic show a much stronger gradient. These data suggest that Triassic marine invertebrates were more sensitive to differences in ambient temperature than land vertebrates or that ambient temperature differences were greater in the ocean than on land. There is also the possibility that both these conditions existed.

Triassic life. Periodic large-scale mass extinctions have occurred throughout the history of life; indeed, it is on this basis that the geologic eras were first established. One of the most severe and widespread of such extinction events took place at the end of the Mesozoic; another was at the end of the Paleozoic, and it is the latter that profoundly affected life during the Triassic. A third episode of mass extinctions occurred at the end of the Triassic, drastically reducing some marine and terrestrial groups, such as the ammonoids, mammallike reptiles, and primitive amphibians.

Mass extinctions

The Permo-Triassic extinction was perhaps the most drastic in the history of life on Earth, although it should be noted that many groups were showing evidence of a gradual decline long before the end of the Paleozoic. The trilobites, a group of arthropods long past their zenith, made their last appearance in the Permian, as did the closely related eurypterids. Rugose and tabulate corals became extinct at the end of the Paleozoic. Several superfamilies of Paleozoic brachiopods, such as the productaceans, chonetaceans, spiriferaceans, and richthofeniaceans, also disappeared at the end of the Permian. Fusulinid foraminiferans, useful as late Paleozoic index fossils, did not survive the crisis, nor did the cryptostomate and fenestrate bryozoans that inhabited many Carboniferous and Permian reefs. Gone also were the blastoids, a group of echinoderms that persisted in what is now Indonesia until the end of the Permian, although their decline had begun much earlier in other regions.

Many possible causes have been advanced to account for these extinctions. Cataclysmic events, such as intense volcanic activity and the impact of a celestial body, or more gradual changes brought about by widespread marine regression, oceanic salinity and nutrient fluctuations, climatic cooling, and cosmic radiation, have been proposed to explain the Permo-Triassic crisis. Any theory, however, must take into account that not all groups were affected to the same extent. Whatever the cause, Early Triassic biotas were impoverished, although they progressively increased in diversity and abundance during Middle and Late Triassic times. While the fossils of many Early Triassic life-forms tend to be Paleozoic in aspect, those of the Middle and Late Triassic are decidedly Mesozoic in appearance and clearly the precursors of things to come.

Invertebrates. The difference between Permian and Triassic faunas is most noticeable among the marine invertebrates; the number of families was reduced by half, with an estimated 95 percent of all species disappearing at the Permian–Triassic boundary. The ammonoids were common in the Permian but suffered drastic reduction at the end of that period. Only a few genera belonging to the prolecanitid group survived the crisis, but their descendants, the ceratitids, represented by such Early Triassic genera as *Otoceras* and *Ophiceras,* provided the rootstock for an explosive adaptive radiation in the Middle and Late Triassic. Ceratitids have varying external ornamentation, but all share the distinctive ceratitic internal suture line of rounded saddles and denticulate lobes. The group reached its acme in the Carnian, with more than 150 genera; it declined to less than 100 in the Norian and to less than 10 in the Rhaetian. In the Late Triassic bizarre heteromorphs with loosely coiled body chambers, such as the genus *Choristoceras,* or helically coiled whorls (*e.g., Cochloceras*) evolved. These aberrant forms, however, were short-lived. A small group of smooth-shelled forms with more complex suture lines, the phylloceratids, also arose in the Early Triassic. They are regarded as the earliest true ammonites and gave rise to all post-Triassic ammonites, even though Triassic ammonoids as a whole almost became extinct at the end of the period.

Adaptive radiation of the order Ceratitida

Other marine invertebrate fossils found in Triassic rocks, albeit much reduced in diversity compared with the Permian, include gastropods, bivalves, brachiopods, bryozoans, corals, foraminiferans, and echinoderms. These groups are either poorly represented or absent in Lower

Triassic rocks but increase in importance later in the period. Most are bottom-dwellers (benthos), but the bivalve genera *Claraia, Posidonia, Daonella, Halobia,* and *Monotis,* often used as Triassic guide fossils, were planktonic and may have achieved widespread distribution by being attached to floating seaweed. While the role of colonial scleractinian corals as reef-builders in Middle and Late Triassic structures has already been mentioned, cavities in Rhaetian reefs from Austria were colonized by a cryptofauna of echinoids, foraminiferans, spongiomorphs, and small arthropods. Many successful Paleozoic articulate brachiopod superfamilies became extinct at the end of the Permian, leaving the spiriferaceans, rhynchonellaceans, terebratulaceans, terebratellaceans, thecideaceans, and some other less important groups to continue into the Mesozoic. The brachiopods, however, never again achieved the dominance they held in the benthos of the Paleozoic. Fossil echinoderms are represented in the Triassic by crinoid columnals and the echinoid *Miocidaris,* a holdover from the Permian. The crinoids had begun to decline long before the end of the Permian, by which time they were almost entirely decimated, with both the flexible and camerate varieties dying out. The inadunates survived the crisis; they did not become extinct until the end of the Triassic and gave rise to the articulates that still exist today. Coccolithophores, an important group of living marine pelagic algae, made their first appearance during the Late Triassic, while dinoflagellates underwent rapid diversification during the Late Triassic and Early Jurassic.

Vertebrates. Vertebrate animals appear to have been less affected by the Permo-Triassic crisis than were invertebrates. The fishes show some decline in diversity and abundance at the end of the Paleozoic, with acanthodians becoming extinct and elasmobranchs much reduced in diversity. Actinopterygians, however, continued to flourish during the Triassic, gradually moving from freshwater to marine environments, inhabited by subholostean ray-finned fishes, which were intermediate between palaeoniscoids and holosteans. The shellfish-eating hybodont sharks, already diversified by the end of the Permian, continued into the Triassic. The fossils of marine reptiles, such as the shell-crushing placodonts (which superficially resembled turtles) and the fish-eating nothosaurs, occur in the Muschelkalk of the Germanic facies. The latter forms, sauropterygians, did not survive the Triassic, but are ancestral to the large predatory plesiosaurs of the Jurassic. The largest inhabitants of Triassic seas were the early ichthyosaurs, superficially like dolphins in profile and streamlined for rapid swimming. These efficient hunters were equipped with powerful fins, a long-toothed jaw, and large eyes and may have preyed upon some of the early squidlike cephalopods known as belemnites. There also is evidence that these unusual reptiles gave birth to live young.

Giant marine reptiles

On land, the vertebrates are represented in the Triassic by labyrinthodont amphibians and reptiles, the latter consisting of cotylosaurs, therapsids, eosuchians, thecodonts, and protorosaurs. All these tetrapod groups suffered a sharp reduction in diversity at the close of the Permian; 75 percent of the early amphibian families and 80 percent of the early reptilian families disappeared at or near the Permian–Triassic boundary. While early Triassic forms were still Paleozoic in aspect, new forms appeared throughout the period, and by late Triassic times the tetrapod fauna was distinctly Mesozoic in aspect. The mammallike reptiles, or therapsids, suffered pulses of extinctions in the Late Permian. The group survived the boundary crisis but became extinct by the end of the Triassic, possibly due to competition from more efficient predators, such as the thecodonts. The first true mammals appeared in the Late Triassic. Although their fossilized remains have been collected from the Rhaetian bone bed in Britain, the evolutionary transition from therapsid reptiles to mammals at the close of the Triassic is nowhere clearly demonstrated by well-preserved fossils. Other modern groups with ancestral forms appearing for the first time in the Middle and Late Triassic include lizards, turtles, rhynchocephalians, and crocodilians.

Emergence of the first true mammals

First encountered in the Early Triassic, the thecodonts became common during the Middle Triassic, but disappeared before the beginning of the Jurassic. Typical of this group of archosaurs (or ruling reptiles) in the Triassic were small bipedal forms belonging to the pseudosuchians. These were swift-running predators that had erect limbs directly under the body, which made them more mobile and agile. This group presumably gave rise to primitive dinosaurs belonging to the saurischian and ornithischian orders during the Late Triassic to Early Jurassic. The early dinosaurs were bipedal, swift-moving, and relatively small compared to later Mesozoic forms, but still reached lengths of more than six metres. The group was to achieve much greater importance later in the Mesozoic, resulting in the era being informally called the "Age of Reptiles."

Some of the earliest lizards may have been the first vertebrates to take to the air. Gliding lizards, such as the small Late Triassic *Icarosaurus,* are thought to have developed an airfoil from skin stretched between extended ribs, allowing short glides similar to those made by present-day flying squirrels. These forms became extinct at the end of the Triassic, their role as fliers being taken over by the pterosaurs (flying reptiles) of the Jurassic and Cretaceous.

Plants. Land plants were relatively unaffected by the Permo-Triassic crisis. The dominant understory plants in the Triassic were the ferns, while most middle-story plants were gymnosperms (those having exposed seeds) that belonged to the still-extant cycadeoids and Ginkgoales. The upper story of Triassic forests consisted of conifers; their best-known fossil remains are preserved in the Upper Triassic Chinle Formation in the Petrified Forest National Park of northeastern Arizona. While extensive forests did exist during the Triassic, widespread aridity on the continents limited their areal extent, resulting in generally poor development of fossil floras during this period. In the southern continents the Permian *Glossopteris–Gangamopteris* seed-fern flora was replaced by a Triassic one dominated by *Dicroidium.* This pteridosperm genus was part of an extensive Gondwanan paleoflora that was discovered in the Triassic Molteno Formation of southern Africa and elsewhere. (This paleoflora extended from 30° S to well below 60° S.) In the Northern Hemisphere a subtropical-to-warm temperate Eurasian (Euramerican) flora lay in a belt between about 15° N and 55° N, while to the north was the temperate Siberian (Angaran) flora, extending to within 10° of the Triassic North Pole. Few fossil remains exist from the Triassic for the equatorial zone between 15° N and 30° S, however. (A.Lo.)

JURASSIC PERIOD

General considerations. The Jurassic is the second of three periods of the Mesozoic Era. On the basis of radiometric measurements, it extended from about 208 to 144 million years ago (see Table 4). The rocks that originated during this interval of time compose the Jurassic System. In many regions of the world, the Jurassic lies directly over the Triassic strata and, in turn, is often overlain by those of the Cretaceous. The Jurassic was named early in the 19th century by the French geologist and mineralogist Alexandre Brongniart for the carbonate terrane of the Jura Mountains between France and Switzerland. The presence of similar fossils was used to establish a correlation between the Jura carbonates and the oolite limestones of England.

Major subdivisions. The Jurassic is generally subdivided into three parts—Early, Middle, and Late—after the chronology of the German geologist Leopold Buch. Later, F.A. Quenstadt and C.A. Oppel used the names Lias, Dogger, and Malm, respectively, for these units, which were also referred to as the Black, Brown, and White Jurassic sequences (see Table 19).

Jurassic stages

Each of the triad was further subdivided into stages by Oppel in Germany and Brongniart, A.D. d'Orbigny, and other geologists elsewhere in western Europe, who named the stages after existing rock or geographic names. For example, the Hettangian Stage was named by the Swiss geologist Eugène Renevier after Hettange-Grande of the Lorraine in eastern France (Table 19). Eventually a biostratigraphic basis for recognizing the stages was established through the determination of zone fossils, index fossils, or fossil assemblages, and in some cases fossils accompanying distinctive rock types (Table 19). In this way, d'Orbigny named the following stages: Sinemurian (after Sémur in the south of France), Toarcian (Thouars in western France), Bajocian (Bayeux in Normandy), Bathonian (Bath, Eng.), Callovian (Kellaways, Eng.), and Kimmeridgian (Kimmeridge, Eng.). Brongniart named the Oxfordian and Portlandian after Oxford and Portland Isle in southern England, and Oppel derived Pliensbachian from that location in Germany.

Correlation of fossils and rock layers made it possible for William Smith to prepare a geologic map that showed the aerial distribution of Mesozoic and Cenozoic rocks in southern England, and Georges Cuvier accomplished the same task in northwestern France. These areas are now commonly referred to as the London and Paris basins, respectively. The Jurassic underlies younger rocks in the interior of both basins. The Tithonian Stage was added by Oppel for the uppermost Jurassic of the Alpine region, and Sergey Nikolaevich Nikitin named the Volgian Stage for the upper Jurassic in the Volga basin in Russia. The underlying Triassic and overlying Cretaceous strata are distinguished from those of the Jurassic on the basis of fossils and unconformities.

Development of geosynclines

Distinctive features. Jurassic rocks are widely distributed as part of both oceanic and continental crust. They include deep-sea sediments, coral limestone, carbonate platforms, volcanic island arcs, and interarc basin deposits, as well as terrestrial sediments and extensive plutonic intrusions. While lithospheric plate divergence and continental rifting mark the late Triassic before 208 million years ago, breakup of the supercontinent Pangaea and the opening of the ocean basins date from Early Jurassic time. Geosynclines developed along the new continental margins. Some of these, such as the miogeoclines (prograding wedges of shallow-water sediments) on the trailing, or passive, margin of eastern North America and the Gulf Coast, persist today. Others, like the Tethyan geosyncline of southern Eurasia, its counterpart along the northern margin of Gondwana, and the West Coast geosynclinal complex of western North America—all of which occupied the leading edges of the continents—have been converted to mountain ranges through collisions between continental plates or between oceanic and continental plates.

Jurassic plate tectonics accounts for the accretion to continental plates of 5,000 to 16,000 metres of sediments from continental margins, oceanic crust, island arcs, and arc-related basins, as well as from igneous intrusions. In North America, the Nevadan orogeny of the Late Jurassic involved the collision of an island-arc complex with the western margin of the continent. Because of plate collisions (and the attendant subduction of oceanic crust) and the opening of new ocean basins, there is no ocean floor in the present-day basins that is older than Jurassic age. Due to late- and post-Mesozoic plate collisions between Africa and Europe and the fragments of Gondwana and Asia, Jurassic carbonates of the Tethys Sea lie in extensive thrust sheets, called nappes, which blanket the crystalline core of the region in the mountainous uplands from the Alps to the Himalayas.

Sedimentation continued during the Jurassic in the Mesozoic rift basins of continental eastern North America (see Figure 35), southwestern Europe, and southern Africa—basins that are similar to the expanding rift basins of present-day East Africa. These deposits include red beds and lacustrine shales interbedded with mafic lavas (*i.e.*, pillow lavas where extrusion was into standing water) and coarse-grained alluvial fan conglomerates. Epicontinental seas left sandy coastal plains, shallow-water marine beds, and evaporites with fluvial and deltaic facies intermixed.

Deposition on oceanic crust began in marine basins where evaporation prevailed during Middle Jurassic time (marine sediments of Early Jurassic age are entirely absent on oceanic crust).

Coal and petroleum deposits

Economic significance. Epicontinental seas invaded continental interiors to varying degrees between the Early and Late Jurassic, leaving extensive beds of clay, limestone, sandstone, ironstone, and coal. These deposits have provided economically important resources in many continental interior regions. For example, clay and limestone have been used for brick, cement, and other building materials in various areas of continental Europe. Iron ore and coal for steelmaking are prevalent in western Europe and England. Coal deposits also are found in Siberia and Asia, as, for example, in the Late and Middle Jurassic Yenan Formation in the Ordos Basin of China. Petroleum is produced from strata trapped against salt domes of Jurassic age in the Gulf Coast province of the United States and from the marginal basins of western North America. Oil also is found in northern Germany and Russia, and salt is mined in both the United States and Germany. Lithographic limestone is quarried in Germany as well. Jurassic igneous rocks have yielded chromite in eastern Europe and uranium and gold concentrations in placer deposits on the slopes of the Sierra Nevada in the western United States.

Characteristic fauna and flora. Distinctive Jurassic lifeforms range from microscopic unicellular organisms known as coccolithophores (or coccoliths) to the most diverse animal group, the dinosaurs. After the Late Triassic to Early Jurassic extinctions left only a few ammonoid cephalopod and reptile genera, the ammonoids rebounded so successfully that their remains have come to serve as marine guide fossils in the biostratigraphic zonation of Jurassic stages. Dinosaurs and other reptiles emerged to dominate the land, sea, and sky. The first birds and new varieties of gymnosperms, along with extensive reef-building and other invertebrate faunas, provided Jurassic life with added complexity.

Breakup of Pangaea

Jurassic rocks. *Occurrence and distribution.* Pangaea began to break up as North America separated from Eurasia and Gondwana, with Africa subsequently splitting off from India, Australia, and Antarctica. As a result of this intense tectonic activity, alkalic igneous rocks were emplaced in the New England region of North America, and mafic volcanics were extruded in southern Africa during the Early Jurassic (Sinemurian). By Late Jurassic time, Africa had separated from South America and Australia and Antarctica had broken away from India. At the same time, the Iberian Peninsula rotated away from Europe, while Alaska rotated away from Canada.

Evidence of these plate movements comes from radiometrically dated igneous intrusions, oceanic sediments (the oldest sediments on the oceanic crust in the Atlantic Basin are of Callovian age—about 169 to 163 million years old—and the oldest geosynclinal sediments between North America and Africa are approximately 182 million years old), and magnetic anomalies, the oldest of which in the Atlantic is dated at about 153 million years. In the North Atlantic, the separation of North America and Greenland began in Late Jurassic (Kimmeridgian) time, as shown by the emplacement of dikes between 162 and 138 million years ago. The Late Jurassic continental breakup is associated with tectonic activity in North America during the Nevadan orogeny. The fact that South America separated from Africa between 150 and 130 million years ago has been determined by age measurements of Late Jurassic mafic volcanics, magnetic anomalies, geosynclinal sediments, and alkalic igneous intrusions. India began separating from Australia and Antarctica during the Kimmeridgian.

Eastern North America

In eastern North America, Late Triassic–Early Jurassic extensional basins became filled with synrift deposits (red beds and others produced during continental rifting), and pillow lavas were extruded into lake basins. The Upper Newark Supergroup of these basins is Early Jurassic in age, based on potassium–argon ages of 185- to 194-million-year-old basaltic flows like the Watchung Flows of the Newark Basin. More than 150 metres of Lower Jurassic cyclic fluvial and lacustrine beds were deposited in the Culpeper Basin in northern Virginia. Middle Jurassic volcanoclastic rocks have been found beneath continental shelf sediments on the New England margin of North America. Upper Jurassic marine sediments include clastics interfingering with carbonates in the Atlantic and Gulf Coast miogeoclines that formed on the initial continental margins of North America after its separation from Gondwana. Middle Jurassic strata include evaporites (*e.g.*, Louann Salt), red beds, carbonates, and shelf-margin reefs. The Smackover Formation of the Gulf Coast sequences is a geosynclinal sedimentary unit typical of this interval. Plate activity continued with seafloor spreading and the development of the Caribbean microplate. Paleomagnetic studies of Early Jurassic rocks in eastern North America indicate normal polarity and a correlation with similar magnetostratigraphy in Africa and present-day Russia.

Western continental interior of North America

An Early Jurassic marine transgression, the so-called Sundance sea, covered the western continental interior of North America, depositing thin sandstone, shale, and limestone beds from the Arctic almost to the Gulf of Mexico with accumulations of generally a few hundred metres. Distinctive stratigraphic units include the Early Jurassic Navajo Sandstone, a variable coastal plain sequence that incorporates cross-bedded, dune-formed sandstone and red beds, along with the Late Jurassic Morrison Formation, which is a continental clastic wedge of lacustrine and fluvial mudstone, siltstone, sandstone, and conglomerate that was built to the northeast over the deposits of the epicontinental sea. Uplift of the continental interior occurred between central Arizona and southern California during the interval from the Late Triassic to the Middle Jurassic. Dinosaur fossils (including some tracks) and associated plant and invertebrate fossil remains are especially abundant in the Morrison Formation. Deposition on the Arctic margin of North America was principally of fine-grained marine clastics and a thin continental clastic wedge of sandstone and conglomerate. Early Jurassic deformation was primarily compressional, and deposition continued through Portlandian time—that is to say, into the Late Jurassic.

On the western continental margin of North America, volcanic island arc–continent collisions took place along what is now the foothills of the Sierra Nevada on the eastern edge of California during the Nevadan orogeny. Deformation of the Foothills Terrane in the Sierras occurred from 160 to 150 million years ago. Jurassic ophiolites are dated between 200 and 163 million years, as are intrusive plutons (batholiths and various other large igneous bodies) like the granodiorites of the western Sierras. Plutons in the central Sierras are dated at 150 million years. Volcanics, including pillow lavas, also were emplaced at this time.

During the Middle Jurassic, accretion of oceanic crust in the Coast Range geosyncline involved a basaltic-to-ultramafic arc terrane and ophiolites above an east-dipping subduction zone in the Klamath Mountains of the Oregon–California boundary. This formed Upper Jurassic slate, graywacke, and chert, as exemplified by the Galice Formation and ophiolites of the western Klamath Mountains in southwestern Oregon and the Mariposa Formation in northern California. The Franciscan Formation of the Coast Ranges represents an accretionary wedge of sediments that accumulated in trenches in the plate-collision zone. It is composed largely of deep-water marine deposits called flysch, graywacke, banded radiolarian chert, volcanoclastics, mélange (a mixture of rock fragments of different type, character, and origin), and low-grade metasediments and metavolcanics (metamorphosed sediments and metamorphosed igneous rocks, respectively), together with pillow basalts and greenstone. An Early Jurassic island arc existed in southern Alaska, and a Middle Jurassic back-arc basin and sedimentary mélange—namely, the Coloradito Formation—is found along the western coast of Baja California between the Vizcaíno Peninsula and Cedros Island. The Eugenia Formation of the Late Jurassic represents a younger back-arc basin sequence in the same region. Mafic dikes in northern California also may very well indicate a Late Jurassic volcanic arc. Oceanic sediments from the flat expanse of the deep seafloor known as the abyssal plain and from the continental margin were mixed with carbonates from Pacific atolls to form the accretionary molasse (*i.e.*, thick shore deposits) of the Late Jurassic.

East of the collision zone, deposition of sediments in fore-arc basins of the continental margin gave rise to the Great Valley Group of fine-grained sedimentary rocks. The western margin of the continent evolved into a more extensive system of fore-arc and interarc basin structures of late Kimmeridgian time with an accumulation of up to 16,000 metres of sediment. Subduction of a microplate, known as the Farallon Plate, resulted in Late Jurassic accretion of oceanic crust, arc–arc and arc–continent collisions, emplacement of granitic intrusions, and east-directed thrust faults from northern California to British Columbia due to compressional movement related to the Nevadan orogeny. This process of microplate accretion has incorporated more than 50 Jurassic exotic terranes (see above) to the western Cordilleran orogenic belt. These exotic terranes, which are typified by the Cache Creek Terrane and the Wrangellia Terrane of the Middle Jurassic, consist of segments of oceanic crust that may have originated in tropical regions of the Pacific and were accreted to western North America between southern Alaska and eastern Oregon.

Eurasia and Gondwana

The Tethyan geosyncline on the margins of both Eurasia and Gondwana accumulated thick sequences of Jurassic rock ranging from carbonates and evaporites to sandstone. The carbonates include shallow-water marl, limestone and reefs, and deep-water siliceous limestone. The presence of radiolarian cherts strongly indicates a deep-water origin for some of the sediments. Breccia, found today in nappes of the Alps, was thrust up from submarine rifts, and flysch deposits show the presence of rapidly sinking orogenic basins.

The magnetostratigraphy of Late Jurassic limestone in southern Europe shows normal polarity in the upper part of the M18 magnetic anomaly and reversed polarity in anomaly M17 in the vicinity of the Jurassic–Cretaceous boundary (see Table 4). Based on the first appearance of the nannoplankton fossil *Nannoconus colomi*, the Jurassic–Cretaceous boundary falls at the M17–M18 boundary. Alternatively, the boundary based on the ciliophoride *Calpionella alpina* correlates somewhat differently with magnetic anomalies and is placed at the base of the M18 normal polarity zone.

In the continental interior of Eurasia, shallow seas deposited a complex of carbonates: the limestones, reefs, and marls of the Jura Mountains and of southern France and England, and the fossiliferous, fine-grained lithographic limestone of Germany. Clastic facies include the Lias (Early Jurassic) shales of western Europe, the Oxfordian clays of England and Germany, and the clays of the Russian Platform. While the Arctic region was primarily a clastic province dominated by clay-rich rocks, shale, siltstone, sandstone, and conglomerate, the geosynclinal Pacific margin of Asia developed volcanic island arcs and associated basins from Japan (where thick oceanic crust accreted to the arc) all the way to Indonesia. Both the Australian and Siberian continental interiors received thick continental deposits that include fluvial, eolian, and lacustrine beds.

The rifting and diverging segments of Gondwana variously collided with the adjacent Pacific crust, while rifts in the continental interiors poured out vast amounts of flood basalts—namely, the Ferrar Dolerite of Antarctica, the São Bento Dolerite of South America, the Rajmahal Dolerite of India, and a correlative dolerite in South Africa. Late Jurassic volcanics and deformation extended to New Zealand, as Australia and New Zealand collided with the Pacific Plate. Radiolarian stratigraphy indicates that the Esk Terrane is a tectonic mélange with limestone blocks that was accreted to New Zealand between Late Triassic and Late Jurassic time. In the southern Tethyan region, fine-grained sediments accumulated to form thick shale deposits. Arc–continent collisions in the Andean geosyncline during the Late Jurassic deformed graywackes and volcanics, and volcanism extended into the continental interior of South America. Africa and Madagascar began to separate, eventually opening an oceanic trough for deposition of marine sediments.

Ocean basins

The oldest oceanic sediments date from the mid-Jurassic. Seafloor spreading (and magnetic anomalies) began about 147 million years ago. The Indian Ocean also began to open at this time as India separated from Australia and Antarctica. The oldest crust of the Pacific Basin dates from the Late Jurassic.

Jurassic environment. *Paleogeography.* The continents were still grouped closely in the Pangaean configuration during the Early Jurassic, although divergence in the Atlantic axis was under way at this time. The formation of Pangaea had caused geosynclines to develop on all the coastal margins of the constituent continents. Passive continental margins existed in the Arctic, with a clastic depositional regime, along eastern North America and western Europe, both of which acquired miogeoclinal basins as separation took place, and along the Tethyan geosyncline between Eurasia and Gondwana, which, with its medial deep-sea component, persisted through this interval. Active plate collisions took place around the Pacific rim: the western margins of the North American and South American plates collided with the eastern edge of the Pacific Plate and its microplates and exotic terranes, while Asia, from Japan to Indonesia, and New Zealand collided against the western margin of the Pacific Plate.

Neither of the Jurassic poles was occupied by a landmass. The South Pole lay south of Antarctica, only part of which extended south of 60° S. Most of Antarctica and Australia, as well as the southern tip of South America and Africa, were north of 60° S. The North Pole lay engulfed in the Arctic Sea, and only northernmost North America, along with Greenland and Siberia, extended north of 60° N. The paleoequator cut through the Pacific Ocean and the Tethys Sea, dissecting Gondwana and slicing across the northern edge of South America. As a result of this geographic distribution, tropical and temperate conditions (*i.e.*, those typical of areas between 60° N and 60° S) prevailed on most of the landmasses.

Reefs existed between 30° N and 30° S; most red-bed, evaporite, and dune deposits also occurred in this region. Coal deposits were extensive in northwestern North America, southwestern Europe, much of Siberia, Asia (including China), and Australia. Many of the continental deposits resulted from fluctuations along the margins of the epicontinental seas during the Middle and Late Jurassic, as did the development of multiple interfingering transitional and continental sediments, which in some areas formed cyclothems.

Jurassic spreading centres and mid-oceanic rifts formed between North America and Eurasia, North America and Gondwana, and Eurasia and Gondwana. Such centres and rifts also developed between the various segments of Gondwana itself.

Paleoclimate. Jurassic climates can be deduced from paleogeographic reconstructions that reveal the location of reefs, red beds, evaporites, and dune sandstone. The first three are all indicative of tropical to subtropical conditions, while the presence of the latter suggests semiarid to arid regions and generally subtropical climate. It has been determined that widespread sand sheets, or ergs, covered the desert plains adjacent to the epicontinental seas of the mid-latitude continental interior of North America from Utah to Arizona. Such vast accumulations of sand gave rise to thick eolian sandstone typified by the Early Jurassic Wingate Sandstone. Extensive salt deposits are associated with regions of great aridity, such as the sabkhah (also spelled sebkha) areas that are found near the Red Sea today.

Plate movements

The presence of these indicator rock types in modern temperate, boreal, or polar latitudes indicates that the continental plates moved away from the paleoequator after their deposition during the Jurassic. There is no evidence of glaciation or polar ice caps in the Jurassic, perhaps owing to the lack of a continental landmass in a polar position (see Figure 34). Warm, sun-lit oceans, including the epicontinental seas, abounded in marine life, especially in reef-building invertebrates and the extensive reef infaunas. The widespread development of terrestrial forests and the thick deposits of coal show that most of the existing landmasses were in temperate to tropical climatic regimes with adequate moisture to support the development of plant life.

Jurassic life. *Protists and invertebrates.* Among the prominent marine life-forms of the Jurassic were the Protista, including the foraminiferans, and radiolarians. Foraminiferans, particularly the large-sized varieties in the family Lituolidae, were abundant. Benthic protozoans, planktonic foraminiferans (including the first globigerinids), and radiolarians formed deep-ocean oozes and have provided evidence of the latitude of origin and age of some exotic terranes. Other abundant protists were the flagellates, coccolithophores (calcareous platelet-forming organisms that appeared in the Early Jurassic), dinoflagellates (a Middle Jurassic arrival), hystrichosphaerids (protists of uncertain origin but linked to the dinoflagellates), and the ciliophorans. The latter include the tintinnids, an important group of limestone-secreting organisms of the Late Jurassic particularly in the Tethyan region, and the calcareous calpionellids, important zone fossils, especially for the Upper Jurassic.

Reefs of the Tethys Sea were formed of siliceous sponges and stromatolites, as well as of corals, and had an extensive infauna (see Figure 36). Sponge spicules, along with stromatolites, are prevalent in some limestones in the continental interior of Europe during the Early Jurassic. *Corneyella,* a genus of thick-walled calcareous sponge, emerged in the Upper Jurassic of Germany, and *Pachyterchisma,* a genus of siliceous sponge, also appeared in the Upper Jurassic. Coral reefs were widespread throughout the Tethyan region, with the Anthozoa, mainly the order Scleractinia, dominant during the Late Jurassic in Europe and Africa. A number of scleractinian corals, such as the genera *Actinarea* and *Comophyllia,* were named by d'Orbigny. Scyphozoans, the medusae or jellyfish, are represented in the inland seas of Europe. Genera include *Medusina* and *Rhizostomites.* Large scyphozoan jellyfish are common in Upper Tethyan reef sequences. The contorted, calcareous tubes of serpulid worms are often found clustered in reef-forming masses in the Jurassic carbonates of northwestern Europe.

Few brachiopod families, such as the spiriferids, survived the Paleozoic. Nevertheless, two groups, the rhynchonellids and the terebratulids, evolved in the shallow marine environments and survive today. The spiriferids, on the other hand, became extinct during the Jurassic. Rhynchonellids were widespread in the Jurassic of Europe and North America. Some genera are *Homoeorhynchia* from the Lower to Middle Jurassic of the Alps and western

From E Winson in W S McKerrow (ed), *The Ecology of Fossils*, Gerald Duckworth & Company Ltd

North America, *Costirhynchia* of the Middle Jurassic in Europe, and the Upper Jurassic (Portlandian and Volgian) form *Rhynchonella*. Examples of the terebratulids are *Epithyris* of the Middle Jurassic in Europe and *Somalithyris* of the Oxfordian in Somaliland.

Bryozoans are represented by the encrusting cyclostomes of the warm Jurassic seas and include such genera as *Entalophora, Spiropora* (a spiral-shaped colonial form), and *Idmonea*. Members of another order of bryozoa, the cheilostomes, first appeared in the Jurassic and rapidly became abundant.

The bivalves, or pelecypods, normally a slow-changing group of mollusks, showed rapid expansion during the Jurassic, adding a dozen new families. Jurassic assemblages tended to include the schizodonts, characterized by few and distinct hinge teeth, and dysodonts, distinguished by weak or absent teeth; included in the latter group are the pectinid and oysterlike forms. Heterodonts were relatively unimportant during this time. Oysters and pectinids, such as the genus *Lima*, with eulamellibranch gills (specialized gills in which the lamellae consist of solid sheets of tissue), continued to develop toward modern varieties. Pelecypods and gastropods, particularly the prosobranchs, were prominent in the shallow seas of the Jurassic geosynclines. The high-spired nerineids evolved during the Jurassic. Pulmonate gastropods, such as *Limonaea* and *Helisoma*, are found in lake beds of Purbeckian age, while others, like *Valvata*, are marine. In terms of varying shell morphology *Itieria*, a gastropod from the Upper Jurassic of France, has a complex umbilicate shell. Another group, the archaeogastropods, expanded markedly during the Late Jurassic as well.

Ammonoid index fossils

The ammonoid cephalopods, like the brachiopods, recovered remarkably from near extinction in Late Triassic time on the evolutionary success of two relict genera, *Phylloceras* and *Lytoceras*. Complex suture patterns—the trace of the chamber partitions or septa edges on the shell walls—and varying shell morphology and ornamentation provide the variety of index fossils for the more than 50 ammonoid zones that delineate Jurassic stratigraphy (Table 19). While the Lower Jurassic is characterized by tightly coiled ammonoid shells, loosely coiled forms appear in the Middle Jurassic. Upper Jurassic ammonoids are more distinctively ornamented, and Jurassic ammonoids in general are larger than their predecessors. Later varieties demonstrated regressive shell form, tending toward uncoiling and linear types. Only one group of nautiloid cephalopods survived the Late Triassic extinctions. Coleoid cephalopods—those lacking external skeletons like the belemnoids (or belemnites), are represented in the Jurassic fossil record by abundant mineralized phragmocones (conical internal shells).

Arthropods, mainly the tiny aquatic crustaceans of the subclass Ostracoda, figure prominently in the stratigraphic zonation of the Jurassic. Decapods, crabs, and the first lobsters, which appear in the Upper Jurassic of Europe, are found in Jurassic benthic communities. The modern king crab Xiphosura, commonly called the horseshoe crab, also originated in the Jurassic. Isopods and insects constitute the terrestrial forms. Some insect groups that are represented in the fossil record of the period include the Odonata (dragonflies), Coleoptera (beetles), Neuroptera (lacewings), Diptera (flies), and Hymenoptera (bees, ants, and wasps).

Prominent Jurassic echinoids include both stalked and unstalked varieties of pelmatozoans, such as the crinoids and the free-moving echinoids (sea urchins) and stelleroids. The Mesozoic crinoids are principally in the subclass Articulata, which arose in the Triassic. Stem-bearing forms of this group include *Isocrinus* and *Pentacrinites*. Holothuroid (sea cucumber) impressions and spicules, which take the form of wheels, crosses, and hooks, have been found in the Lias of Germany. *Ophioglypha* is a representative genus of Jurassic sea stars, while *Plesiocidaris* constitutes a representative fossil form of the so-called regular echinoids (those with radially symmetrical bodies). Irregular echinoids (those with bilaterally symmetrical bodies) first appeared in the Jurassic and include *Clypeus*, a European variety.

Zonation

Correlation between European and North American Jurassic strata has been facilitated through biostratigraphic zonations using primarily ammonoid index fossils. The ammonoid zones (Table 19), supplemented by other invertebrate and protozoan index fossils, have been used to identify the stages of the Jurassic rocks found throughout the western interior of North America, as well as in Alaska, Mexico, and Cuba.

Lower to Middle Jurassic ammonoid assemblages that indicate Toarcian and Bajocian ages are characterized by *Sonninia* and *Tmetoceras* and are found in the Kialagvik and Tuxedni formations in Alaska. *Defonticeras* and *Stemmatoceras* occur in the Twin Creek Limestone of Bajocian age in Wyoming, and *Arnioceras* dates the Barranca Formation of the Mexican Sonora as Lias (Early Jurassic) in age.

The macrocephalitid ammonite *Arcticoceras*, which marks the Callovian Stage in Greenland, is found in the Curtis Formation of Utah, the Rierdon Formation of Montana, and the Sundance and Carmel formations of Wyoming. *Arcticoceras* and *Gowericeras* occur in the Lower Callovian in the northern interior of North America, as well as in the Lower Sundance Formation of Wyoming. The *Cadoceras* fauna identifies the Shelikof Formation and the Chinitna Siltstone in Alaska as Callovian, which is the equivalent of the *Proplanuites* to *Erymoceras* zones in Europe. *Cardioceras* and its associated fauna signify the Oxfordian in both Europe and North America; *C. cardiforme* marks the lower Oxfordian, as, for example, in the Stump Sandstone and the Upper Sundance Formation of Utah and Wyoming. *Cardioceras*, together with *Goliathiceras* and *Pachycardioceras*, represent the Late Oxfordian in the Swift Formation of Montana and the Jagua Formation of Cuba. *Phylloceras* and other related ammonites form a zonal equivalent to the Oxfordian *Peltoceras* zone of central Europe. In the Gulf Coast of the United States, the Smackover Formation contains *Dichotomosphinctes* and an associated fauna considered to be Late Oxfordian in age; *Amoeboceras* in the Mariposa Slate in the Sierra Nevada range indicates an Oxfordian to Early Kimmeridgian age; and the presence of *Cardioceras*, along with *Amoeboceras*, in the Naknek Formation in the Cook Inlet area of Alaska suggests that it is of Oxfordian age.

In central and southern Mexico, ammonite zones show the presence of stages between the Bathonian and the Portlandian. Marls of Bathonian age are identified by a *Strenoceras* assemblage. The occurrence of *Idoceras* in the Zuloaga Limestone in southern Mexico and the Olvido Formation in the Sierra Madre Oriental, on the other hand, points to an Oxfordian origin. The Tamán Formation is shown to be Kimmeridgian through a *Haploceras* and *Aspidoceras* assemblage, and the Pimienta Formation is Portlandian, based on the *Parodontoceras* fauna. In the Alaskan Range, Oxfordian to Kimmeridgian beds contain *Aucella*, and Kimmeridgian to Portlandian rocks have *Aucella*, along with *Amoeboceras*. A similar fauna is found in the Kupreanof and Gravina islands in the Alaskan panhandle and in the Kingak Shale in the Canning River area of the Arctic slope.

Vertebrates. Chondrichthyes, mainly sharks, and Osteichthyes, the bony fish, including teleosts, ray-finned fish (or actinopterygians), and holosts (or ganoid fish), were the principal vertebrate swimmers of the Jurassic seas. The teleosts developed ossified vertebrae at this time and showed considerable change in bone structure, fins, and tail. The teleosts are the predecessors of the most prevalent modern fish. Early amphibian groups, such as the labyrinthodonts, became extinct by the Late Triassic and were succeeded by the first Anura (frogs and toads) and salamanders in the Jurassic.

The dominant land animals of the Jurassic were reptiles, the most significant of which belonged to the superorder known as Archosauria. The archosaurs included the thecodonts of the Triassic from which the dinosaurs descended, as well as the crocodiles and pterosaurs (flying reptiles).

The dinosaurs are divided into two principal groups on the basis of pelvic and hip structure: the saurischians and the ornithischians. The pelvis and hip of saurischians were reptilian (or lizardlike), whereas those of the ornithischians were birdlike. The sauropods, one of the basic types of saurischians, appeared in the Early Jurassic and became abundant in the Late Jurassic. They included both carnivorous and herbivorous forms. The latter were among the largest of the dinosaurs, with certain varieties reaching up to 30 metres in length. These gigantic vegetarians included the genera *Apatosaurus, Brachiosaurus,* and *Diplodocus.* (The *Apatosaurus* was long referred to as "Brontosaurus," which was in actuality a form created by workers who inadvertently placed the wrong skull on the body of an *Apatosaurus.*) Another basic saurischian type was the meat-eating theropod, an early representative of which was *Epanteria.* This genus was succeeded by *Tyrannosaurus* and the smaller *Allosaurus.* The apatosaurs presumably could fend off the allosaurs but not the other larger carnivores. The theropods were all bipedal; they had powerful hind legs and shortened forelegs with sharp claws.

The ornithopods, the first major suborder of ornithischians, appeared in the Late Jurassic and were much smaller, ostrichlike forms with large brains. They included the hadrosaurs and the anatosaurs, the bipedal duckbill forms formerly known as trachodons. The anatosaurs were hollow-boned and probably warm-blooded and may have been the ancestors of the birds. It is thought that other dinosaur groups may also have been warm-blooded.

Armoured dinosaurs emerged during the Jurassic. One notable variety that roamed North America during the Middle Jurassic was the stegosaur, a relatively large ornithischian type characterized by a double row of vertical bony plates along the dorsal midline and a spiked tail. (For a detailed treatment of the dinosaurs, see the article DINOSAURS.)

The reptiles of the Jurassic had diverse habitats. The plesiosaurs, with paddle-shaped limbs and generally long necks, shared the seas with the ichthyosaurs, highly specialized marine reptiles that have often been likened to such fast-swimming modern fish as tuna and marlin. Two other reptile groups, the crocodiles and marine turtles, are also known from the Early Jurassic, while the lizard made its appearance during Late Jurassic time. The pteropods, airborne flyers or perhaps gliders, were common throughout the Jurassic. The Jurassic pteropods were very small, comparable in size to sparrows and somewhat larger birds. They had hollow bones and were thought to be warm-blooded.

Early birds and mammals

Birds evolved in the Late Jurassic and closely resembled some small dinosaurs. Fossils of the first bird, the crow-sized *Archaeopteryx,* were found in the lithographic limestones at Solenhofen in Germany. This bird was very reptilian in appearance, having teeth, a vertebrae-supported tail, three claws at the wing tips, and scales. The specimens, however, have feathers. By Jurassic time, six orders of mammals—mainly small, shrewlike creatures—existed. Multituberculates, pantotheres, and triconodont mammals were important stock from which later forms developed. These early mammals have been classified on the basis of tooth morphology and were probably omnivorous in diet.

Plants. Jurassic plant communities differed considerably from their predecessors. The seed-fern floras of the early Mesozoic, like the *Glossopteris* flora of Gondwana, declined in importance. The cycads and cycadeoides, the palmlike gymnosperms, proliferated to the extent that the Jurassic has been called the "Age of Cycads." Another variety of gymnosperms, the conifers, made up a large component of Jurassic forests. These included araucarian pines, such as the Norfolk pine that exists today in the South Pacific. The ginkgo, a fruit-bearing gymnosperm, also was widespread during the Jurassic. It has been debated whether or not angiosperms, the flowering plants, evolved as early as the Jurassic; however, pollen of monocotyledonous angiosperms and palm stems have been reported in rocks of Jurassic age. (L.Si.)

CRETACEOUS PERIOD

General considerations. The Cretaceous, the third and final period of the Mesozoic Era, began about 144 million years ago and ended 66.4 million years ago (see Table 4). Spanning more than 77 million years, the Cretaceous is the longest of all the Phanerozoic periods; it represents more time than has elapsed since the last dinosaurs roamed the Earth. The rocks that were either deposited or formed during the Cretaceous Period make up the Cretaceous System.

The name Cretaceous is derived from *Creta,* the Latin word for chalk, and was first proposed by J.B.J. Omalius d'Halloy in 1822. D'Halloy had been commissioned to make a geologic map of France, and part of his task was to decide upon the geologic units to be represented by it. One of his rock units, the Terrain Crétacé, included chalks and underlying sands. Chalk is a soft, fine-grained type of limestone composed predominantly of the armour-like plates of planktonic coccolithophores, floating algae that flourished during the Late Cretaceous. Most Cretaceous rocks are not chalks, but most chalks were deposited during the Cretaceous.

Major subdivisions. The Cretaceous Period is divided into two nearly equal epochs, the Early Cretaceous and the Late Cretaceous. Each of these epochs is subdivided into six ages of quite variable duration, as shown in Table 20. The longest age, the Albian, lasted some 15.5 million years, more then 15 times the Coniacian, which lasted a mere 1 million years.

Stages

The definition of these Cretaceous ages was initiated during the mid- to late 1800s, when geologists working in France, Belgium, The Netherlands, and Switzerland recognized and named the 12 Cretaceous stages. The unit of time, age, is measured from the beginning of a given stage to the beginning of the succeeding stage. Each of the stages was defined by the rocks, sediments, and fossils at a particular locality. For example, A.D. d'Orbigny defined and described the Cenomanian Stage in 1847, based on some 847 species characteristic of the strata, and confirmed Le Mans, Fr., as the type area. The Cenomanian Age is defined on the basis of the rocks, sediments, and fossils in the type area for the Cenomanian Stage.

A type area is not always the best place to define a stage. The type area for the Coniacian Stage, for example, is in the environs of Cognac, Fr., but there the boundary with the underlying Turonian is marked by a discontinuity, and one stratigraphically important fossil group, the inoceramid bivalves, is poorly represented. These conditions make correlation of the base of the Coniacian Stage difficult at sites away from the type area.

Since the inception of the 12 Cretaceous stages, geologists have worked to solve such problems caused by incompleteness of the stratigraphic record and fossils of poor biostratigraphic utility in type areas. It is now customary to define the base of one stage and to consider that stage as continuing until the beginning of the next younger stage. Researchers meet periodically to discuss problems of stage boundaries and to suggest solutions. In 1983 a group of geologists from around the world met in Copenhagen and suggested that alternative type areas be designated for all the 11 stage boundaries discussed. Further, they suggested that the overly long Albian Stage be divided into three substages: the Lower, Middle, and Upper Albian. It was agreed at that symposium that stages are "packages of zones" and that the most sensible way to define a stage is by the base of the earliest biozone at a boundary type area. Traditionally, ammonites have been used to define biozones within the type area of Cretaceous stages, but other animals, such as inoceramid bivalves, belemnites, and even calpionellids, are sometimes used.

The number of usable biozones for the Cretaceous varies from area to area. For example, about 25 ammonite zones are employed in the type areas of western Europe for the whole of the Cretaceous, but at least 55 are recognized in the Upper Cretaceous alone for the western interior of North America.

The mid-Cretaceous is an informal subdivision of the Cretaceous and is usually taken to mean the Aptian, Albian, Cenomanian, Turonian, and Coniacian ages. A project called "Mid-Cretaceous Events" was undertaken from 1974 to 1985 and focused the efforts of several hundred geologists on that particular period of time. These investigators were particularly interested in the his-

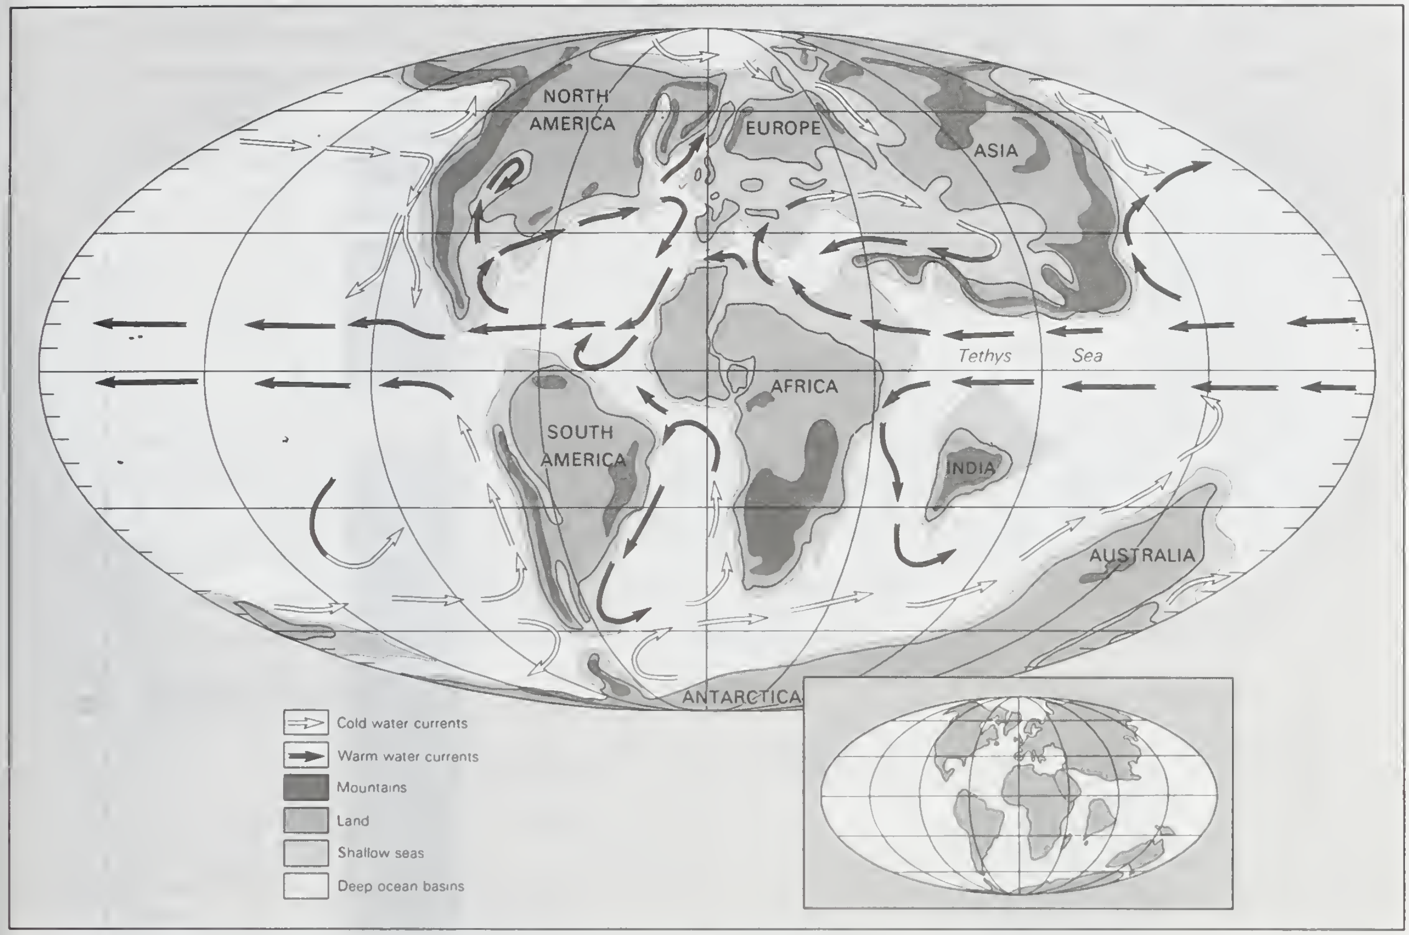

Figure 37: Distribution of landmasses, mountainous regions, shallow seas, and deep ocean basins during Late Cretaceous time. Included in the paleogeographic reconstruction are cold and warm ocean currents. The present-day coastlines and tectonic boundaries of the configured continents are shown in the inset at the lower right.

tory of major transgressions and regressions, the geologic evolution of the South Atlantic Ocean, "oxygen-deficient sedimentational processes" (mostly those associated with black shales), and biological issues, such as evolutionary sequences, biogeography, and paleoecology. Much of the information that follows is derived from the findings of this project and its participants.

Time of transition

Distinctive features. The Cretaceous Period has many distinctive features, partly because of its long duration and partly because it is a major part of the period of transition between the very different earlier Earth and the Cenozoic, a world relatively similar to that of the present day in terms of life-forms and the positions of continents. In addition, the Cretaceous is young enough so that many of the rocks which contain details about the period have not been deformed or eroded and are relatively close to the surface.

The Cretaceous opened with the landmasses assembled essentially into two continents, Laurasia in the north and Gondwana in the south, nearly separated by the equatorial Tethys seaway. (As was noted elsewhere, the various segments of Laurasia and Gondwana had already started to rift apart by this time. North America had just begun pulling away from Eurasia during the Jurassic, and South America had started to split off from Africa, from which India, Australia, and Antarctica were also in the process of separating.) The period closed with most of the present-day continents separated from each other by such expanses of water as the North Atlantic and South Atlantic. At the end of the Cretaceous, India was adrift in the Indian Ocean, and Australia was still connected to Antarctica. Figure 37 shows the positions of the landmasses for the Maastrichtian, about 4 million years before the close of the period.

Sea level was high throughout much of the Cretaceous Period. At its maximum height, only about 18 percent of the Earth's surface remained uncovered by water, as compared to approximately 28 percent today. At times, Arctic waters were connected to the Tethys seaway through the middle of North America and the central portion of Russia. Marine animals living in the South Atlantic had a seaway for migration to the Tethys via what is presently Nigeria, Niger, Chad, and Libya on several occasions during the Cretaceous. Most of western Europe, eastern Australia, parts of Africa, South America, India, Madagascar, Borneo, and certain other areas that are now land were entirely covered by marine waters for some interval of Cretaceous time.

Water circulation and mixing was not as great as it is today because most of the oceans (*e.g.*, the developing North Atlantic) were constricted, and the temperature differences between the poles and the equator were minimal. Thus the oceans experienced frequent periods of anoxic bottom water that reveal themselves today as black shales. Sometimes, particularly during the mid-Cretaceous, oxygen-deficient conditions extended to the waters covering the present-day land areas, the so-called epicontinental seas, as attested to by the black shales in the western interior of North America.

The Late Cretaceous was a time of great productivity in the world's oceans, as borne out by the deposition of thick beds of chalk in western Europe, eastern Russia, southern Scandinavia, the Gulf Coast of North America, and Western Australia.

The Cretaceous was magnetically quiet relative to the subsequent Tertiary Period. In fact, magnetic reversals are not noted from the early Aptian to the late Santonian, a period of some 34 million years. Table 20 shows the Cre-

Table 20: Stratigraphic Subdivisions of the Cretaceous Period*

taceous magnetic reversals. The Earth's synodic months have changed regularly for at least the last 600 million years owing to tidal friction and other forces that slow up the Earth's rotation. The rate of change in the synodic month was minimal for most of the Cretaceous but has accelerated since. The reasons for these two anomalies are not well understood.

Major oil deposits

Economic significance. In approximately 30 million years during the middle of the Cretaceous, more than 50 percent of the world's known petroleum reserves were formed. Almost three-fourths of this mid-Cretaceous petroleum accumulated in a relatively small region around the Persian Gulf. Much of the remainder accumulated in another limited region of the Americas between the Gulf of Mexico and Venezuela. Evidently the low-latitude Tethys seaway collected large amounts of organic matter along its margins, which today is found as petroleum in the Gulf Coast of the United States and Mexico, the Maracaibo Basin in Venezuela, the Surt (or Sirte) Basin in Libya, and the Persian Gulf region.

Other mineral deposits of commercial value occur in the circum-Pacific mountain systems and chain of island arcs. Such metals as gold, silver, copper, lead, zinc, molybdenum, tungsten, tin, iron, and manganese were concentrated into ore deposits of various dimensions during episodes of igneous activity in the late Mesozoic.

Cretaceous rocks. *Occurrence and distribution.* The occurrence and distribution of Cretaceous rocks resulted from the interplay of many forces. The most important of these are the position of the continental landmasses, level of the sea relative to these landmasses, local tectonic and orogenic activity, climatic conditions, availability of source material (for example, sands, clays, and even the remains of marine animals and plants), igneous activity, and the history of the rocks and sediments after intrusion or deposition. Many Cretaceous sedimentary rocks

have been eroded since their deposition, while others are merely covered by younger sediments or are presently underwater or both.

Figure 37 shows the position of the present-day continental landmasses during the Maastrichtian approximately 70 million years ago. At the very beginning of the Mesozoic these landmasses had been together. As was mentioned earlier, South America, Africa (including the adjoining pieces of what are now the Arabian Peninsula and Middle East), Antarctica, Australia, India, Madagascar, and several smaller landmasses were joined as Gondwana in the south, while North America, Greenland, and Eurasia (including Southeast Asia) formed Laurasia in the north. The breakup of the supercontinent of Pangaea, which had started more than 100 million years earlier during the Early Jurassic, showed major developments in the Cretaceous. Africa split from South America, the last land connection being that between Brazil and Nigeria. This separation was complete by about Aptian–Albian time, resulting in the joining of the South Atlantic Ocean with the widening North Atlantic. In the region of the Indian Ocean, Africa and Madagascar separated from India, Australia, and Antarctica in Late Jurassic to Early Cretaceous times. Once separated from Australia and Antarctica, India began its journey northward, which culminated in a collision with Eurasia during the Cenozoic (see below the section *Cenozoic Era*). Madagascar broke away from Africa during the later Cretaceous. During the Late Cretaceous, Greenland separated from North America. A graphic example of the influence of continental fragmentation on the Cretaceous rock record can be seen in the stratigraphic column for southeastern Nigeria in Table 20. The stratigraphic record begins in the Albian only after the South Atlantic opened.

High sea levels

Sea level was higher during most of the Cretaceous than at any other time in Earth history. In general, the world oceans were about 100 to 200 metres higher in the Early Cretaceous and roughly 200 to 250 metres higher in the Late Cretaceous than at present. The high Cretaceous sea level is thought to have been primarily the result of water in the ocean basins being displaced by the enlargement of the mid-oceanic ridges. Table 20 gives the overall trend in sea level, but minor peaks and troughs are known to have occurred. The rocks shown in the Table illustrate well the effect of the high Cretaceous sea level. Chalks and limestones, for example, were deposited in the western interior of North America only during the early Late Cretaceous, when sea levels were at their highest.

As a result of higher sea levels during the Late Cretaceous, marine waters inundated the continents, creating relatively shallow epicontinental seas in North America, South America, Europe, Russia, Africa, and Australia. In addition, all continents experienced diminution of land area adjacent to the major oceans.

The effects of these higher sea levels were not felt to the same extent by each continent, because the various continents experience movement of their crustal level due to isostasy and tectonism. For example, if a continent is emergent due to isostatic rebound, the vertical movement could exceed the rise in sea level and so the continent would not experience transgression of marine water but rather regression. Table 21 shows the records of transgression and regression during the Cretaceous Period in selected platforms of the world. When a platform is underwater, sedimentation occurs; when it is not, erosion takes place. The rock record for the Great Artesian Basin in east-central Australia (see Table 20), for instance, shows marine rocks for much of the Aptian–Albian but nonmarine sediments during the Cretaceous maximum transgression near the end of the Cenomanian.

A comparison of the rock record for the North American western interior with that for eastern England (see Table 20) reveals chalk deposition in eastern England from Cenomanian to Maastrichtian time, but chalks and marine limestone are limited to late Cenomanian through early Santonian time in North America. The two areas have nearly identical histories of transgression, as indicated in Table 21. It has been noted that the land areas of western Europe during the Late Cretaceous were limited to a few stable regions that represent low-lying islands within a chalk sea. Furthermore, sedimentological evidence indicates an arid climate that would minimize erosion of these islands and limit the input of sands and clays into the basin. In contrast, the North American western interior was receiving abundant clastic sediments that were being eroded from the new mountains along its western margin created by the Sevier orogeny of Cretaceous time.

In addition to the areas that have been mentioned above, Cretaceous rocks crop out in the Arctic, Greenland, central California, the Gulf and Atlantic coastal plains of the United States, central and southern Mexico, and the Caribbean islands of Jamaica, Puerto Rico, Cuba, and Hispaniola. In Central and South America, Cretaceous rocks are found in Panama, Venezuela, Colombia, Ecuador, Peru, eastern and northeastern Brazil, and central and southern Argentina. Most European countries have Cretaceous rocks exposed at the surface. North Africa, West Africa, coastal South Africa, Madagascar, Arabia, Iran, and the Caucasus all have extensive Cretaceous outcrops, as do eastern Siberia, Tibet, India, China, Japan, Southeast Asia, New Guinea, Borneo, Australia, New Zealand, and Antarctica.

Types. The rocks and sediments of the Cretaceous System show considerable variation in their lithologic character and the thickness of their sequences. Mountain-building episodes accompanied by volcanism and plutonic intrusion took place in the circum-Pacific region and in the area of the present-day Alps. The erosion of these mountains produced clastic sediments, such as conglomerates, sandstones, and shales, on their flanks. The igneous rocks of Cretaceous age in the circum-Pacific area are widely exposed.

The Cretaceous Period was a time of great inundation by shallow seas that created swamp conditions favourable for the accumulation of fossil fuels at the margin of land areas. Coal-bearing strata are found in some parts of Cretaceous sequences in Siberia, Australia, New Zealand, Mexico, and the western United States.

Farther offshore, chalks are widely distributed in the Late Cretaceous. Another rock type called the "Urgonian" limestone is similarly widespread in the Upper Barremian–Lower Aptian. This massive limestone facies, whose name is commonly associated with rudists (a reef-building bivalve of the Mesozoic), is found in Mexico, Spain, southern France, Switzerland, Bulgaria, the southern Soviet Union, and North Africa.

Formation of black shales

The mid-Cretaceous was a time of extensive deposition of carbon-rich shale with few or no benthic fossils. These so-called black shales result when there is severe deficiency of oxygen in the bottom waters of the oceans. Poor ocean circulation is suggested as the cause, and the poor circulation is thought to have resulted from the generally warmer climate that prevailed during the Cretaceous, the much smaller than present temperature difference between the poles and the equator, and the restriction of the North Atlantic, South Atlantic, and Tethys. Cretaceous black shales are extensively distributed on various continental areas, such as the western interior of North America, the Alps, the Apennines of Italy, western South America, Western Australia, western Africa, and southern Greenland. They also occur in the Atlantic Ocean, as revealed by the Deep Sea Drilling Program (a scientific program initiated in 1968 to study the ocean bottom), and in the Pacific, as noted on several seamounts.

In North America the Nevadan orogeny took place in the Sierra Nevada and Klamath Mountains from Late Jurassic to Early Cretaceous times; the Sevier orogeny produced mountains in Utah and Idaho in the mid-Cretaceous; and the Laramide orogeny, with its thrust faulting, gave rise to the Rocky Mountains and Sierra Madre Oriental during the Late Cretaceous to Early Tertiary. In the South American Andean system, mountain building reached its climax in mid-Late Cretaceous. In Japan the Sakawa orogeny proceeded through a number of phases during the Cretaceous.

In typical examples of circum-Pacific orogenic systems, regional metamorphism of the high-temperature type and large-scale granitic emplacement occurred on the inner continental side, whereas sinking, rapid sedimentation, and regional metamorphism predominated on the outer oceanic side. The intrusion of granitic rocks, accompanied in some areas by extrusion of volcanic rocks, had a profound effect on geologic history. This is exemplified by the upheaval of the Sierra Nevada, with the intermittent emplacement of granitic bodies and the deposition of thick units of Cretaceous shales and sandstones with many conglomerate tongues in the Great Valley of California.

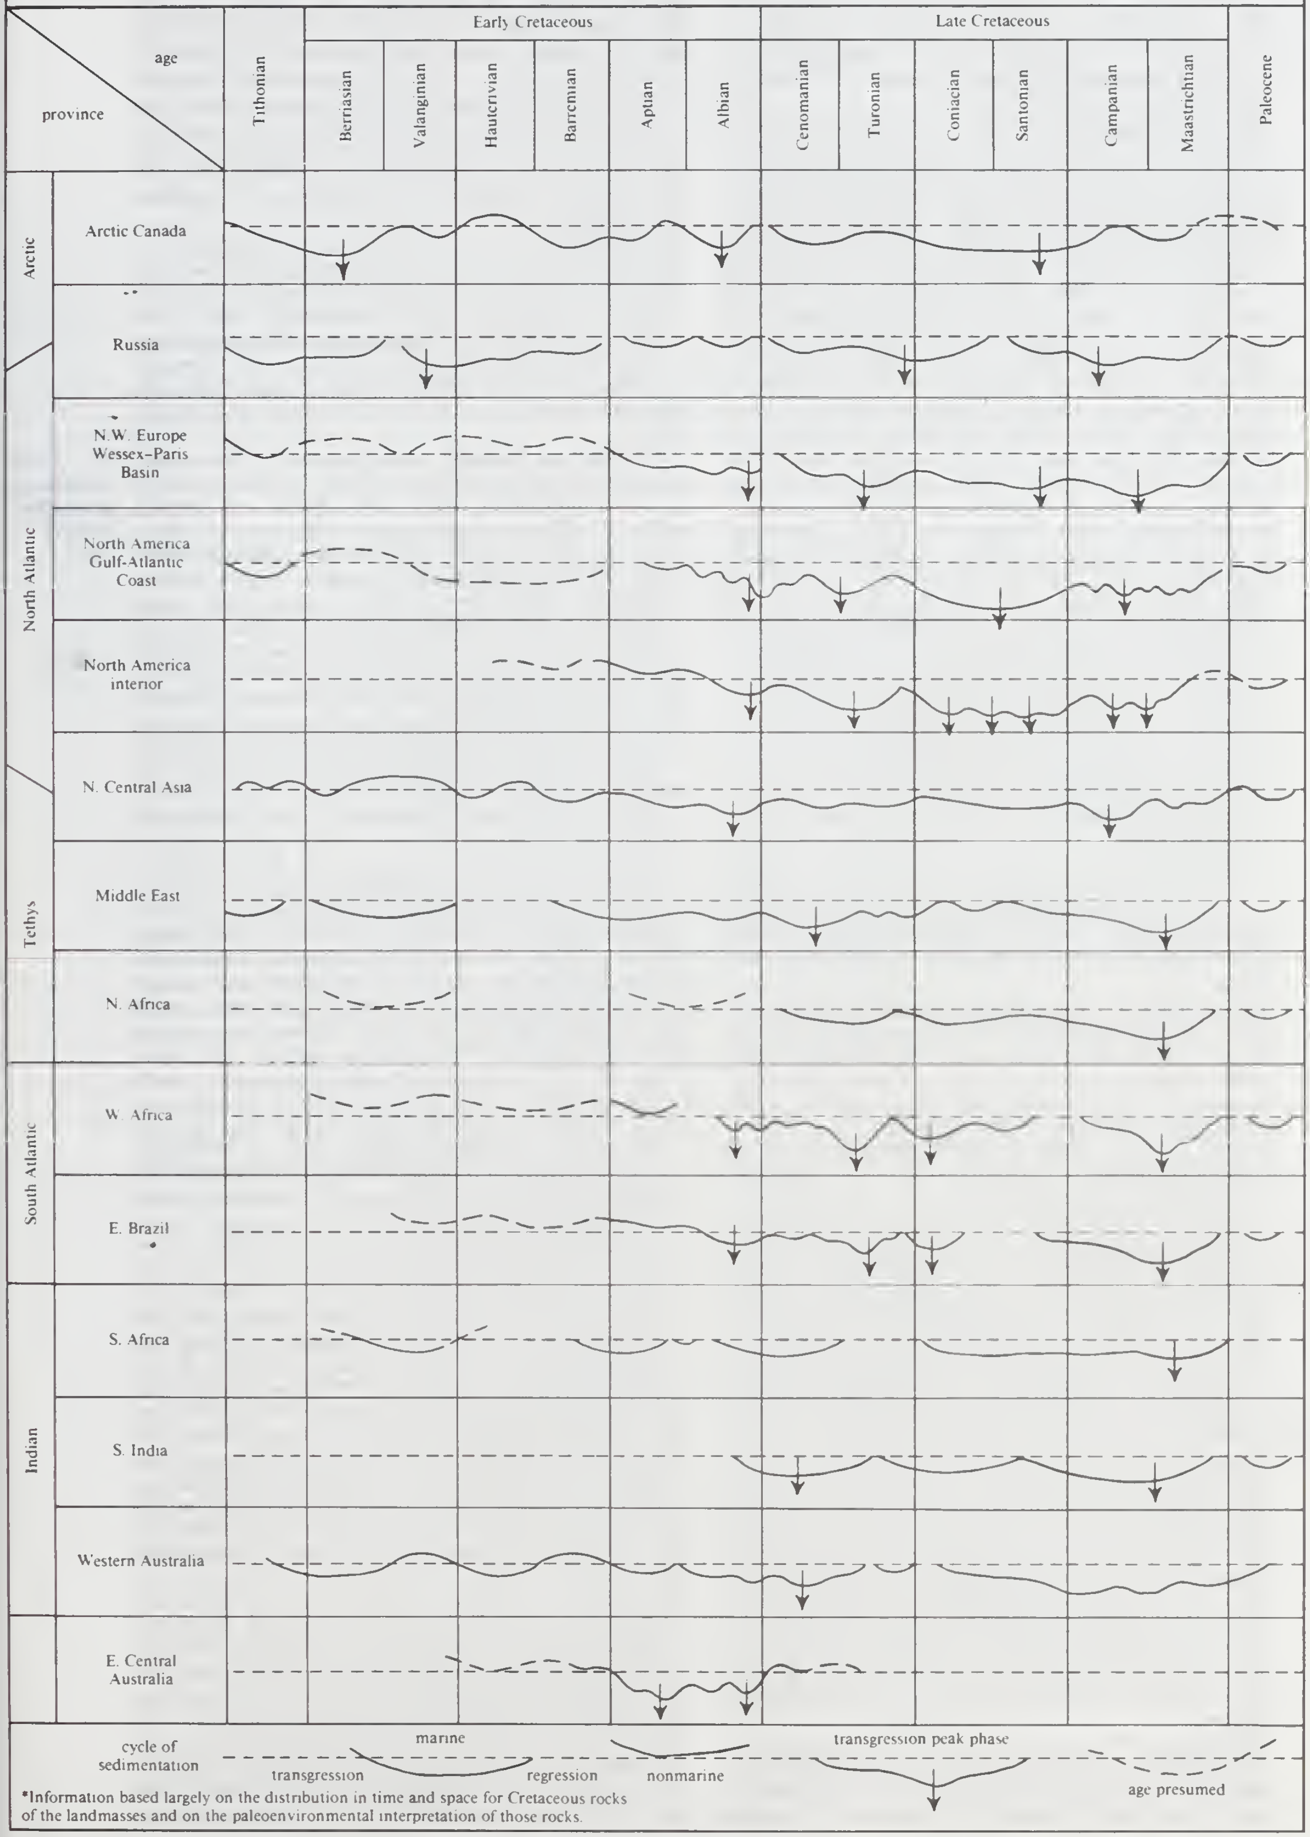
Volcanic seamounts of basaltic rock with summit depths of 1,300 to 2,100 metres are found in the central and western Pacific. Some of them are flat-topped, with shelves on their flanks on which reef deposits or gravels accumulated, indicating a shallow-water environment. Some of the deposits contain recognizable Cretaceous fossils. Although the seamounts were formed at various times during the late Mesozoic and Cenozoic eras, a large number of them were submarine volcanoes that built up to the sea surface during the Cretaceous. They sank to their present deep levels some time after the age indicated by their youngest shallow-water fossil.

In west-central India, the Deccan traps consist of more than 1,200 metres of basaltic lava flows that erupted from the Late Cretaceous to the Eocene Epoch of the Tertiary over an area of some 500,000 square kilometres. Volcanic activity on the western margin of the North American epicontinental sea frequently produced ashfalls over much of the western interior seaways. One of these, the "X" bentonite near the end of the Cenomanian, can be traced more than 2,000 kilometres from central Manitoba to north Texas.

Ammonite index fossils

Correlation. Correlation of Cretaceous rocks is usually accomplished using fossils. Ammonites are the most widely employed fossils in terms of both frequency of use and geographic extent, but no single fossil group is capable of worldwide correlation of all sedimentary rocks. Most

Table 21: Cretaceous Record for Transgressions and Regressions of Marine Waters onto Selected Landmasses*



*Information based largely on the distribution in time and space for Cretaceous rocks of the landmasses and on the paleoenvironmental interpretation of those rocks.

ammonites, for example, did not occur in all latitudes because some preferred the warmer waters of the Tethys seaway, while others resided in cooler boreal waters. Furthermore, ammonites are rarely found in sediments deposited in nonmarine and brackish environments, and they are seldom retrieved from boreholes sufficiently intact for confident identification.

Many ammonites are very good index fossils, but they are not perfect. When Cretaceous stage boundaries were proposed by the above-mentioned international group of geologists in Copenhagen in 1983, the problems of correlating the boundary between the Campanian Stage and the underlying Santonian were examined. The ammonite *Placenticeras bidorsatum,* the index species to the oldest Campanian zone of the "classic" zonation, is extremely rare in the type area of western France and appears to be restricted to northwestern Europe. Other ammonites discussed as possible alternatives were *Submortaniceras,* a genus known from Spain, the Natal province of South Africa, Madagascar, Mexico, and the Gulf and Pacific coasts of the United States and British Columbia but not from the type area, and the *Scaphites hippocrepis,* a species described from North America. In Europe, *Scaphites aquisgranensis,* a late form of *S. hippocrepis,* occurs together with *P. bidorsatum.* This *S. hippocrepis* form occurs widely in the Gulf and Atlantic coastal plains of North America, western Germany, Belgium, and The Netherlands, as well as in the North American western interior and the Aquitane basin of France. The belemnite species *Gonioteuthis granulataquadrata* is widely used in western Germany for definition of the boundary, but it has a restricted boreal distribution (see below *Cretaceous environment*). The extinction level of the free-living crinoid *Marsupites testudinarius,* the appearance of the coccolith *Aspidolithus parcus,* and the first occurrence of the foraminiferans *Bolivinoides strigillatus* and *Globotruncana arca* are all used to define the boundary in some regions but not in others.

It was generally agreed that a boundary level close to the currently used appearance of the belemnite species *G. granulataquadrata* in the boreal realm—*i.e.,* temperate paleobiogeographic region—would be desirable because this boundary could be correlated with a number of other events.

It is desirable to have a reference section for the boundaries of all Cretaceous stages, and the Campanian example above serves to illustrate the variety of fossil groups used to define boundaries and the complexity of the definition problem. The boundaries of the other stages have similar problems of restricted distribution for fossils in the classic type areas. Other fossil types useful for defining Cretaceous stage boundaries are inoceramid bivalves, echinoids, larger foraminiferans, and calpionellids.

On a more local scale, correlation can be achieved using a variety of fossil groups. Rudist, inoceramid, and exogyrid bivalves have been used in many areas to subdivide or zone the Cretaceous Period for the purpose of correlation. Rudist bivalves, for example, have been employed in conjunction with larger foraminiferans to zone sediments of the Tethyan regions of France and Yugoslavia. Echinoids and belemnites have been used together to zone the Late Cretaceous of eastern England. Angiosperm pollen provides for recognition of zones for the Late Cretaceous of the North American Atlantic Coastal Plain.

Use of angiosperm pollen

Some fossil groups are useful for correlation between several regions because of their nektonic or planktonic life habit. Principal among these are ammonites, belemnites, planktonic foraminiferans, calcareous nannofossils, and radiolarians. In North America, for instance, Late Cretaceous strata in Texas, Arkansas, Mexico, and the Caribbean have been correlated using planktonic foraminiferans. Occasionally ostracods (small bivalved crustaceans) are useful; *e.g.,* they have been used to correlate Early Cretaceous strata of northwestern Europe with those of the Russian Platform.

The epicontinental sea of the North American western interior has been particularly well studied, primarily because it can be zoned to great precision. Sixty ammonite zones, to cite a case in point, are recognized in the rocks deposited between the late Albian and the late Maastrichtian. In addition, frequent bentonite beds resulting from the volcanic ash of the Sevier orogenic events provide radiometric dates with which to independently verify the synchronicity of the ammonite zones. This detailed resolution of about 0.5 million years per zone is unusual for the Cretaceous Period. Interestingly, the youngest Cretaceous biozone of the North American western interior is recognized regionally by the occurrence of the dinosaur genus *Triceratops,* because the last approximately one million years in that area are characterized by nonmarine sediments.

For some of the geologic record, more detailed subdivisions within zones can be developed on the basis of magnetic reversals. The Cretaceous Period, however, has a dearth of magnetic reversals. Specifically, only 16 reversals are noted for latest Jurassic to Aptian time, none for Aptian to late Santonian time, and just 9 from the late Santonian to the Cenozoic boundary (see Table 20). Magnetic reversals occur far more frequently in Cenozoic rocks.

Cretaceous environment. *Paleogeography.* The major geographic subdivisions of the world for the Cretaceous Period are the northern boreal, southern boreal, and Tethyan regions. The Tethyan region separates the other two and is recognized by the presence of reef-forming rudist bivalves, corals, larger foraminiferans, and certain ammonites that inhabited only the warmer Tethyan waters. Early in the Cretaceous, North America and South America separated sufficiently for the marine connection between the Tethys and Pacific to deepen substantially. The Tethys to Pacific marine connection allowed for a strong westward-flowing current, which is inferred from faunal patterns. For example, as the Cretaceous progressed, the similarity between rudist bivalves of the Caribbean and western Europe decreased, while some Caribbean forms have been found on Pacific seamounts, in Southeast Asia, and possibly in the Balkans.

Cretaceous geographic subdivisions

The Cretaceous of the northern boreal realm in North America, Europe, Russia, and Japan has been extensively studied because of many years of geologic research and the generally wealthier political entities that exist in those areas. It is known, for instance, that sediments in the southwestern Netherlands indicate several temperature swings for the Late Cretaceous. These temperature swings imply that the paleogeographic boundary between the northern boreal areas and the Tethys was not constant with time. Russian workers recognized six paleobiogeographic zones: boreal, which in this situation is equivalent to Arctic; European region; Mediterranean region, including the central Asian province; Pacific region; and two paleofloristic zonations of land. At present, studies of the southern boreal areas and the rocks representing the southern Tethys margin lack this level of detail.

As pointed out earlier, the positions of the landmasses changed significantly during the Cretaceous. This is not unexpected considering that the period lasted more than 77 million years. At the onset there existed the two supercontinents of Gondwana and Laurasia, which were barely attached at the junction of North and South America. When these enormous landmasses divided, the South Atlantic Ocean, Indian Ocean, Gulf of Mexico, and Caribbean came into being. By the end of the Cretaceous, the present-day continents were separate entities except for Australia, which was still joined to Antarctica. Also, India had not yet fused to Asia. The positions of the various continents were very nearly those shown in Figure 37 for the Maastrichtian shortly before the close of the Cretaceous.

Very high sea stand was a major factor influencing the paleogeography of the Cretaceous. In general, the maximum was lower in the Early Cretaceous than in the Late Cretaceous, but detailed study indicates from 5 to 15 different episodes of rises and falls in sea level. The high sea stands were not expressed equally in all regions.

Some regions were especially tectonically active during the Cretaceous. The Pacific margin of Canada, for one, shows evidence of an Early Cretaceous transgression, but by the Late Cretaceous much of the region had been uplifted some 800 to 2,000 metres. Japan also was very tectonically active, giving it a Cretaceous sedimentary record that varies from north to south, island to island, and time to time.

The history of sea-level change for the stable platforms is summarized in Table 21. Although the patterns are quite similar for many of the platform areas, several differences are notable. During the Berriasian, Valanginian, Hauterivian, and Barremian, parts of Arctic Canada, Russia, and Western Australia were underwater, but most of the other platforms were not. During the Aptian and Albian, east-central Australia experienced major transgressions, but those of the Late Cretaceous are not recorded there.

In the Late Cretaceous, most continental landmasses were transgressed but not always at the same time. One suggestion for the lack of a synchronous record is the concept of geoidal eustacy. It has been suggested based on observed patterns of Cretaceous rocks and physical calculations that, as the Earth's continents move about, the oceans bulge out at some places to compensate, and thus sea level rise is different from ocean basin to ocean basin.

Warm climatic conditions

Paleoclimate. In general, the climate of the Cretaceous Period was much warmer than at present, perhaps the warmest on a worldwide basis than at any other time during the Phanerozoic. The climate was also more equable in that the temperature difference from the poles to the equator was about one-half the present gradient. Floral evidence suggests that tropical to subtropical conditions existed as far north as 45°, and temperate conditions extended to the poles.

Temperatures were lower at the beginning of the period, rising to a maximum in the late Albian and then declining slightly with time until the decline was accentuated during the Campanian and Maastrichtian. Ice sheets and glaciers were almost entirely absent except in the high mountains. The late Maastrichtian was the coolest part of the Cretaceous, but the temperature was still much warmer than it is today.

Models of the Earth's climate for the mid-Cretaceous based on the positions of the continents, location of water bodies, and topography suggest that winds were weaker than at present. Westerly winds were dominant in the lower to mid-latitudes of the Pacific for the entire year. Winds were, however, westerly in the North Atlantic during winter but easterly during summer. Surface water temperatures were about 30° C at the equator year round, but 14° C in winter and 17° C in summer at the poles. A temperature of 17° C is suggested for the ocean bottom during the Albian but may have declined to 10° C by the Maastrichtian. These temperature values have been calculated from oxygen-isotope measurements of the calcitic remains of belemnites, planktonic foraminiferans, and benthic foraminiferans. These temperatures support models that suggest diminished ocean circulation both vertically and latitudinally. Such circulation patterns could account for the periods of black shale deposition during the Cretaceous.

In general, the Cretaceous would rank as the most arid period of the Phanerozoic. Not all scientists agree with this assessment, however. Evaporites are plentiful in the Early Cretaceous, a fact that seems to point to an arid climate. Yet, this situation may result more from constricted ocean basins than from climatic effects. The occurrence of evaporites mainly between 10° and 30° latitude suggests arid subtropics, but the presence of coals poleward of 30° indicates humid mid-latitudes. Occurrences of early Cretaceous bauxite and laterite, which are products of deep weathering in warm climates with seasonal rainfall, support the notion of humid mid-latitudes.

Other paleontological indicators suggest details of ocean circulation. The occurrence of early and mid-Cretaceous rudists and larger Tethyan foraminiferans in Japan may very well mean that there was a warm and northward-flowing current in the region. A similar occurrence of these organisms in Aptian–Albian sediments as far south as southern Tanzania seems to indicate a southward-flowing current along the east coast of Africa. The fact that certain warmwater life-forms that existed in the area of present-day Argentina are absent from the west coast of Africa suggests a counterclockwise gyre in the South Atlantic. In addition, the presence of larger foraminiferans in Newfoundland and Ireland points to the development of a "proto-Gulf Stream" by the mid-Cretaceous.

Cretaceous life. The lengthy Cretaceous Period constitutes a major portion of the interval of transition between ancient life-forms and those forms that dominate the Earth today. Many of these modern animals and plants, as, for example, the placental mammals and angiosperms, made their first appearance during the Cretaceous. (Some authorities maintain that certain varieties of angiosperms belonging to the class Monocotyledoneae evolved in the Late Jurassic based on fossil evidence.) Other groups, such as clams and snails, snakes and lizards, and teleost fishes (the ray-finned variety considered to be the most advanced of the bony fishes) developed distinctively modern characteristics by the end of the Maastrichtian.

Marine life

Characteristic fauna and flora. The marine realm can be divided into two paleobiogeographic regions, the Tethys and the boreal. The division is based on the occurrence of rudist-dominated organic reeflike structures. Rudists were large, rather unusual bivalves that had one valve shaped like a cylindrical vase and another that resembled a flattened cap. The rudists were generally dominant over the corals as framework builders. They rarely existed outside the Tethyan region, and the few varieties found elsewhere did not create reeflike structures. Rudist reeflike structures of Cretaceous age serve as reservoir rocks for petroleum in Mexico, Venezuela, and the Middle East.

Other organisms that were almost entirely restricted to the Tethys region were actaeonellid and nerineid snails, colonial corals, calcareous algae, larger benthic foraminiferans, and certain kinds of ammonites and echinoids. In contrast, belemnites were apparently confined to the colder boreal waters. Important bivalve constituents of the Cretaceous boreal marine biota were the reclining forms (*e.g., Exogyra* and *Gryphaea*) and the inoceramids, which were particularly widespread and therefore useful for biostratigraphic zonation.

Ammonites were numerous and were represented by a variety of forms ranging from the more usual coiled types to straight forms. Some of the more unusual ammonites, called heteromorphs, were shaped like fat corkscrews and fat hairpins. Such aberrant forms most certainly had difficulty moving about. Ammonites preyed on other nektonic and benthic invertebrates and were themselves prey to many larger animals, including the marine reptiles called mosasaurs.

Other marine reptiles were the long-necked plesiosaurs and more fishlike ichthyosaurs. Sharks and rays also were marine predators, as were the teleosts. One Cretaceous fish, *Xiphactinus,* grew to more than 4.5 metres and is the largest known teleost.

Flying reptiles and birds

In the air, the flying reptiles called pterosaurs dominated. One pterosaur from the latest Cretaceous of what is now Texas, *Quetzalcoatlus,* had a wingspan of about 15 metres. While it has been determined that birds developed from a reptilian ancestor during the Jurassic and Cretaceous, the fossil record for birds is too sparse to accurately document their evolution. *Hesperornis* was a genus of Cretaceous flightless, diving bird that had large feet and sharp backward-directed teeth adapted for preying on fish.

Although the fossil record is irregular in quality and quantity during the Early Cretaceous, it is obvious that dinosaurs continued their lengthy dominance on land. The Late Cretaceous record is much more complete, particularly in the case of North America and Asia. It is known, for instance, that during the Late Cretaceous many dinosaur types lived in relationships not unlike the present-day terrestrial mammal communities. Although the larger dinosaurs such as the carnivorous *Tyrannosaurus* and the herbivorous *Iguanodon* are the best known, many smaller forms also lived in Cretaceous times. *Triceratops,* a large three-horned dinosaur, inhabited western North America during the Maastrichtian age.

The land plants of the Early Cretaceous were similar to those of the Jurassic. They included the cycads, ginkgoes, conifers, and ferns. The angiosperms appeared by the Barremian, became common by the end of the Albian, and came to represent the major component of the terrestrial flora by the mid-Late Cretaceous. This flora included figs, magnolias, poplars, willows, sycamores, and herbaceous plants. With the advent of many new plant types, insects also diversified.

Emergence of placental mammals and marsupials

Forerunners of modern life-forms. Various types of small mammals that are now extinct existed during the Triassic and Jurassic. On the other hand, two important groups of modern mammals evolved during the Cretaceous. Placental mammals, which include most modern mammals (*e.g.*, rodents, cats, dogs, cows, pigs, and primates), evolved during the Late Cretaceous. Although almost always smaller than present-day rabbits, the Cretaceous placentals were poised to take over the terrestrial environments as soon as the dinosaurs vanished. Another mammal group, the marsupials, evolved during the Cretaceous as well. This group includes the native species of Australia, such as kangaroos and koalas, and the North American opossum.

Marine plankton took on a distinctly modern appearance by the end of the Cretaceous. The coccolithophores became so abundant in the Late Cretaceous that vast quantities accumulated to form the substance for which the Cretaceous Period was named—chalk. The planktonic foraminiferans also contributed greatly to fine-grained calcareous sediments. Less abundant but important single-celled animals and plants of the Cretaceous include the diatoms, radiolarians, and dinoflagellates. Other significant marine forms of minute size were the ostracods and calpionellids.

Mass extinctions. At or very close to the end of the Cretaceous, many animals that were important elements of the Mesozoic world became extinct. On land the dinosaurs perished, but the plant life was little affected. Of the planktonic marine flora and fauna, only about 13 percent of the coccolithophore and planktonic foraminiferan genera survived the extinction event (or events). Ammonites and belemnites became extinct, as did such marine nektonic reptiles as ichthyosaurs, mosasaurs, and plesiosaurs. Among the marine benthos, the larger foraminiferans (orbitoids) died out, and the hermatypic corals were reduced to about one-fifth of their genera. Rudist bivalves disappeared, as did bivalves with a reclining life habit such as the *Exogyra* and *Gryphaea*. The stratigraphically important inoceramids also died out. With the extinction of these animals, modern life-forms diversified and came to dominate the Earth.

Many theories have been proposed to explain the Late Cretaceous mass extinction. Since the early 1980s, much attention has been focused on the so-called asteroid theory formulated by the American scientists Walter and Luis Alvarez. In brief, this theory states that the impact of an asteroid (or meteorite) on the Earth may have triggered the extinction event by ejecting a huge quantity of rock debris into the atmosphere, enshrouding the Earth in darkness for several months or longer. With no sunlight able to penetrate this global dust cloud, photosynthesis ceased, resulting in the death of green plants and the disruption of the food chain. (For more detailed information on this hypothesis, see DINOSAURS: *Extinction.*)

The asteroid theory has met with considerable skepticism among paleontologists, many of whom prefer to look to environmental factors as the underlying mechanism for changes in biota. It has been noted that tectonic plate movements caused a major rearrangement of the world's landmasses, particularly during the latter part of the Cretaceous. The climatic changes resulting from such continental drift could have effected a gradual deterioration of habitats favourable to the dinosaurs and other animal groups that suffered extinction. It is, of course, possible that sudden catastrophic phenomena like an asteroid impact could have contributed to this environmental deterioration that brought about the demise of numerous faunal groups. (C.F.K.)

Cenozoic Era

The Cenozoic began about 66.4 million years ago and extends to the present (see Table 4). The term, originally spelled Kainozoic, was introduced by John Phillips in an 1840 *Penny Cyclopaedia* article to designate the most recent of the three major subdivisions of the Phanerozoic. Derived from the Greek for recent life, it reflects the sequential development and diversification of life on Earth from the Paleozoic (ancient life) through the Mesozoic (middle life). Today, the Cenozoic is internationally accepted as the youngest of the three subdivisions of the fossiliferous part of Earth history.

The Cenozoic Era is generally divided into two periods, the Tertiary and the Quaternary. The designations Tertiary and Quaternary, however, are relics of early attempts in the late 18th century at formulating a stratigraphic classification that included the now wholly obsolete terms Primary and Secondary. In 1856 Moritz Hörnes introduced the terms Paleogene and Neogene, the latter encompassing rocks equivalent to those described by Charles Lyell as Miocene and older and newer Pliocene (which included what he later called the Pleistocene; see above *Completion of the Phanerozoic time scale*). Subsequent investigators have determined that the designation Neogene correctly applies to the rock systems and corresponding time intervals delineated by Lyell, though some authorities prefer to exclude the Pleistocene from the Neogene. The Paleogene encompasses the Paleocene, Eocene, and Oligocene. (The terms Paleocene and Oligocene were coined subsequent to Lyell's work and inserted in the lower part of the Cenozoic stratigraphic scheme.)

Cenozoic rocks

Cenozoic rocks are extensively developed on all the continents, particularly on lowland plains, as, for example, the Gulf and Atlantic coastal plains of North America. They are generally less consolidated than older rocks, although some are indurated (cemented) as a result of high pressure due to deep burial, chemical diagenesis, or high temperature—namely, metamorphism. Sedimentary rocks predominate during the Cenozoic, and more than half the world's petroleum occurs in such rocks of this age. Igneous rocks are represented by extensive early Cenozoic flood basalts (those of East Greenland and the Deccan trap of India) and the late Cenozoic flood basalts of the Columbia River in Washington, as well as by numerous volcanoes in the circum-Pacific System and ocean island chains such as Hawaii.

Several of the world's great mountain ranges were built during the Cenozoic. The main Alpine orogeny, which produced the Alps and Carpathians in southern Europe and the Atlas Mountains in northwestern Africa, began roughly between 37 and 24 million years ago. The Himalayas were formed some time after the Indian Plate collided with the Eurasian Plate. These lofty mountains marked the culmination of the great uplift that occurred during the late Cenozoic when the Indian Plate drove many hundreds of kilometres into the underbelly of Asia. They are the product of the low-angle underthrusting of the northern edge of the Indian Plate under the southern edge of the Eurasian Plate.

From about five million years ago, the Rocky Mountains and adjoining areas were elevated by rapid uplift of the entire region without faulting. This upwarping sharply steepened stream gradients, enabling rivers to achieve greater erosional power. As a result, deep river valleys and canyons, such as the Grand Canyon of the Colorado River in northern Arizona, were cut into broad upwarps of sedimentary rock during late Cenozoic time.

On a global scale the Cenozoic witnessed the further dismemberment of the Northern Hemispheric supercontinent of Laurasia: Greenland and Scandinavia separated during the early Cenozoic about 55 million years ago and the Norwegian-Greenland Sea emerged, linking the North Atlantic and Arctic oceans. The Atlantic continued to expand while the Pacific experienced a net reduction in size as a result of continued seafloor spreading. The equatorially situated east–west Tethyan seaway linking the Atlantic and Pacific oceans was modified significantly in the east during the middle Eocene—about 45 million years ago—by the junction of India with Eurasia, and it was severed into two parts by the confluence of Africa, Arabia, and Eurasia during the early Miocene approximately 18 million years ago. The western part of the Tethys evolved into the Mediterranean Sea not long after it had been cut off from the global ocean system about 6 to 5 million years ago and had formed evaporite deposits which reach up to several kilometres in thickness in a land-locked basin that may have resembled Death Valley in present-day California. Antarctica remained centred on the South Pole throughout the Cenozoic, but the northern continents converged in a northward direction.

The global climate was much warmer during the early Cenozoic than it is today, and equatorial-to-polar thermal gradients were less than half of what they are at present. Cooling of the Earth began about 50 million years ago and, with fluctuations of varying amounts, has continued inexorably to the present interglacial climatic period. It is to be noted that a unique feature of the Cenozoic was the development of glaciation on the Antarctic continent about 35 million years ago and in the Northern Hemisphere between 3 and 2.5 million years ago. Glaciation left an extensive geologic record on the continents in the form of predominantly unconsolidated tills and glacial moraines, which in North America extend in a line as far south as Kansas, Illinois, Ohio, and Long Island, N.Y., and on the ocean floor in the form of ice-rafted detritus dropped from calving icebergs.

Extensive glaciation

Cenozoic life was strikingly different from that of the Mesozoic. The great diversity that characterizes modern-day flora is attributed to the explosive expansion and adaptive radiation of the angiosperms that began during the Late Cretaceous. As climatic differentiation increased over the course of the Cenozoic, flora became more and more provincial. Deciduous angiosperms, for instance, came to predominate in colder regions, whereas evergreen varieties prevailed in the subtropics and tropics.

Fauna also underwent dramatic changes during the Cenozoic. As was discussed in earlier sections, the end of the Cretaceous brought the eradication of dinosaurs on land and of large swimming reptiles (*e.g.,* ichthyosaurs, mosasaurs, and plesiosaurs) in marine environments. Nektonic ammonites, squidlike belemnites, sessile reef-building mollusks known as rudistids, and most microscopic plankton also died out at this time. The Cenozoic witnessed a rapid diversification of life-forms in the ecological niches left vacant by this great terminal Cretaceous extinction. In particular, mammals, which had existed for more than 100 million years before the advent of the Cenozoic Era, experienced substantial evolutionary radiation. Marsupials developed a diverse array of adaptive types in Australia and South America free from the predations of carnivorous placentals. The placental mammals, which today make up more than 95 percent of known mammals, radiated at a rapid rate. Ungulates (or hoofed mammals) with clawed feet evolved during the Paleocene (66.4 to about 57 million years ago). This epoch saw the development and proliferation of the earliest perissodactyls (odd-toed ungulates, such as horses, tapirs, rhinoceroses, and two extinct groups, the chalicotheres and titanotheres) and artiodactyls (even-toed ungulates, including pigs, peccaries, hippopotamuses, camels, llamas, chevrotains, deer, giraffes, sheep, goats, musk-oxen, antelopes, and cattle). During the later Cenozoic, perissodactyl diversity declined markedly, but artiodactyls continued to diversify. Elephants, which evolved in the late Eocene about 40 million years ago, spread throughout much of the world and underwent tremendous diversification at this time. Many placental forms of giant size, like the sabre-toothed cat, giant ground sloths, and woolly mammoths, inhabited the forests and the plains in the Pliocene (5.3 to 1.6 million years ago). It was also about this time that the first hominids appeared. Early modern humans, however, did not emerge until the Pleistocene.

Among marine life-forms, mollusks (primarily pelecypods and gastropods) became highly diversified, as did reef-building corals characteristic of the tropical belt. Planktonic foraminiferans underwent two major radiations—the first in the Paleocene and the second in the Miocene—punctuated by a long (15–20-million-year) mid-Cenozoic reduction in diversity related in all likelihood to global cooling.

Cenozoic life was affected significantly by a major extinction event that occurred between 10,000 and 8,000 years ago. This event, which involved the sudden disappearance of many Ice Age mammals, has been attributed to either of two factors: climatic change following the melting of the most recent Pleistocene glaciers or overkill by Paleolithic hunters. The latter is regarded by many as the more likely cause, as the rapidly improved technology of Paleolithic humans permitted more efficient hunting. (For a more detailed discussion of this matter, see below *Pleistocene Epoch: Pleistocene fauna and flora.*)

Late Cenozoic extinction event

TERTIARY PERIOD

General considerations. The Tertiary, the initial period of the Cenozoic Era, began about 66.4 million years ago and ended approximately 1.6 million years ago (see Table 4). The name Tertiary was introduced by Giovanni Arduino in 1760 as the youngest of a tripartite division of the Earth's rocks: the Primitive schists, granites, and basalts that formed the core of the high mountains (of Europe); the fossiliferous Secondary, or Mesozoic, in northern Italy (predominantly shales and limestones); and a younger group of fossiliferous sedimentary rocks, the Tertiary rocks, found chiefly at lower elevations. Although originally intended as a descriptive generalization of rock types, many of Arduino's contemporaries and successors gave these categories a temporal connotation and equated them with rocks formed prior to, during, and after the Noachian deluge.

In 1810 Alexandre Brongniart included all the sedimentary deposits of the Paris Basin in his *terrains tertiares,* or Tertiary, and soon thereafter all rocks younger than Mesozoic in western Europe were called Tertiary (Table 22). The recognition of the Quaternary Period in 1829 by Jules Desnoyers—based on the post-Tertiary deposits of the Seine valley—placed a somewhat different connotation on the term Tertiary, particularly in regard to its upper limits. Controversies regarding the connotation of the term Quaternary and its limits continue today in professional circles. Quaternary is not a satisfactory name in the hierarchy of stratigraphic nomenclature. The terms Primary and Secondary have been supplanted by Paleozoic and Mesozoic, and Tertiary is being gradually replaced by Paleogene and Neogene as formal period names in scientific literature (see below *Changing nomenclature*).

Subdivisions. The Tertiary faunas of western Europe that were known to 19th-century natural scientists consisted primarily of mollusks exhibiting varying degrees of similarity with modern types. At the same time, the science of stratigraphy was in its infancy, and the primary focus of its earliest practitioners was to use the newly discovered sequential progression of fossils in layered sedimentary rocks to establish a global sequence of temporally ordered stages of what was until that time an undivided record of Earth history. Lyell employed a simple statistical measure based on the relative percentages of living species of mollusks to fossil mollusks found in different layers of Tertiary rocks. These percentages had been compiled by his colleague and friend Gérard-Paul Deshayes, the French conchologist, who had amassed a collection of more than 40,000 mollusks and was preparing a monograph on the mollusks of the Paris Basin. In 1833, Lyell divided the Tertiary into four subdivisions (from older to younger): Eocene, Miocene, older Pliocene, and newer Pliocene (the latter was renamed the Pleistocene in 1839). The Eocene contained about 3 percent of the living mollusk species, the Miocene about 20 percent, the older Pliocene more than one-third and often over 50 percent, and the newer Pliocene about 90 percent. Lyell traveled extensively in Europe (and North America as well for that matter) and had a broad and comprehensive understanding of the regional geology for his day. He understood, for example, that rocks of the Tertiary were unevenly distributed over Europe and that there were no rocks of the younger part of the period in the Paris Basin. He used the deposits in the Paris and Hampshire and London basins as typical for the Eocene; the Faluns (shelly marls) of the Loire Basin near Touraine as well as the deposits in the Aquitaine Basin near Bordeaux in southwestern France and the Bormida River valley and Superga near Turin, Italy, for the Miocene; the sub-Apennine formations of northern

Lyell's subdivisions of the Tertiary

Italy for the older Pliocene; and the marine strata in the Gulf of Noto and the Island of Ischia (also in Italy) and Uddevalla (in Sweden) for the newer Pliocene.

The limits between Lyell's Tertiary subdivisions were not rigidly specified, and Lyell himself clearly recognized the approximate and imperfect nature of his scheme. Indeed, in their original form Lyell's subdivisions would today be termed biostratigraphic units (bodies of rocks characterized by particular fossil assemblages) rather than chronostratigraphic units (bodies of rocks deposited during a specific interval of time).

Subsequent stratigraphic studies in northern Europe showed that there were contemporaneous deposits that were included variously in the upper Eocene or lower Miocene by different geologists of the day. This situation led H.E. Beyrich, in 1854, to create the term Oligocene for rocks in the North German Basin and Mainz Basin and to insert it between the Eocene and the Miocene in the stratigraphic scheme. As originally proposed, the Oligocene included the Tongrian and Rupelian stages as well as strata that subsequently formed the basis for the Chattian Stage. The Tongrian is no longer used as a standard unit, its place being taken by the Rupelian. The term Paleocene was proposed by Wilhelm P. Schimper on the basis of fossil floras in the Paris Basin that he considered intermediate between Cretaceous and Eocene forms. Typical strata included the sands of Bracheux, the travertines of Sézanne, and the lignites and sandstones of Soissons (the Suessonian of Alcide D. d'Orbigny). As originally defined, the Paleocene was based on strata believed to be equivalent to the Ypresian Stage (the oldest unit of the Eocene), but it is now known in fact to lie stratigraphically below the oldest levels assigned to the Eocene in the Paris Basin. The problem of the Paleocene is that, of all the chronostratigraphic units of the Tertiary, it alone is defined on the basis of nonmarine strata, making recognition of its upper limit and general correlation difficult elsewhere. Acceptance of the term Paleocene into the general system of stratigraphic names was irregular, and only in 1939 did the United States Geological Survey, general arbiter of standard stratigraphic nomenclature in North America, formally accept it. The Danian Stage was proposed by the geologist Pierre Jean Édouard Desor in 1846 for chalk deposits in Denmark and was assigned to the Cretaceous by virtue of the similarity of its invertebrate megafossils to those of the youngest Cretaceous elsewhere. Since the late 1950s, micropaleontologists have recognized, however, that calcareous planktonic foraminiferans (pelagic, single-celled protozoans) and nannoplankton (marine phytoplankton) exhibit a major taxonomic change at the boundary between the Maastrichtian (uppermost Cretaceous) Stage and the Danian (lowermost Tertiary) Stage and that the affinities of both micro- and megafauna lie with the overlying Cenozoic. The Danian is now widely regarded as being the oldest stage of the Cenozoic.

In 1948 the 18th International Geological Congress placed the base of the Pleistocene at the base of the marine strata of the Calabrian Stage of southern Italy, using the initial appearance of northern or cool-water invertebrate faunas in Mediterranean marine strata as the marker. Subsequent studies showed that the type section was ill-chosen and that the base of the Calabrian Stage was equivalent to much younger levels within the Pleistocene. A newly designated stratotype section was chosen at Vrica in Calabria, and the base of the Pleistocene was found comparable to a level dated at nearly 1.65 million years. This was formally ratified by the 27th International Geological Congress in Moscow in 1984. The oldest stage of the Pleistocene, however, remains the Calabrian.

Changing nomenclature. As was noted above, a growing number of authorities consider the terms Tertiary and Quaternary to be outmoded. The Pleistocene is interpreted as equivalent to the Quaternary and the youngest of the epochs of the Neogene Period, whereas the Paleogene is regarded as the older part of the Cenozoic Era, equivalent to the Paleocene, Eocene, and Oligocene epochs. Inasmuch as substitution of the terms Paleogene and Neogene for Tertiary and Quaternary is still not universally accepted in the scientific community at this time, it seems appropriate to discuss Cenozoic history in terms of the Tertiary and the Quaternary. Nonetheless, the discussion of the controversies that currently exist is presented to demonstrate the fact that geology and, in particular, stratigraphy—like all sciences—is a dynamic and changing field, whose basic concepts are subject to modification as knowledge and understanding increase.

Tertiary rocks. *Types and distribution.* With the exception of the great Tethyan seaway, the basins of western Europe, and the extensive Mississippi embayment of the Gulf Coast region, Tertiary marine deposits are located predominantly along continental margins. They occur on all continents and are found in situ as far north as Alaska (Miocene), eastern Canada (Eocene), and Greenland (Paleocene). Deposits of Paleogene age occur on Seymour Island in the Antarctic Peninsula, and Neogene deposits containing marine diatoms (silica-bearing marine phytoplankton) have recently been identified intercalated between glacial tills on Antarctica itself.

Sedimentary deposits along continental margins

Global sea level is believed to have fallen gradually but inexorably about 300 metres over the past 100 million years, but superimposed upon that trend is a higher-order series of globally fluctuating increases and decreases in sea level with a periodicity of several million years. The resultant transgressions and regressions of the sea onto passive (*i.e.,* tectonically stable) continental margins has left a record of interfingered marine brackish and continental sedimentary deposits in Europe, North Africa, the Middle East, southern Australia, and the Gulf and Atlantic coastal plains of North America. In most regions, the Paleogene seas extended farther inland than did those of the Neogene; in fact, the most extensive transgression of the Tertiary is that of the Lutetian Age (Middle Eocene), about 49–45 million years ago, when the Tethys Sea expanded onto the continental margins of Africa and Eurasia and left extensive deposits of shallow-water carbonate rocks characterized by tropical foraminiferans of large size called *Nummulites* from Indonesia to Spain and as far north as Paris and London. Sediments of Tertiary age are widely developed on the deep ocean floor and elevated seamounts as well. In the shallower parts of the ocean above 4.5 kilometres, sediments are calcareous or siliceous (or both), depending on local productivity. Below 4.5 kilometres the sediments are principally siliceous or inorganic (*i.e.,* red clay) owing to dissolution of calcium carbonate.

Nonmarine (terrestrial, or continental, as they are called) Tertiary sedimentary and volcanic deposits are widespread in North America, particularly in the intermontane basins west of the Mississippi River. During the Neogene, volcanism and terrigenous deposition extended almost to the coast. In South America thick nonmarine clastic sequences (conglomerates, sandstones, and shales) occur in the mobile tectonic belt of the Andes Mountains and along their eastern front; these sequences extend eastward for a considerable distance into the Amazon Basin. Tertiary marine deposits occur along the eastern margins of Brazil and Argentina, and they were already known to Charles Darwin during his exploration of South America in 1833 and 1834.

Volcanism and orogenesis. Volcanism has continued throughout the Cenozoic on land and at the major oceanic ridges, such as the Mid-Atlantic Ridge and the East Pacific Rise, where new seafloor is continuously generated and carried away laterally by seafloor spreading. Iceland was formed in the middle Miocene, and it remains one of the few places where the processes that occur at the Mid-Atlantic Ridge can be observed today.

Massive outpourings of lava

Two of the most extensive volcanic outpourings recorded in the geologic record occurred during the Tertiary. The Deccan trap of India was the site of massive outpourings of basaltic lava near the boundary between the Cretaceous and Tertiary about 67–66 million years ago, whereas massive explosive volcanism took place near the Paleocene–Eocene boundary between 57 and 54 million years ago in northwestern Scotland, northern Ireland, and the Faeroe Islands and East Greenland, as well as along the rifted continental margins of both sides of the North Atlantic Ocean. This volcanic activity was associated with the initial rifting and separation of Eurasia and North America between Scandinavia and Greenland and left a stratigraphic record in the form of distal ash deposits as far south as the Bay of Biscay and the marine sedimentary basin of England. In both instances, comparable volumes of extensive basalts in the amount of 1 to 2 by 10,000,000 cubic kilometres were erupted. The well-known volcanics of the Massif Central of south central France, which figured so prominently in early (18th-century) investigations into the nature of igneous rocks, are of Oligocene age, as are those in central Germany. The East African Rift Zone preserves a record of mid-to-late Tertiary rifting and separation of the East African continent that eventually led to the formation of a marine seaway linking the Indian Ocean with the Mediterranean. During the Early Tertiary, volcanism occurred in the Caucasus Mountain region but was essentially absent elsewhere in Asia.

The circum-Pacific "Ring of Fire," an active tectonic belt that extends from the Philippines through Japan around the west coast of North and South America, was subject to seismic activity and andesitic volcanism throughout much of the Tertiary. The extensive Columbia Plateau basalts were extruded over Washington and Oregon during the Miocene, and many of the volcanoes of Alaska, Oregon, southern Idaho, and northeastern California date to the Late Tertiary. Active volcanism occurred in the newly uplifted Rocky Mountains during the Early Tertiary, whereas in the southern Rocky Mountains and Mexico volcanic activity was more common in the mid- and late Tertiary. The linear volcanic trends, such as the Hawaiian, Emperor, and Line island chains in the central and northwestern Pacific, are trails resulting from the movement of the Pacific Plate over volcanic "hot spots" (*i.e.,* magma-generating centres) that are probably fixed deep in the Earth's mantle. The major island groups such as the Hawaiian (which has been active over the past 30 million years), Galápagos, and Society islands (Miocene) are volcanoes that rose from the seafloor. Finally, Central America, the Caribbean region, and northern South America were the sites of active volcanism throughout the Cenozoic.

In contrast to the passive-margin sedimentation on the Atlantic and Gulf coastal plains, the Cordilleran (or Laramide) orogeny in the Late Cretaceous, Paleocene, and Eocene produced a series of upfolded and upthrusted mountains and deep intermontane basins in the area of the modern Rocky Mountains. Deeply downwarped basins accumulated as much as 8,000 metres of Paleocene and Eocene sediment in the Green River basin of southwestern Wyoming and 14,000 metres of sediment in the Uinta Basin of northeastern Utah. Other basins ranging from Montana to New Mexico accumulated similar but thinner packages of nonmarine fluvial and lacustrine sediments rich in fossil mammals and fish. In the Oligocene and Miocene, Cordilleran influences on what is now the western United States had ceased, and the basins were gradually filled to the top by sediments and abundant volcanic ash deposits from eruptions in present-day Colorado, Nevada, and Utah. These basins were exhumed during the Pliocene-Pleistocene with renewed uplift of the long-buried Rocky Mountains, along with uplift of the Colorado Plateau, producing steep stream gradients that resulted in the cutting of the Grand Canyon to a depth of more than 5,000 metres.

Volcanism along the Cascade Mountain chain was active from the late Eocene to today, as evidenced by the 1980 eruption of Mount St. Helens. This volcanism was gradually shut off in California as the movement of plate boundaries changed from one of subduction to a sliding and transform motion (see also EARTH, THE; *The major geologic features of the Earth's exterior: The surface of the Earth as a mosaic of plates; Types of plate boundaries*). With the development of the San Andreas Fault system, the western half of California started sliding northward. The Cascade–Sierra Nevada Mountain chain began to swing clockwise, causing the extension of the Basin and Range Province in Nevada, Arizona, and western Utah. This crustal extension broke the Basin and Range into a series of north–south-trending fault-block mountains and downdropped basins, which filled with thousands of metres of upper Cenozoic sediment. These fault zones (particularly the Wasatch Fault in central Utah and the San Andreas zone in California) remain active today and are the source of most of the damaging earthquakes in North America. The Andean mountains were uplifted during the Neogene as a result of subduction of the South Pacific beneath the South American continent.

Alpine orogeny

Complex tectonic activity occurred in Asia and Europe during the Tertiary. The main Alpine orogeny began during the late Eocene and Oligocene and continued throughout much of the Neogene. Major tectonic activity in the eastern North Atlantic (Bay of Biscay) extended into southern France and culminated in the uplift of the Pyrenees in the late Eocene. On the south side of the Tethys, the coastal Atlas Mountains of North Africa experienced major uplift during this time, but the Betic region of southern Spain and the Atlas region of northern Morocco continued to display mirror-image histories of tectonic activity well into the late Neogene. In the Middle East the suturing of Africa and Asia occurred about 18 million years ago. Elsewhere, India had collided with the Asian continent about 45 million years ago, initiating the Himalayan uplift that was to intensify in the late Neogene (*i.e.,* Pliocene and Pleistocene) and culminate in the uplift of the great Tibetan Plateau and the Himalayan Mountain range. Major orogenic movement also occurred in the Indonesian-Malaysian-Japanese arc system during the Neogene. In New Zealand, which sits astride the Indian-Australian and Pacific plate boundary, the major tectonic uplift (the Kaikoura orogeny) of the southern Alps began about 10 million years ago.

Sedimentary sequences. Northwestern Europe contains a number of Tertiary marine basins that essentially rim the North Sea Basin, itself the site of active subsidence during the Paleogene and basinal infilling during the Neogene. The marine Hampshire and London basins, the Paris Basin, the Anglo-Belgian Basin, and the North German Basin have become the standard for comparative studies of the Paleogene part of the Cenozoic, whereas the Mediterranean region (Italy) has become the standard for the Neogene. The Tertiary record of the Paris Basin is essentially restricted to the Paleogene (namely, those of Paleocene–late Oligocene age), whereas scattered Pliocene–Pleistocene deposits occur in England and Belgium above the Paleogene. The strata are relatively thin, nearly horizontal, and often highly fossiliferous, particularly in the middle Eocene *calcaire grossier* of the Paris Basin from which a molluscan fauna of more than 500 species has been described. The Paris Basin is a roughly oval-shaped basin centred on Paris, whereas the Hampshire and London basins lie to the southwest and northeast of London, respectively. The London Basin and the Anglo-Belgian Basin were part of a single sedimentary basin across what is now the English Channel during the early part of the Paleogene. The total Paleogene stratigraphic succession in these basins is less than 300 metres and consists of clays, marls, sands, carbonates, lignites, and gypsum, reflecting alternations of marine, brackish, lacustrine, and terrestrial environments of deposition. The alternating transgressions and regressions of the sea have left a complex sedimentary record punctuated by numerous unconformities and associated temporal hiatuses, and the correlation of these various units and events has challenged stratigraphers since the early 19th century. The integration of biostratigraphic zonal schemes based on calcareous marine protozoans, phytoplankton and armoured dinoflagellates, paleomagnetic stratigraphy, and tephrochronology (ash-bed correlations) has resulted in a refined correlation of the stratigraphic succession in these separate basins.

In contrast, extensive Tertiary sediments occur on the Atlantic and Gulf Coastal plains and extend around the margin of the Gulf of Mexico to the Yucatán Peninsula, a distance of more than 5,000 kilometres. Seaward these deposits can be traced from the Atlantic Coastal Plain to the continental margin and rise and in the Gulf Coastal Plain into the subsurface formations of this petroliferous province of the Gulf of Mexico. During the Paleocene the embayment of the Gulf Coastal Plain extended inland to southwestern North Dakota and Montana about 2,000 kilometres from the present shoreline, where the lower Paleocene (Danian) Cannonball Formation was deposited. Although eroded between northwestern South Dakota and southern Illinois, marine outcrops continue southward to the coastline where they continue in the subsurface of the Gulf of Mexico. Tertiary sediments with a thickness in excess of 15,000 metres are estimated to lie beneath the continental margin in the Gulf of Mexico. In the Tampico embayment of eastern Mexico, thicknesses of more than 3,000 metres have been estimated for the Paleocene Velasco Formation, which developed under conditions of active subsidence and associated rapid deposition. Exposures in the Atlantic Coastal Plain and most of the Gulf Coastal Plain are of Paleogene age, but considerable thicknesses of Neogene sediment occur in offshore wells in front of the Mississippi delta, where thicknesses in excess of 10,000 metres have been recorded for the Neogene alone. Sediments are dominantly calcareous in the Florida region and become more marly and eventually sandy and muddy to the west, reflecting the input of terrigenous matter transported seasonally by the Mississippi River and its precursor(s). A large number of local stratigraphic names are used, but outcropping Gulf Coast units of Paleogene age are now placed, in ascending order, in the Midwayan, Sabinian, Claibornian, Jacksonian, Vicksburgian, and Chickasawhayan stages. Overlying Neogene sediments, mostly known in the subsurface, are placed in the Anahuacan, Napoleonvillian, Duck Lakean, Clovellyan, and Foleyan stages. Owing to general faunal and floral similarities, it is possible to make relatively precise stratigraphic correlations in the Paleogene between the Gulf and Atlantic Coastal Plain region and the basins in northwestern Europe.

Tertiary sediments on the Atlantic and Gulf coastal plains

Correlation. The boundaries of the Tertiary were originally only qualitatively estimated on the basis of the percentages of living species of (primarily) mollusks in the succession of marine strata in the western European basins. Early correlations were made by direct correlations with the faunas in the type areas in Europe. It was soon realized that faunal provincialization led to spurious correlations, and in 1919 an independent set of percentages for the Indonesian region was proposed, which was subsequently modified into the so-called East India Letter Stage classification system based on the occurrence of taxa of larger foraminiferans. In this system, the Tertiary *a* corresponds to upper Paleocene, *Ta2* to lower Eocene, *Ta3* to middle Eocene, *Tb* to upper Eocene, *Tc* to lower Oligocene, *Td* to middle Oligocene, lower *Te* to upper Oligocene, upper *Te* to lower Miocene, lower *Tf* to middle Miocene, upper *Tf* to upper Miocene, *Tg* to lower Pliocene, and *Th* to upper Pliocene.

In Europe the need for more precise correlations of Mesozoic and Cenozoic marine strata led to the concept of stages, which was introduced in 1842 by d'Orbigny. These stages were originally defined as rock sequences composed of distinctive assemblages of fossils that were believed to change abruptly as a result of major transgressions and regressions of the sea. This methodology has since been improved and refined, but it forms the basis for modern biostratigraphic correlation.

Geochronology and microfossil zones. Since about the mid-1900s, increasing efforts have been made to apply radioisotopic dating techniques to the development of a geochronologic scale, particularly for the Cenozoic (see above *Relative and absolute dating: Absolute dating*). The decay of potassium-40 to argon-40 has proved very useful in this respect, and recent refinements in mass spectroscopy and the development of laser-fusion dating involving the decay of argon-40 to argon-39 has resulted in the ability to date volcanic mineral samples in amounts as small as single crystals with a margin of error of less than 1 percent over the span of the entire Cenozoic Era.

Also, since the mid-1960s, investigators have demonstrated that the Earth's magnetic dipole field has undergone numerous reversals in the past and that most rocks pick up and retain the magnetic orientation of the field at the time they are formed through either sedimentary or igneous processes. With the development of techniques for measuring the original magnetization, a sequence of polarity reversals has been dated for the late Neogene and a paleomagnetic chronology built up for the entire Cenozoic. This work is based on the recognition that the magnetic lineations detected on the ocean floor were formed when basaltic magma which had extruded from the oceanic ridges assumed the ambient magnetic polarity; the resulting strips of normal and reversed polarity reflected the magnetic reversals observed in deep-sea cores. Calibration of the composite geomagnetic polarity succession to time and the relation of this chronology to the isotopic time scale, however, have proved to be the greatest source of disagreement over various current versions of the geologic time scale. Calibrations of a time scale must ultimately be based on the application of meaningful isotopic ages to the succession of polarity intervals and geologic stages. A geochronologic scheme is thus an integration of several methodologies; it makes use of the best attributes of seafloor spreading history (*i.e.,* pattern of seafloor magnetic anomalies), magnetostratigraphy, and biostratigraphy in the application of relevant isotopic ages to derive a high-resolution and internally consistent time scale. The recent application of astronomically forced cyclical components of the stratigraphic record, such as lithological couplets of marl and chalks, fluctuations in the ratios and percentages of fossil taxa, and so forth, with a periodicity of 100,000 years, has resulted in fine-tuning the geologic time scale to a resolution of about 5,000 years in the late Neogene.

Over the past few decades, micropaleontologists have created a number of zones based on the regional distribution of calcareous plankton (foraminiferans and nannoplankton) and those of the siliceous variety (radiolarians and diatoms), making it possible to correlate sediments from the high northern to high southern latitudes by way of the equatorial region. The resulting high-resolution zonal biostratigraphy and its calibration to an integrated geochronology provide the framework in which a true historical geology has became feasible.

Boundaries and chronologies. Precise stratigraphic positions for the boundaries of the various Tertiary series were not specified by early workers in the 19th century. It is only in more recent times that the international geologic community, working mainly through the International Geological Congress and under the inspiration and leadership of Hollis D. Hedberg, has formulated a philosophical framework for stratigraphy by delineating what might be termed the holy trinity of stratigraphic concepts—lithostratigraphy, biostratigraphy, and chronostratigraphy. As has been already mentioned, by specifying the (lower) limits of rock units deposited during successive increments of geologic time at designated stratotype points in the rock record, geologists established a series of calibration points at which time and rock coincide. These boundary stratotypes are the linchpins of global chronostratigraphic units and serve as the point of departure for global correlation. In recent years the Eocene–Oligocene boundary has been stratotypically established in southern Italy, with a currently estimated age of 34 million years, and the Pliocene–Pleistocene boundary in Calabria, southern Italy, with a numerical age estimate of close to 1.65 million years. The Miocene–Pliocene boundary is stratotypified in Sicily and has been dated at about 5 million years ago, although the location of this boundary may be repositioned in the future. The Cretaceous–Cenozoic boundary has been stratotypified in Tunisia in North Africa; its estimated age is 66.4 million years. The Paleocene–Eocene boundary is currently under investigation and has an estimated age of 57–55 million years. The Oligocene–Miocene boundary (which corresponds to that between the Paleogene and Neogene) also is under study; its age has been calculated to be roughly 23.7 million years. An example of Neogene chronology and correlations is shown in Table 23.

Boundary stratotypes

Tertiary environment. *Paleogeography.* The present-day continent–ocean configuration is the result of a complex sequence of events involving the dynamic evolution and geometric rearrangement of the major landmasses and oceans that began almost 200 million years ago. By the beginning of the Cenozoic the continent–ocean geometry had assumed an essentially modern, or recent, aspect with several notable exceptions. The fragmentation and dispersal of the Southern Hemispheric supercontinent Gondwana continued in the Cenozoic. Australia separated from Antarctica in the late Paleocene (Figure 38), and the initial subsidence of the South Tasman Rise (at the eastern end of the Australia–Antarctica marginal contact) in the late Eocene resulted in a shallow but inexorably widening connection between the Indian and Pacific oceans (Table 24). The injection of relatively warm eastward-flowing currents and associated evaporation at relatively high latitudes set the stage for the initiation of glaciation on Antarctica by early Oligocene time about 34 million years ago. Progressive separation of the two continents led to the initiation of the circum-Antarctic Current, which sweeps around Antarctica and thermally isolates it from the effects of warmer waters and climates to the north.

The junction of India and Asia occurred during the middle Eocene approximately 45 million years ago and resulted in an effective, though not total, blockage of the westward-flowing Tethys. This was achieved about 18 million years ago with the junction of Africa and Asia near present-day Iran. Although the eastern and western Tethyan seaway was now severed, brief intermittent marine connections were reestablished 14 to 13 million years ago.

The present-day Mediterranean Sea is the geologically recent descendant of the Tethys. Between six and five million years ago the western remnant of the formerly extensive Tethyan seaway was subject to a brief (approximately one-million year) paroxysm that saw the entire basin virtually isolated from the world ocean; it experienced severe desiccation and the precipitation of a vast suite of evaporite deposits which reach up to several kilometres in thickness. The basin was subsequently refilled by the Atlantic and underwent significant geologic evolution during the past five million years. About one million years ago this part of the ancient Tethys was transformed into the Mediterranean Sea by the elevation of the Gibraltar sill and the consequent isolation of the basin from deep oceanic bottom waters and development of the present-day circulation pattern (Table 25).

Formation of the Mediterranean Sea

In the Northern Hemisphere the fragmentation and separation of Eurasia was completed during the early Paleogene with the opening of the Norwegian-Greenland Sea about 56 to 55 million years ago. Breaching of the subsiding subaerial Greenland-Scotland Ridge—formed during the Hebridean-Greenland eruptive volcanic episode of the late Paleocene mentioned above—allowed exchange of surface water between the Arctic and Atlantic oceans. Climatic conditions remained subtropical at high latitudes during the Paleogene as attested to by the remains of molluscan and shark faunas of tropical affinities in Spitsbergen. Furthermore, a fauna featuring such forms as the boid snake and durophagous alligator (a variety possessing teeth designed to crush food), as well as anguid and varanid lizards, emydid turtles, plagiomenids (flying lemurs), and paromomyids (primates), has been discovered on Ellesmere Island in the Canadian Arctic Archipelago, whose latitude has remained essentially stable—77° N—during the Cenozoic.

On the Eurasian continent the Ural Trough, a marine seaway linking the Tethys with the Arctic region that had constituted a barrier to the east–west migration of terrestrial faunas, was terminated by regional uplift at the end

Table 24: Major Paleogene Paleogeographic Events*

age	paleogeographic events
Middle Oligocene (33–30 Ma)	Isolation of Antarctica completed after further subsidence of South Tasman Rise
Early Oligocene (*c.* 35–33 Ma)	Tethys severely restricted in the eastern part due to uplift of the Himalayas
Early Oligocene (37–35 Ma)	Separation of Greenland and Svalbard and availability of higher-latitude water to North Atlantic
Early Oligocene (38–35 Ma)	Shallow connection between the South Pacific and Atlantic developed at Drake Passage
Eocene/Oligocene Boundary (34–35 Ma)	Completion of the opening of Labrador Sea that had begun in the Maastrichtian
Late Eocene (*c.* 38 Ma)	Iceland–Faeroe sill sinks below sea level for the first time
Late Eocene (40–37 Ma)	Tethys partially restricted north and east of the Indian Plate
Late Eocene (*c.* 40 Ma)	Subsidence of South Tasman Rise permits shallow connection between Indian and Pacific oceans
Early Eocene (*c.* 53 Ma)	Opening Norwegian–Greenland Sea develops surface water exchange with the Arctic Ocean
Late Paleocene (55–53 Ma)	Australia and Antarctica separate and Australia begins northward drift; formation of the ocean between the two continents
Early Paleocene (56–55 Ma)	Separation of Greenland and Scandinavia and the formation of the Norwegian–Greenland Sea begins

*Listed are those paleogeographic events that affected global ocean circulation and certain climatic and faunal/floral migration patterns.

of the Eocene (Figure 39). The resulting immigration of Eurasian faunas into western Europe and the consequent faunal changes that occurred in terrestrial vertebrate faunas is known as the Grande Coupure (Big Break) among vertebrate paleontologists.

Relatively small changes in land–sea geometry have played an important role in the migration of terrestrial faunas and ultimately in the evolution of life itself. For example, during the early Paleogene land mammal exchange between Europe and North America occurred freely via a northern route owing to the close proximity of Spitsbergen, eastern Canada, and the subaerial Greenland-Scotland Ridge. The separation of the former two and the partial subsidence of the latter about 50 to 49 million years ago (middle Eocene) led to the termination of this free interchange and the development of separate evolutionary patterns among terrestrial vertebrate faunas in Europe and North America. The only route for faunal exchange between Eurasia and North America was the Bering Land Bridge that united Siberia and Alaska. It

age	paleogeographic events
Pleistocene (*c.* 1 Ma)	Uplift of Gibraltar sill and development of present-day Mediterranean circulation patterns (surface water inflow, deep water outflow)
Middle Pliocene (3 Ma)	Uplift of Panamanic Isthmus, joining North and South America
Early Pliocene (*c.* 5 Ma)	Opening of Straits of Gibraltar
Late Miocene (*c.* 5.5 Ma)	Closure of Betic and Riffian (Moroccan) corridor, isolation of western Tethyan Sea from global ocean circulation, and evaporation of the basin
Middle Miocene (*c.* 13 Ma)	Final severance of the Tethys and Paratethys (epeiric continental seaway in southwestern Eurasia)
Early Miocene (*c.* 18 Ma)	Junction of Africa and Eurasia

*Listed are those paleogeographic events that affected global ocean circulation and certain climatic and faunal/floral migration patterns.

seems to have been breached only in the past 2.5 million years, allowing the transit of cold water currents from the Pacific into the Atlantic. Evidence for this occurs in the form of North Pacific cryophylic molluscan faunas in the mid-Pliocene faunas of Iceland. To the south, the Atlantic and Pacific oceans had been linked since the Early Cretaceous by the Panamanic Seaway in the Central American–northwest Colombian region. This seaway prevented terrestrial faunal interchange between North and South America, with the possible exception of a brief interlude during the Paleocene. It was closed by the elevation of the Isthmus of Panama about three million years ago with two significant geologic results. First, the emergence of the Isthmus of Panama permitted a major migration in land mammal faunas between North and South America—the so-called Great American Interchange—which saw South American ground sloths in North America in areas as dispersed as California, the Great Plains, and Florida, and North American faunas as far south as Patagonia. Second, the emergence of the Isthmus of Panama deflected the westward-flowing North Equatorial Current northward where it enhanced the northward-flowing Gulf Stream. The latter then carried warm, salty waters into high northern latitudes, contributing to greater precipitation through evaporation over the region of eastern Canada and Greenland and eventually to the development of the polar ice cap, which began forming between 3 and 2.5 million years ago in the Northern Hemisphere.

Emergence of the Isthmus of Panama and its effects

Significant geologic events. The concept of dynamic paleogeography provides a unifying framework within which to understand the causal link between changes in oceanic circulation, climate, and evolution—which together constitute geologic events. These events may be divided into two categories: physical and biotic.

The early Eocene opening of the Norwegian-Greenland Sea completed the fragmentation of the Northern Hemispheric supercontinent Laurasia and eventually united the Atlantic and Arctic oceans (Figure 40 and Table 24), although modern circulation patterns were not achieved until the subsidence of the Greenland–Scotland Ridge about 15 million years ago. In the Southern Hemisphere the separation of Australia and Antarctica reached a critical point about 34 million years ago, at which time the continent of Antarctica was covered by a major ice sheet. The junction of Eurasia and Africa about 18 million years ago severed the once more extensive Tethyan seaway, and the western part evolved, after being cut off from the world ocean for a relatively brief time, into the modern-day Mediterranean Sea (see above). Finally, the emergence of the Isthmus of Panama about 3 million years ago and concomitant changes in ocean circulation patterns led to the formation of a polar ice cap shortly thereafter in the late Pliocene. The history of the Earth over the past 2.5 million years has been intimately linked with repeated oscillations between glacial advances and retreats.

Biotic events reflect changes in paleogeography and climate. Among mammals the earliest equids (horses) and primates appeared during the early Eocene—a time of

Figure 39: Principal Cenozoic faunal migration routes and barriers.

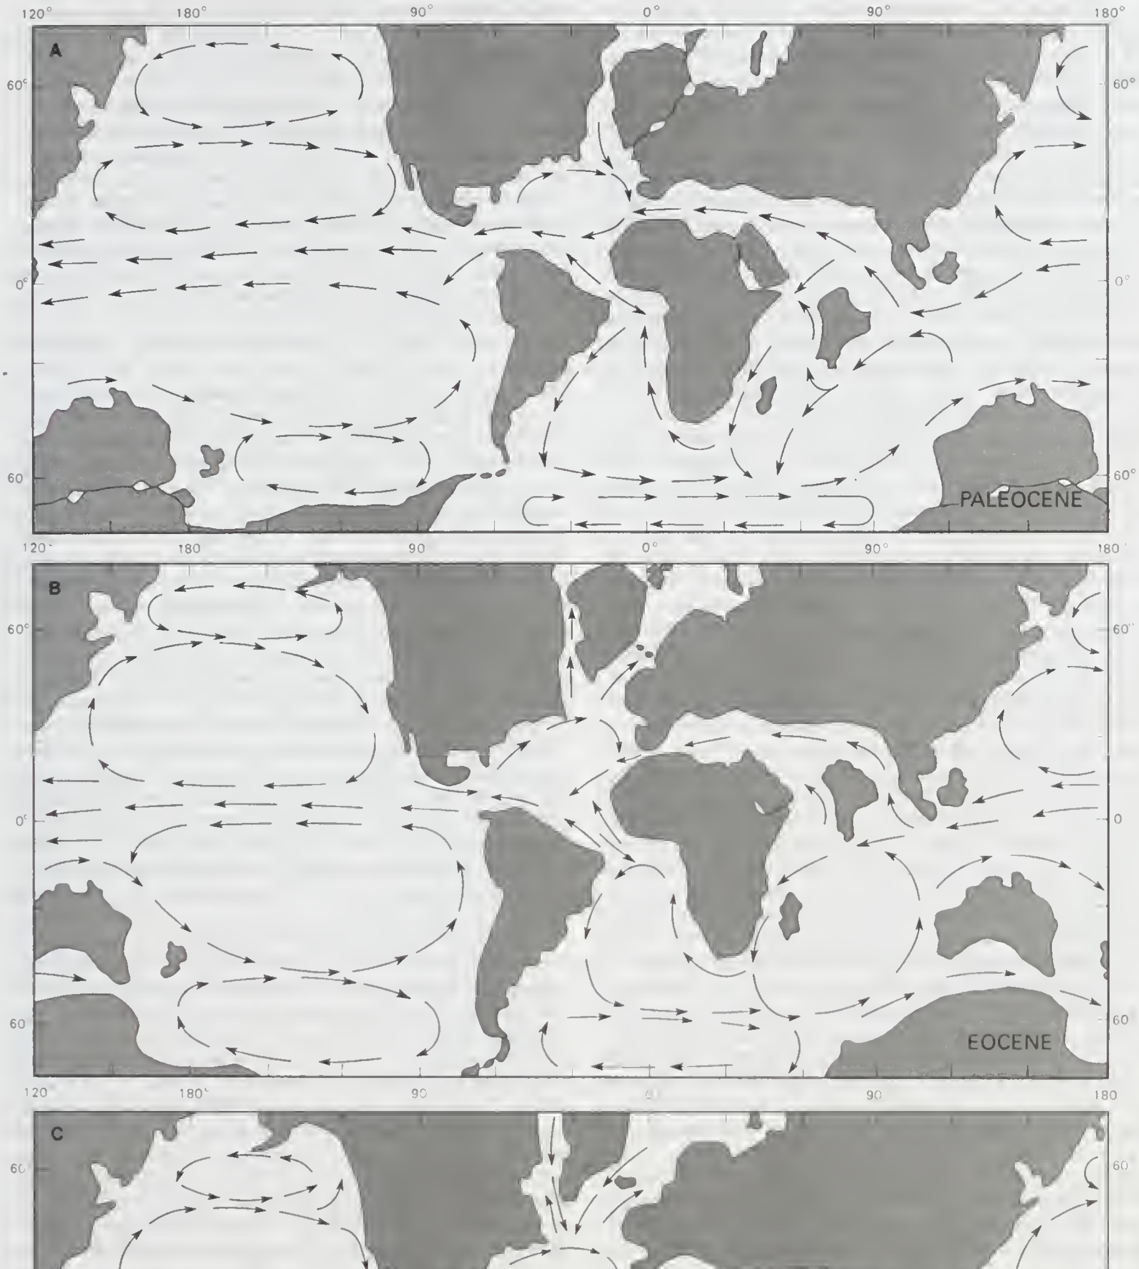

Figure 40: Inferred global ocean surface circulation patterns of the Paleogene plotted on a series of paleogeographic maps. (A) Clockwise-circulating subpolar gyres occur in the absence of a circum-Antarctic current system in the early Paleocene. (B) The Tethyan current north of India is restricted as the Indian Plate approaches the Eurasian continent during the mid-Eocene. Clockwise southern Atlantic and Pacific gyres persist owing to the disrupted flow of circulation around Antarctica resulting from continued closure of the Drake Passage. (C) During the late Oligocene, Tethyan flow is more restricted, having been diverted to the south of India after that continent's junction with Eurasia in the mid-Eocene. Cool water currents issue from the Arctic regions, and the circum-Antarctic current thermally isolates Antarctica from the world ocean, giving rise to colder climates and glacial conditions on Antarctica.

Migration of mammalian faunas

diversification of mammals. In the middle Eocene free land-mammal faunal migration between North America and Europe was interrupted by the severance of the land-bridge connection that had existed prior to this time. Although Europe was cut off from North America, Asia (especially Siberia) remained in contact with the latter in the late Eocene, and repeated migrations occurred throughout the Oligocene and Miocene. In the early Miocene, the first wave of immigration from Europe occurred, bringing bear-dogs, European rhinoceroses, weasels, and a variety of European deerlike animals to North America. In the early Miocene, mastodons escaped from their isolation in Africa, and by the middle Miocene they had reached North America. Rodents and early anthropoids evolved in the middle Eocene and the first elephants (Proboscidea) in the early Oligocene. Immigration of African mammalian faunas, including proboscideans, into Europe occurred about 18 million years ago (early Miocene).

The earliest apparent hominids have been reported in East Africa at about six to five million years ago and the subsequent australopithecine–hominid evolution in East Africa has been traced over the past three million years. In the late Pliocene, the Panamanic land bridge allowed porcupines, armadillos, and ground sloths to migrate from South America and live in the southern United States. A much larger wave of typically Northern Hemispheric animals, however, moved south and drove most of the South American endemic mammals to extinction. These North American invaders included dogs and wolves, raccoons, cats, horses, tapirs, llamas, peccaries, and even mastodons.

In the deep sea several major biotic events stand out. A major extinction event at the boundary between the Mesozoic and Cenozoic eras, 66.4 million years ago, affected dinosaurs, large marine reptiles, marine invertebrate faunas (rudists, belemnites, ammonites), and planktonic protozoans (foraminiferans) and phytoplankton (see above). On the other hand, deep-sea benthic protozoans suffered no effect until about 10 million years later at the boundary between the Paleocene and the Eocene, when more than half of all species suffered extinction under conditions that still remain unexplained but may be linked to changing deep-water circulation patterns. The present-day psychrospheric (*i.e.*, cold), benthic fauna evolved in the deep sea in the late Eocene about 36 to 35 million years ago, concomitant with significant cooling of oceanic deep waters of some 3°–5° C. The closure of the Tethyan seaway in the late early Miocene about 15 million years ago resulted in the disappearance of many of the larger tropical nummulitid-type foraminiferans that had ranged from Indonesia to Spain during most of the Tertiary. Although the descendants of these forms can be found today in the Indo-Pacific region, they show much less diversity.

The marine faunas of the eastern Pacific and West Indies–Caribbean region were similar throughout the Tertiary until about three million years ago. The elevation of the Isthmus of Panama at that time created a land barrier between the two regions that resulted in faunal provincialization.

Paleoclimate. Climatic history is intimately linked to the dynamic evolution of ocean-continent geometry and associated changes in oceanic circulation. The continued fragmentation of the world ocean due to changing positions of the main continental masses—principally a poleward shift in the Northern Hemisphere—led to increasingly inefficient latitudinal thermal-energy exchange. Paleobiogeographic and oxygen-isotope studies yield a complementary picture of a long-term global temperature decline, development of a thermally stratified ocean, and enhanced climatic differentiation during the Cenozoic. This climatic decline followed a faunally and florally recognizable climatic optimum in the early Eocene, which is also reflected in the oxygen-isotope records. In general terms Mesozoic oceanic circulation was latitudinal (and meridional transport of heat energy was relatively inefficient), whereas Cenozoic circulation has been predominantly longitudinal (meridional), although meridional heat transport has become increasingly less efficient during the Neogene as global temperatures have decreased.

Intensified climatic differentiation

During the early Paleogene, warm equable climates extended from pole to pole, with pole-to-equator temperature gradients of about 5° C during the Paleocene as compared to about 25° C today. The early Eocene witnessed the warmest conditions of the entire Cenozoic, with subtropical floras occurring on the margins of the Hampshire and London basins of southeastern England and varanid lizards, emydid turtles, alligators, and flying lemurs living on Ellesmere Island in the Canadian Arctic Archipelago. These circumstances attested to the presence of subtropical climates at 77° N latitude during this climatic optimum. Global cooling occurred during the middle and late Eocene and accelerated rapidly across the Eocene–Oligocene boundary at which time Antarctic continental glaciation was initiated.

Sea-level ice sheets had developed on West Antarctica during the early Oligocene and over most of the continent by the middle Miocene about 13 million years ago. Glaciation on the Antarctic continent in the late Miocene about 5.5 million years ago has been linked with the isolation of the Mediterranean Basin from the world ocean and its transformation into a desiccated basin not unlike present-day Death Valley for about 500,000 years. Mountain glaciers occurred in the Gulf of Alaska by the mid-Miocene and were followed by glaciers in Patagonian Argentina during the early Pliocene. The large ice sheets that covered northern Europe and North America first expanded about 3 million years ago, but major growth occurred 2.5 million years ago, at which time the Earth may be said to have passed over a thermal threshold initiating the so-called Ice Age, in which mode the Earth is still locked today. Repeated waxing and waning of the Northern Hemispheric glaciers over the past 2.5 million years resulted in significant and repeated expansions of the high-latitude belts of westerly winds toward the equator, changes in ocean circulation pattern (deflection of the Gulf Stream to an essentially east–west transit at about 40° N latitude), and the southward displacement of cool, dry climatic belts to southern Europe and North Africa during the cold periods.

As has been seen, the gradual breakup of Pangaea and Laurasia, closure of the Tethys Sea, and closure of the Panamanic Seaway have combined to provide greater provinciality in marine faunas during the Neogene.

Tertiary life. The end of the Mesozoic Era marked a major transition in Earth history. Major extinctions took place among marine and terrestrial animals; plant life suffered to a much lesser extent. The cause of this major event, whether single or multiple, is still being widely debated among specialists (see above *Mesozoic Era: Cretaceous Period: Cretaceous life: Mass extinctions*). In any case, the net result in the oceans was a marked reduction in diversity, primarily of calcium carbonate-secreting organisms (*i.e.*, coccolithophorids and planktonic foraminiferans), followed by a gradual recovery and radiation of new forms within a few hundred thousand years. The present-day ecosystem is for the most part populated by animals, plants, and single-celled organisms that survived and redeployed after the great extinction event at the end of the Mesozoic. Deep-sea benthic foraminiferans, mollusks, and teleost fishes survived and became prominent elements in the Paleogene seas. Following the extinction of the reef-building rudists at the end of the Cretaceous, reef-building corals recovered by the Eocene, and their low-latitude, continuous stratigraphic record is taken as an indicator of the persistence of the tropical realm. Whales (cetaceans) are descended from carnivorous terrestrial mesonychid Condylarthra; they had become adapted to the marine environment by the middle Eocene. Another enormous marine carnivore was the shark, which descended from an essentially similar form of the early Jurassic. Other new forms in the late Paleogene seas were the penguins, a group of swimming birds, and the pinnipeds, a group that includes seals, sea lions, and walruses.

New marine forms

The Cretaceous–Paleogene transition was not marked by any significant change in terrestrial floras. Angiosperms continued the radiation that had begun in the mid-Cretaceous about 100 million years ago. Grasses were present by late Paleocene time, but they did not expand to form the upland grasslands and prairies that are intimately linked to expansion of grazing animals until late Oligocene and Miocene time.

Evolution and distribution of foraminiferans. Since about the 1960s detailed studies have shown that the calcareous planktonic protozoan foraminiferans (superfamily Globigerinacea) have evolved rapidly and dispersed widely, following a major extinction at the end of the Cretaceous. These organisms have proved to be extremely useful in regional and global correlation of oceanic sediments and uplifted marine strata found on land. Differential rates of evolution within different groups give rise to the greater utility of some forms in stratigraphic zonation and correlation than others. For example, conical species of the Paleogene *Morozovella* and Neogene *Globorotalia* have stratigraphic ranges that vary from one to five million years.

The larger foraminiferans—the nummulitids—were a group of circular-to-elliptical, shallow-water, tropical, benthic forms that had complex, labyrinthine interiors and internal structural supports to strengthen their adaptation to life in high-energy environments. They contained symbiotic algae in life conditions and received nourishment from symbiosis performed by the entrained algae. The genus *Nummulites* occurred in massive numbers and large size (diameters up to 150 millimetres) during the great middle Eocene transgression and formed extensive limestone deposits in Egypt from which the pyramids were built. *Nummulites* lived throughout the Eurasian Tethyan province from late Paleocene to early Oligocene time but did not reach the New World. Following their extinction in the Oligocene, larger foraminiferans, the miogypsinids and lepidocyclinids, flourished during the Neogene. These forms are characterized by increased complexity in the internal part of the test (structural hard parts) by the addition of lateral chambers and changes in the geometry of the embryonic initial successive chambers. The miogypsinids ranged from the Oligocene to middle Miocene, while the lepidocyclinids disappeared in the early Pliocene, the last representative being recorded in Fiji.

Mammalian diversification and dominance

Vertebrates. In the terrestrial environment the most spectacular event of the Cenozoic has been the diversification and rise to dominance of the mammals. From only a few groups (opossums, archaic hoofed mammals, insectivorous mammals, and a number of extinct groups) that lived in the undergrowth hiding from the dinosaurs at the end of the Cretaceous, more than 20 orders of mammals evolved rapidly and were established by the early Eocene. During the Eocene, the first perissodactyls (such as primitive horses, rhinoceroses, and tapirs), artiodactyls (including camels and deer), rodents, and rabbits underwent wide dispersal, migrating via a northern Holarctic route, probably from Eurasia to North America. By the end of the Eocene, global climatic variations triggered changes in the vegetation from thick jungles to open forest/grasslands, causing extinction in most of the archaic browsing mammals typical of the Paleocene and Eocene. From the Oligocene onward, land mammal communities were dominated by groups living today, such as horses, rhinoceroses, antelopes, deer, camels, elephants, cats, and dogs. These groups, however, evolved significantly as the climate and vegetation changed to a more open, grassy habitat in the Miocene. Starting with primitive forms that had low-crowned teeth for browsing leafy vegetation, most of the herbivorous mammals evolved specialized teeth for grazing gritty grasses and long limbs for running and escaping more efficient predators. By the late Miocene, a savanna community analogous to that of the modern East African savanna was established on most continents. Beginning with the Messinian crisis of the late Miocene, climatic deterioration caused extinction in most of these mammals. Today, there remains but a pitiful remnant that has survived the subsequent Ice Age and the overhunting and habitat destruction caused by humans. (W.A.Be.)

QUATERNARY PERIOD

The Quaternary is both the shortest and most recent period of geologic time. It is the second period of the Cenozoic Era and began about 1.6 million years ago (see Table 4). The Quaternary is subdivided into two epochs, the Pleistocene and Holocene. The Pleistocene Epoch comprises almost all of Quaternary time; the Holocene, the latest and current interval, began a mere 10,000 years ago.

The term Quaternary originated early in the 19th century when it was applied to the youngest deposits in the Paris Basin in France. The designations Pleistocene and Holocene also date from the 19th century, when they were defined with respect to strata containing certain fossils or a certain percentage of fossils of plants and animals that were still living. Since their introduction, these terms have undergone a complex and confusing evolution with respect to their usage, and neither is used as originally defined.

In 1948 a decision was made at the 18th International Geological Congress in London that the Pliocene–Pleistocene boundary should be fixed in marine rocks exposed in the coastal areas of Calabria in southern Italy. As ratified by the International Commission on Stratigraphy in 1985, the type section for the Pliocene–Pleistocene boundary occurs in a sequence of marine strata at Vrica in Calabria (see below *Pleistocene Epoch: Stratigraphy*). A type section for the Pleistocene–Holocene boundary has yet to be agreed upon, but most investigators concur that it should be placed about 10,000 years ago.

Cycles of climatic change

The Quaternary is best characterized as a time of many cycles of climatic change. Some of these cycles resulted in the episodes of extensive glaciation of the Earth for which the Quaternary is well known. Although earlier studies suggested that there were four major glaciations, it is now recognized that many more occurred and that the climate of the Quaternary has alternated between periods of extensive ice buildup on land and periods of warmer climate, like today, when only about 10 percent of the land area is covered by glacial ice. The low-latitude regions of the Earth became increasingly arid during the Quaternary, and they were subject to fluctuating arid and more humid conditions. The climatic cycles and their resultant glaciations and periods of aridity had a dramatic effect on geologic processes, sedimentological regimes, the morphology of the terrestrial surface, and the fauna and flora on land and in the oceans. In addition, it was during the Quaternary that much of human evolution occurred, and these climatic cycles must have exerted a strong impact on the activities and distribution of early humans.

Understanding the Quaternary and its environments and climatic conditions is particularly important for interpreting past geologic time and for considering the future. According to the premise underlying the principles of uniformitarianism, studies of modern natural processes are the basis on which the past geologic record can be interpreted. Thus, studies of modern Holocene environments and processes provide the data base upon which inferences can be made on the origin and environments of older rocks, structures, landforms, and other Earth features. Of equal and probably greater importance are concerns regarding the current situation and the future. Present-day climatic conditions, ocean and continent configurations, and environments are similar to conditions that occurred during past Quaternary climatic cycles. Therefore, an understanding of the characteristics of these cycles and their cause provides a basis for predicting future climatic change and the environmental consequences of such change.

The significance of the Quaternary as a period of time was recognized more than a century ago. Grove K. Gilbert, an early prominent geologist of the United States Geological Survey, wrote in 1890: "When the work of the geologist is finished and his final comprehensive report written, the longest and most important chapter will be upon the latest and shortest of the geologic periods."

PLEISTOCENE EPOCH

The Pleistocene Epoch is best known as a time during which extensive ice sheets and other glaciers formed repeatedly on the landmasses and has been informally referred to as the "Great Ice Age." Modern research, however, has shown that large glaciers had formed prior to the Pleistocene—during the latter part of the Tertiary Period as well as during earlier periods of geologic time—and that glaciation is not unique to the Pleistocene.

Stratigraphy. *Pliocene–Pleistocene boundary.* Definition of the base of the Pleistocene has had a long and controversial history. Because the epoch is best recognized for glaciation and climatic change, many have suggested that its lower boundary should be based on climatic criteria—for example, the oldest glacial deposits or the first occurrence of a fossil of a cold-climate life-form in the sediment record. Other criteria that have been used to define the Pliocene–Pleistocene include the appearance of humans, the appearance of certain vertebrate fossils in Europe, and the appearance or extinction of certain microfossils in deep-sea sediments. These criteria continue to be considered locally, and some workers advocate a climatic boundary at about 2.4 million years.

Pre-Pleistocene intervals of time are defined on the basis of chronostratigraphic and geochronologic principles related to a marine sequence of strata. Following studies by a series of international working groups, correlation programs, and stratigraphic commissions, agreement was reached in 1985 to place the lower boundary of the Pleistocene series at the base of marine claystones that conformably overlie a specific marker bed in the Vrica section in Calabria. The boundary occurs near the level of several important marine biostratigraphic events and, more significantly, is just above the position of the magnetic reversal that marks the top of the Olduvai Normal Polarity Subzone, thus allowing worldwide correlation.

The Pleistocene is subdivided into informal time units, the early, middle, and late Pleistocene. The early Pleistocene extends to the Brunhes–Matuyama paleomagnetic boundary at 730,000 years ago, and the middle Pleistocene extends to the end of the next to the last glaciation at about 130,000 years. The late Pleistocene includes the last interglacial–glacial cycle ending at the Holocene boundary 10,000 years ago.

Chronology and correlation. The chronology of the Pleistocene originally developed through observation and study of the glacial succession, which in both Europe and the United States was found to contain either soils that developed under warm climatic conditions or marine deposits enclosed between glacial deposits. From these studies, as well as studies of river terraces in the Alps, a chronology was developed that suggested the Pleistocene consisted of four or five major glacial stages which were separated by interglacial stages with climates generally similar to those of today. Beginning with studies in the 1950s, a much better chronology and record of Pleistocene climatic events have evolved through analyses of deep-sea sediments, particularly from the oxygen isotope record of the shells of microorganisms that lived in the oceans.

Marine oxygen isotope record

The isotopic record is based on the ratio of two oxygen isotopes, oxygen-16 (^{16}O) and oxygen-18 (^{18}O), which is determined on calcium carbonate from shells of microfossils that accumulated year by year on the seafloor. The ratio depends on two factors, the temperature and the isotopic composition of the seawater from which the organism secreted its shell. Shells secreted from colder water contain more oxygen-18 relative to oxygen-16 than do shells secreted from warmer water. The isotopic composition of the oceans has proved to be related to the storage of water in large ice sheets on land. Because molecules of oxygen-18 evaporate less readily and condense more readily, an air mass with oceanic water vapour becomes depleted in the heavier isotope (oxygen-18) as the air mass is cooled and loses water by precipitation. When moisture condenses and falls as snow, its isotopic composition is also dependent on the temperature of the air. Snow falling on a large ice sheet becomes isotopically lighter (*i.e.,* has less oxygen-18) as one goes higher on the glacier surface where it is both colder and farther from the moisture source. As a result, large ice sheets store water that is relatively light (has more oxygen-16), and so during a major glaciation the ocean waters become relatively heavier (contain more oxygen-18) than during interglacial times when there is less global ice. Accordingly, the shells of marine organisms that formed during a glaciation contain more oxygen-18 than those that formed during an interglaciation. Although the exact relationship is not known, about 70 percent of the isotopic change in shell carbonate is the result of changes in the isotopic composition of seawater. Because the latter is directly related to the volume of ice on land, the marine oxygen isotope record is primarily a record of past glaciations on the continents (see Figure 41).

Long core samples taken in portions of the ocean where sedimentation rates were high and generally continuous and where water temperature changes were relatively small have revealed a long record of oxygen isotope changes that indicate repeated glaciations and interglaciations going back to the Pliocene. The record is relatively consistent from one core sample to the next and can be correlated throughout the oceans. Warmer periods (interglacials) are assigned odd numbers with the current warm interval, the Holocene, being 1, while the colder glacial periods are assigned even numbers. Subdivisions within isotopic stages are delineated by letters (see Figure 41). The ages of the stage boundaries cannot be measured directly, but they can be estimated from available radiometric ages of the cores and from position with respect to both paleomagnetic boundaries and biostratigraphic markers, and also by using sedimentation rates relative to these data.

The record for the last 730,000 years indicates that eight major glacial and interglacial events or climatic cycles of about 100,000 years' duration occurred during this interval. Similar cycles but of greater frequency and lesser magnitude continue back to the late Pliocene (see Figure 41). An isotopic record from the North Atlantic suggests the first major glaciation in that region occurred about 2,400,000 years ago, some 800,000 years before the start of the Pleistocene. It also suggests that the first glaciation likely to have covered extensive areas of North America and Eurasia occurred about 850,000 years ago during oxygen isotope stage 22. The largest glaciations appear to have taken place during stages 2, 6, 12, and 16; the interglacials with the least global ice, and thus possibly the warmest, appear to be stages 1, 5, 9, and 11. The last interglaciation occurred during all of stage 5 or just substage 5e, depending on location; the last glaciation took place during stages 4, 3, and 2; and the current interglaciation falls during stage 1.

The marine isotopic record is a continuous record, unlike most terrestrial records, which contain gaps because of erosion or lack of sedimentation and soil formation or a combination of these factors. Because of its continuity and its excellent record of climatic events on land (glaciations), the marine oxygen isotope record is the standard to which the terrestrial and other stratigraphic records are correlated. Correlations to it are based on available chronometric ages, on paleomagnetic data where available, and on attempts to match the terrestrial record and its interpretation with specific characteristics of the isotopic curve. Unfortunately, most terrestrial records contain few radiometric ages and are incomplete, and specific correlations, except for the most recent part of the record, are difficult and uncertain. A few terrestrial records, however, are exceptional and can be correlated with confidence.

Loess–paleosol records

Central China is covered by deposits of windblown dust and silt, called loess. Locally the loess is more than 100 metres thick, mantling hillsides and forming loess plateaus and tablelands. The loess accumulated primarily during times that were colder and drier than present, and most of it was derived from desert areas to the west. The loess succession contains many colourful buried soils or paleosols that formed during periods which were both warmer and wetter than today. Thus, on stable tablelands with minimal erosion, the succession provides an exceptional climatic and chronological record that extends back 2.4 million years to the late Pliocene. In total, up to 44 climatic cycles have been delineated, with more frequent cycles occurring during the early Pleistocene. Although not directly related to glaciation, correlation with the marine oxygen isotope record is excellent, and many of the specific loess and soil units have similar climatic inferences, as do their correlative oxygen-18 stages.

Another loess–paleosol succession occurs in the Czech Republic, Slovakia, and Austria, where loess blankets terraces of the major rivers that drained eastward and southward from the principal glaciated areas in the Alps and northern Europe. As in China, buried soils are common in the loess succession and, along with gastropod shells, provide

paleoclimatic data and evidence for climatic change. The climatic cycles varied from cold and dry conditions when loess accumulated to warm and wet conditions with hardwood forests and well-developed soils. In the last 730,000 years, eight climatic cycles have been delineated; these correlate with the eight oxygen-18 cycles that occurred in the marine record during the same time interval. During the entire Pleistocene, about 17 glacial episodes alternated with 17 interglacials.

Glacial records

Glacial till, which was directly deposited by glaciers, covers extensive areas of northern Eurasia and northern North America and occurs as well in many mountain regions and other areas that currently are not covered by glacial ice. Soils of warm climate origin buried between tills were recognized long ago and provided the basis for the development of the idea of multiple glaciation during the Pleistocene. However, because direct dating of the deposits generally is not possible and the glacial sequence is not complete as a result of erosion or nondeposition or a combination of the two, the development of long chronological records and correlation to the oxygen-18 record are difficult. Correlations generally are possible for the last two climatic cycles. They also are feasible in areas where the glacial succession contains interbedded volcanic rocks from which radiometric ages can be obtained.

In the mid-continental region of the United States, early work recognized tills that were interpreted to represent four major glaciations and three major buried soils that were viewed as representing interglaciations (see Table 26). Subsequent work showed that the glaciated record was more complex and that parts of the older record were miscorrelated. Consequently, the older portion of the record is informally referred to as the pre-Illinoian, and the older glacial and interglacial terms are no longer used except locally. Volcanic ash occurs within the succession in Iowa, Kansas, and Nebraska and is useful for correlation and dating. In one core, till occurs below ash that has been dated at about 2.2 million years old, suggesting late Pliocene glaciation. Other tills of the pre-Illinoian sequence probably are correlative with oxygen-18 stages 22, 16, and 12, and possibly others. The Illinoian correlates with oxygen-18 stage 6 and possibly stage 8, and the Sangamonian correlates with stage 5. The last glacial interval, the Wisconsinan, is subdivided into three parts, an early stade (substage) of glaciation, a middle interstadial, or time of restricted glaciation, and a late stade of glaciation. These intervals generally correlate with oxygen-18 stages 4, 3, and 2, respectively. Deposits of the early and middle Wisconsinan are poorly known in the mid-continental region of the United States; the area probably was not glaciated. Tills of the early Wisconsinan and even some that are correlative with oxygen-18 substages 5d or 5b, however, are common in the Canadian Arctic and on Baffin Island, where the ice sheet developed much earlier. It was not until the late Wisconsinan, about 18,000 years ago, that the southern ice sheet margin reached its maximum extent in the United States and eastern and western Canada. The ice sheet margin began to retreat and downwaste (*i.e.,* thin out) soon after reaching its maximum position, and the United States was deglaciated by about 10,000 years ago. Hudson Bay, near the centre of the ice sheet, was open to the ocean by 8,000 years ago, and, except for the Barnes and Penny ice caps on Baffin Island, the ice sheet had dissipated from the upland areas of central Canada by 6,000 years ago, well into the Holocene and oxygen-18 stage 1.

A somewhat similar chronology has been developed for the glaciated areas of Eurasia and the British Isles based on a variety of criteria. In addition to tills and buried soils, marine deposits, permafrost features, and fossil pollen and beetles have been used to subdivide the succession on a climatic basis. As elsewhere, the earlier portion of the record is not well established, and correlations among different geographic areas, as well as to the marine oxygen-18 record, are uncertain (see Table 26). The first cold period, known as the Pretiglian and based on pollen data from The Netherlands, began about 2.3 million years ago, soon after e:tensive ice-rafted material first appears in North

Atlantic deep-sea cores. The Pretiglian was followed by a succession of warm and cold intervals, which also are based on pollen and on other flora and fauna evidence and which have been given different names in different areas. Although several old gravels with glacial erratics are known, the oldest major glacial episodes with extensive till deposits are the Elsterian in northern Germany and the Anglian in England. These glaciations probably are correlative with oxygen-18 stage 12, and local evidence suggests the possibility of earlier glacial events. Along coastal areas, these tills are overlain by the marine Holstein deposits, which also may represent more than one high sea-level stand. The next major glacial sequence is the Saalian of Germany, which is subdivided into the Drenthe and the Warthe; these probably correlate with oxygen-18 stages 8 and 6, respectively. Deposits and soils of the last interglaciation, the Eemian and Ipswichian, are correlative with oxygen-18 stage 5e, and those of the last glaciation, the Weichselian and Devensian, correlate with oxygen-18 stages 5d–a, 4, 3, and 2. As in central North America, tills and other deposits are well known only from the last part of this interval. The deglacial history generally is similar, except for a widespread but short interval of renewed glacial activity and cold climatic conditions that is known as the Younger Dryas in Scandinavia and Loch Lomond in the British Isles. This event occurred about 11,000 years ago, some 2,000 years before the dissipation of the ice sheet.

Ice-core records

A relatively short but important late Pleistocene and Holocene climatic record is derived from ice cores that have been taken from the ice sheets of Antarctica, Greenland, and Arctic Canada. The ice record in several cores extends back to the last interglaciation (oxygen-18 stage 5) and, in one case, to the next-to-the-last glaciation (stage 6). Although dating of the lower portions of the ice cores is difficult, annual layers of snow and ice can be counted in the upper parts and an accurate time scale reconstructed. Because the air temperature at the time when moisture condenses to fall as snow controls the oxygen and hydrogen isotopic composition of the snow, investigators are able to reconstruct temperature variations through isotopic studies of the ice cores. Data from the Vostok core taken from the East Antarctic Ice Sheet indicate that the climatic record of the Southern Hemisphere is similar to that interpreted from Northern Hemisphere records with respect to times of glaciation and interglaciation (see Figure 42). It also is possible to measure the amount of microparticles (very fine dust) in the ice, and studies of this kind show that there are many more particles in the portions of the core that accumulated during periods of extensive glaciation, apparently reflecting greater atmospheric circulation and dust in the atmosphere at those times. Trapped air preserved in small bubbles in the ice gives an indication of the composition of the atmosphere at the time the ice (snow) accumulated. An important result from this work indicates that the amount of carbon dioxide in the atmosphere during the last glacial (stages 2, 3, and 4) was substantially less than during the Holocene (stage 1) and the last interglaciation (stage 5e). This observation has significant implications with respect to climate and climatic change during glacial and interglacial transitions.

Pleistocene events and environments. Environments during the Pleistocene were dynamic and underwent dramatic change in response to cycles of climatic change and the development of large ice sheets. Essentially all regions of the Earth were influenced by these climatic events, but the magnitude and direction of environmental change varied from place to place. The best-known are those that occurred from the time of the last interglaciation, about 125,000 years ago, to the present.

Glaciation. The growth of large ice sheets, ice caps, and long valley glaciers was among the most significant events of the Pleistocene. During times of extensive glaciation, more than 45 million square kilometres (or about 30 percent) of the Earth's land area were covered by glaciers, and portions of the northern oceans were either frozen over or had extensive ice shelves. In addition to the Antarctic and Greenland ice sheets, most of the glacial ice was located in the Northern Hemisphere, where large ice sheets extended to mid-latitude regions. The largest was the Laurentide Ice Sheet in North America, which at times stretched from the Canadian Rocky Mountains on the west to Nova Scotia and Newfoundland on the east and from southern Illinois on the south to the Canadian Arctic on the north (see Figure 43). The other major ice sheet in North America was the Cordilleran Ice Sheet, which formed in the mountainous region from western Alaska to northern Washington. Glaciers and ice caps were more widespread in other mountainous areas of the western United States, Mexico, Central America, and Alaska, as well as on the islands of Arctic Canada where an ice sheet has been postulated.

Although smaller in size, the Scandinavian Ice Sheet was similar to the Laurentide in character (see Figure 43). At times, it covered most of Great Britain, where it incorporated several small British ice caps, and extended south across central Germany and Poland and then northeast across the northern Russian Plain to the Arctic Ocean. To the east in northern Siberia and on the Arctic Shelf of Eurasia, a number of small ice caps and domes developed in highland areas, and some of them may have coalesced to form ice sheets on the shallow shelf areas of the Arctic Ocean. Glaciers and small ice caps formed in the Alps and in the other high mountains of Europe and Asia. In the Southern Hemisphere, the Patagonia Ice Cap developed in the southern Andes, and ice caps and larger valley glaciers formed in the central and northern Andes. Glaciers also developed in New Zealand and on the higher mountains of Africa and Tasmania, including some located on the equator.

Glaciers and ice caps in the Andes

The results of glaciation varied greatly, depending on regional and local conditions. Glacial processes were concentrated near the base of the glacier and in the marginal zone. Material eroded at the base was transported toward the margin, where it was deposited both at the glacier bed and in the marginal area. These processes resulted in the stripping of large quantities of material from the central zones of the ice sheet and the deposition of this material in the marginal zone and beyond the ice sheet. The Laurentide and Scandinavian ice sheets scoured and eroded bedrock terrain in their central areas, leaving behind many lakes and relatively thin glacial drift. On the other hand, the Central Lowland and the northern Great Plains of the United States and the western plains of Canada, as well as northern Germany and Poland, southern Sweden, and portions of eastern and northern Russia, contain relatively thick deposits of till and other glacial sediment. The landscape of such areas is flat to gently rolling. Today, these areas are among the great agricultural regions of the world, which is in large part attributable to glaciation.

The effects in mountainous terrain were even more dramatic. Glacial processes were concentrated in the upper regions where snow accumulated and in the valleys through which the glaciers moved to lower elevations. These valley glaciers carved towering peaks (such as the Matterhorn in the Alps), large rock basins, and sweeping U-shaped valleys and left some of the most spectacular scenery on the Earth, with many high-level lakes and waterfalls. The lower portions of the valleys commonly contain ridges of glacial drift. Ridges of this sort that form along valley slopes are called lateral moraines, while those that loop across a valley at the lower end of a glacier are termed end moraines. The earliest observations and interpretations of more extensive Pleistocene glaciation were made on such deposits and landforms in the Alps during the early part of the 19th century.

Periglacial environments. The environment around the ice sheets was markedly different from that of today in these formerly glaciated areas. Temperatures were much lower, and a zone of permafrost (perennially frozen ground) developed around the southern margin of the ice sheets in both North America and Eurasia. This zone was relatively narrow in central North America, on the order of 200 kilometres, but in Europe and Russia it extended many hundreds of kilometres south of the ice margin. Mean annual temperatures near the ice margin were about −6° C or colder and increased away from the ice margin to about 0° C near the southern extent of the permafrost. Compared to present-day conditions, the mean air temperature was on the order of 12° to 20° C colder near the ice margin. These conditions are indicated by ice-wedge casts and large-scale patterned ground, which are relict forms of ice wedges and tundra polygons that form today only in areas with continuous permafrost. Frost activity through freezing and thawing was intensified, and in areas of more relief talus accumulations and large block fields formed along escarpments and valley sides. Mass-wasting processes also were intensified and much material was eroded from slopes in periglacial areas. Deposits and landforms from such activity are known from the British Isles, northern Europe, and what was formerly the Soviet Union.

Lacustrine environments. Large lakes, usually many times bigger than their modern counterparts, were common during the Pleistocene. They fluctuated in level in response to the major climatic cycles or the opening and closing of outlets due to glaciation and vertical movements of land areas. Some lakes were closely tied to glaciation. In North America a series of large proglacial lakes formed around the margin of the Laurentide Ice Sheet during backwasting (recession) of the ice margin into Hudson Bay. The lakes were confined in part by the ice margin and in part by higher land to the south, east, and west. One of the largest was Lake Agassiz, which covered sizable areas of Manitoba, Ontario, and Saskatchewan and extended into North Dakota and Minnesota. The Great Lakes also formed as a result of glaciation as lobes of ice moved down preexisting lowlands and scoured out the weak rocks in the basins. Other lakes formed in the Champlain and Hudson valleys in eastern North America during deglaciation. Similar glacial lakes developed around the Scandinavian Ice Sheet and in other glaciated regions.

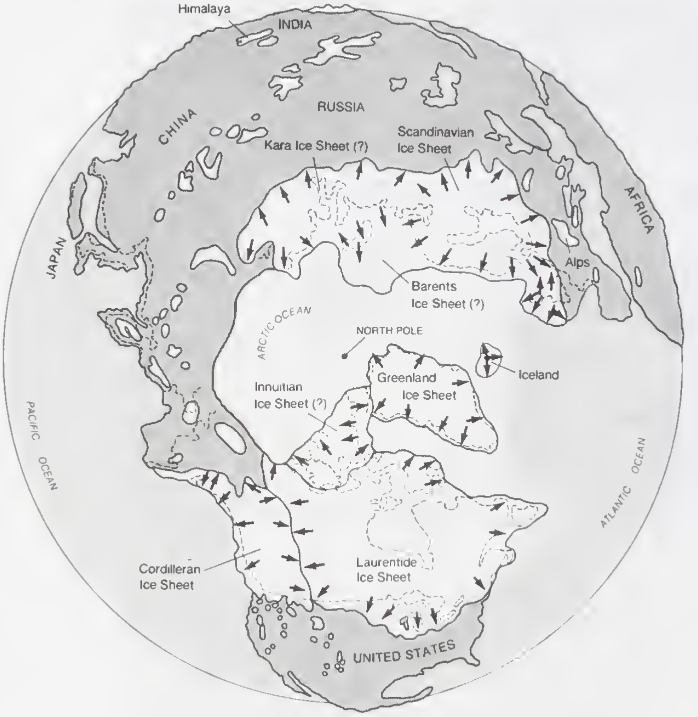

Figure 43: Areas of the Northern Hemisphere that were covered by glacial ice during the last glaciation. The arrows indicate the general direction of ice flow, and sea ice is shown covering the Arctic Ocean and extending south into the North Atlantic. The existence of the Barents, Kara, and Innuitian ice sheets remains open to dispute.

Pluvial lakes

Of equal interest was the development of large lakes in areas that today have arid to semiarid climatic regimes and generally lack lakes or have modern lakes that are much reduced in size and are saline in character. Such lakes are referred to as pluvial lakes, and the climate under which they existed is termed a pluvial climate. Most of these lakes existed in closed basins that lacked outlets, and thus their levels were related to relative amounts of precipitation and evaporation. A record of fluctuating lake levels is provided by ancient shorelines and beach deposits that are present along the slopes of the enclosing mountains as well as by the sediment and soil record preserved in the subsurface deposits of the lake basins. The history of lake fluctuations varies somewhat locally within a region but may be much different from one region of the world to another, depending on the local and regional climate.

In the Great Basin of Utah, Nevada, California, and Oregon and in other areas of the western and southwestern United States and Mexico, about 100 basins contained lakes during the Pleistocene (see Figure 44). The largest of these was Lake Bonneville, the predecessor of the modern Great Salt Lake in Utah. At its highest stage Lake Bonneville covered an area of about 52,000 square kilometres, and its maximum depth was approximately 370 metres. These conditions existed about 15,000 years ago during the interval of the last major Pleistocene glaciation. Lake Bonneville shrank rapidly in size and, by 12,000 years ago, had permanently shrunk to a point where it had become smaller than the Great Salt Lake. A long record of fluctuating lake levels is evident from a 930-metre core taken in the Searles Lake basin in California. Parts of the sediment record from the core sample indicate a deep lake with lacustrine silts and clays and freshwater fossils. Other parts contain unusual evaporite minerals which indicate that the lake was shallow and highly saline or even evidence of sediment exposure indicative of the complete dessiccation of the lake. The inferred climatic record from the core is similar to the marine oxygen isotope record but differs in that it shows more variation in the amplitude of the climatic cycles.

Pluvial lakes in these areas were most extensive during times of widespread glaciation in the Northern Hemisphere and were low or dry during times of reduced glacial cover. Paleoclimatic modeling suggests that the Laurentide Ice Sheet forced the polar jet stream south of its present-day position during glaciation. This brought more moisture from the Pacific into the desert areas of the southwestern United States, causing greater precipitation as well as producing more cloud cover, which, together with lower temperatures, resulted in less evaporation.

Pluvial lakes also were common in other dry regions of the world, particularly in the subtropical zones, including eastern and northern Africa and portions of Australia, Asia, and the Middle East. Examples of these pluvial bodies are the Dead Sea in Jordan and Israel and Lake Chad in the southern Sahara. The latter, now a shallow saline lake, covered some 300,000 square kilometres and was about six times the size of Lake Bonneville. A number of lakes in the rift valleys of East Africa were larger and deeper than they are today. Among the better-known and better-understood are Lakes Rudolf, Victoria, Nakuru, Naivasha, Magadi, and Rukwa. Most of these lakes in the tropical and subtropical regions were not in phase with those in the Great Basin of North America. They were relatively high for some 20,000 or more years immediately before the last glaciation and again just after the last glaciation in the early Holocene. A long climatic record inferred from sediments in Lake George in southeastern Australia has characteristics similar to those of the marine oxygen isotope record. Alternating humid and arid climatic cycles were more rhythmic and of greater magnitude in the middle and late Pleistocene than earlier, and a major change in basin hydrology occurred approximately 2.5 million years ago.

Rivers and river valleys

Fluvial environments. Rivers and the valleys that they occupy were affected strongly by the changing climates of the Pleistocene. River channels and their sediment record are controlled in large part by the amount and type of load that is supplied by their drainage basins and the discharge or quantity of water available for flow. Both are closely related to climate, which not only includes precipitation, evaporation, and seasonality but also controls the extent of

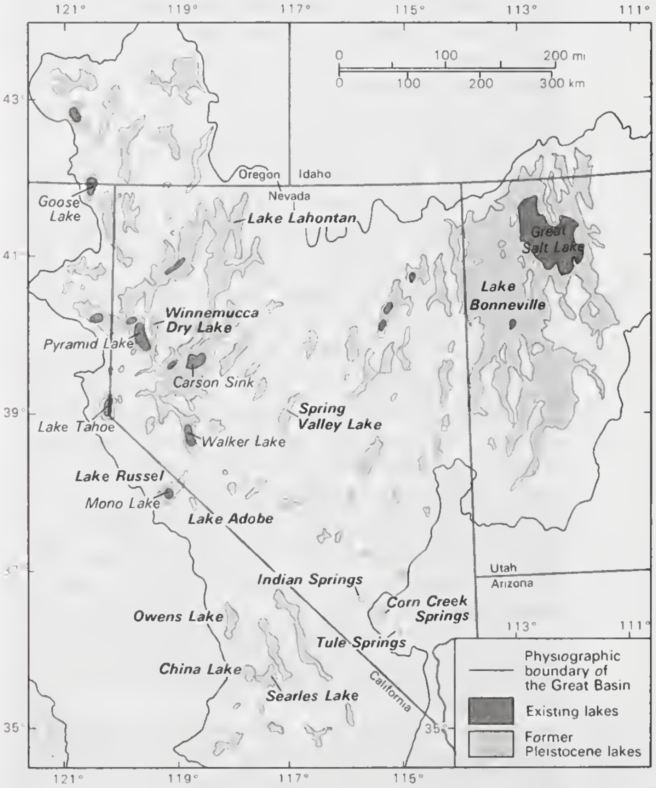

Figure 44: Distribution of late Pleistocene pluvial lakes and existing lakes in the Great Basin of the western United States.

Adaptation ot map "Lakes and Marshes ot Assumed Late-Pleistocene Age in the Great Basin," "Late Wisconsin Paleoecology of the American Southwest" by W G Spaulding, Leopold and Van Deuender *Late-Quaternary Environments of the United States*, H E Wright, Jr , ed , vol 1, *The Late Pleistocene*, Stephen C Porter, ed the vegetative cover of the land and the type and intensity of weathering processes. In addition, because of sea-level changes related to glaciation, the base level of rivers in coastal regions also fluctuated by significant amounts. As a result, river environments were dynamic and variable.

This was true for most rivers, but particularly so for those rivers that drained large quantities of meltwater and sediment from the glacier margins. During glaciation, rivers of the latter kind developed braided-channel patterns in response to the input of large quantities of sediment derived from the melting glaciers and subglacial waters and to the large fluctuations in the quantity of water flowing at any one time, which varied because of seasonal and diurnal controls on the generation of meltwater. During times of glaciation many of these rivers deposited thick sequences of sand and gravel in their valleys; examples include those of the Hudson, Mississippi, and Ohio rivers in the United States and of the Thames, Elbe, Rhine, and Seine rivers in Europe. Similar valleys have been buried by younger glacial deposits and are no longer evident at the surface. They exist today as bedrock valleys with thick fills of fluvial sand and gravel or lacustrine silt in localities where lakes existed in the valleys as a result of glacial damming. The sand and gravel fill in the surface valleys provide aggregate material for construction, and much groundwater is derived from the fills of both surface and buried valleys.

Some glacial valleys, as well as large upland areas, were sites of major catastrophic floods that resulted from the sudden drainage of proglacial and subglacial lakes. Such floods are known as jökulhlaups, an Icelandic term for subglacial lake outbursts. The largest and best-known floods of this type occurred in the Channeled Scabland of the Columbia Plateau region in eastern Washington state. Ice tongues flowing south from the Cordilleran Ice Sheet periodically dammed the Clark Fork River, forming glacial Lake Missoula. At times, Lake Missoula stretched more than 200 kilometres upvalley and was about 600 metres deep near the ice dam. Sudden failure of the ice dam released over 2,000 cubic kilometres of water, which flooded westward and southward across the Columbia Plateau and down the Columbia River valley. The floods cut through a loess cover into basalt and left a system of large dry channels with waterfalls, potholes, and longitudinal grooves in the basalt. Associated with the dry channels are huge, coarse gravel bars and giant current ripples. Other large catastrophic floods resulted from the sudden drainage of glacial Lake Agassiz and from the ancestral Great Lakes, as well as from some nonglacial lakes such as Lake Bonneville in the Great Basin (see above). During the Anglian–Elsterian glaciation in Europe a large ice-dammed lake formed in the North Sea, and large overflows from it initiated cutting of the Dover Straits.

During the transition from glacial to interglacial conditions, river channel patterns evolved from braided to meandering as a result of decreased load and possibly discharge. Near glaciated areas, rivers eroded into glacial oûtwash and left a system of stream terraces along the sides of most valleys. These modern interglacial rivers are much smaller than their glacial counterparts and are underfit (*i.e.*, appear too small) with respect to the large valleys in which they flow. In contrast, near coastal areas rivers actively built up their channels during the transition to interglacial conditions in response to rising sea level.

Coastal environments and sea-level changes. Coastal environments during the Pleistocene were controlled in large part by the fluctuating level of the sea as well as by local tectonic and environmental conditions. As a result of the many glaciations on land and the subsequent release of meltwater during interglacial times, sea level has fluctuated almost continuously between interglacial levels, like those of today, and levels during times of maximum glaciation, such as 18,000 years ago when sea level was more than 100 metres lower. At that time all the continental land areas were larger, and extensive areas of the world's continental shelves were exposed to weathering, soil formation, and fluvial and eolian activity and were inhabited by plants and animals. The Bering Shelf was exposed at this time and Siberia was connected to Alaska by a land bridge, thus allowing intercontinental migration of animals, including early humans. Rapid melting of the last large ice sheets resulted in a rising sea level that reached near modern level by the mid-Holocene, about 5,000 years ago. As a consequence, Pleistocene coastal environments are submerged below sea level in most parts of the world and are poorly known.

Fortunately some coastal areas of the world were undergoing tectonic uplift during the Pleistocene, and as a result older shorelines and their deposits are exposed above modern sea level. Study of these deposits is important in understanding the recent sea-level record and in relating it to the record of glaciation. The most important are shorelines that contain coral reefs, because it is possible to obtain radiometric ages on fossils in the reef complex. Two of the most important and best-dated records are on the island of Barbados in the Caribbean and along the Huron Peninsula of New Guinea (see Figure 45). The latter area exposes a spectacular suite of coastal terraces due to steady and rapid uplift during the Pleistocene. Age determinations of the terraces indicate times of relatively high sea level and suggest that they occurred at intervals of about 20,000 years. The highest sea level prior to the modern level occurred about 125,000 years ago and correlates with the peak warm interval of the last interglaciation (oxygen-18 stage 5e). Sea level at that time was about six metres higher than it is today.

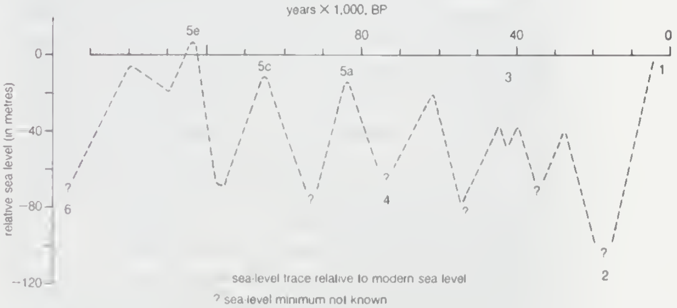

Figure 45: Late Pleistocene paleosea levels based primarily on data from New Guinea and Barbados. Correlative marine oxygen isotope stages are indicated.

Eolian activity. Eolian deposits are important in the Pleistocene record and indicate widespread wind action at certain times and in certain areas of the world. Mention has already been made of the importance of loess–paleosol records in working out regional chronologies and paleoclimatic history. Loess blankets large portions of the central and northwestern United States, Alaska, the east European plain of Russia, and southern Europe, where it is closely related to episodes of glaciation or to the cold periglacial climate beyond the ice sheet margins or to both. The loess was derived primarily from the broad floodplains of the braided rivers draining meltwater and sediment away from the glaciers as well as from newly exposed glacial drift. Locally, sand dunes and sheets of sand occur near the valley sources and in some cases cover large upland areas, as in central and northern Europe. The loess in China, on the other hand, is considered to have been deflated mostly from such desert areas as the Gobi.

Correlation between periods of peak aridity and peak glaciation

The deserts of the subtropical regions also experienced eolian activity during the Pleistocene. In Australia, the time of peak aridity and maximum dune activity (about 20,000 to 12,000 years ago) correlates with the time of peak glaciation in the Northern Hemisphere. This also was the case in the Sahara and other deserts in Africa, India, and the Middle East. One estimate is that the tropical arid zones were five times larger during times of peak glaciation. Sea level was lower at these times, the water was colder, and tropical cyclones were less extensive, resulting in decreased rainfall. These episodes of intensified eolian activity are recorded in other Pleistocene records. Ocean cores taken downwind of these regions contain windblown sediment in the portions of the core that accumulated during times of maximum eolian activity. In addition, microparticles occur in ice cores taken from the Greenland and Antarctic ice sheets and are concentrated at times of maximum glaciation and aridity in the subtropical deserts (see above Figure 42). At other times, the climate was less arid and the desert areas contracted, and vegetation developed to stabilize the dunes under more humid (pluvial) conditions.

Tectonic and isostatic movements. The lithospheric plates continued to shift during the Pleistocene, but the continents essentially were in their modern position at the start of the epoch. Of more importance to subsequent Quaternary events were the late Tertiary tectonic movements that affected the evolution of climate toward that of the Quaternary. Among these were the formation of the Isthmus of Panama, which affected oceanic circulation, and the uplift of the Tibetan Plateau and broad regional areas of the western United States, which affected atmospheric circulation, particularly the position and configuration of the polar jet stream.

Vertical movements of the Earth's crust also were caused by the formation and melting of large ice sheets. The area beneath an ice sheet subsides during glaciation because the crust is not able to sustain the weight of the glacier. These isostatic movements take place through the flow of material in the Earth's mantle, and the amount of subsidence amounts to about one-third the thickness of the ice sheet—for example, about one kilometre in the central area of the Laurentide Ice Sheet in Canada. Melting of the ice sheet removes the load and causes the ground to rise, or rebound. Such uplift is rapid at first but decreases with time. More than 300 metres of uplift has occurred in the eastern Hudson Bay area since that area was deglaciated. Substantial uplifting also took place prior to the complete melting of the ice sheets, and upward crustal movement continues today at a maximum rate of about 1.3 centimetres per year. A similar record of glacio-isostatic adjustments is encountered in Fennoscandia, where the greatest depression and subsequent uplift related to the Scandinavian Ice Sheet is located in the Gulf of Bothnia.

Pleistocene fauna and flora. The plants and animals of the Pleistocene are, in many respects, similar to those living today, but important differences exist. Moreover, the spatial distribution of various Pleistocene fauna and flora types differed markedly from what it is at present. Changes in climate and environment caused large-scale migrations of both plants and animals, evolutionary adaptations, and in some cases extinction. Study of the biota provides not only data on the past paleoenvironments but also insights into the response of plants and animals to well-documented environmental change. Of particular importance is the evolution of the genus *Homo* during the Pleistocene and the extinction of large mammals at the end of the epoch.

Evolutionary changes. Evolutionary changes during the Pleistocene generally were minor because of the short interval of time involved. They were greatest among the mammals. In fact, the epoch has been subdivided into mammalian ages on the basis of the appearance of certain immigrant or endemic forms (Table 27).

Table 27: Pleistocene Mammalian Ages in North America and Europe

North America	Europe
Rancholabrean	Steinheimian
Irvingtonian	Biharian
Blancan*	Villanyian*
	Villafranchian*

*These mammalian ages are Pliocene, but the associated forms are relatively similar to those of Pleistocene faunas.

Mammalian evolution included the development of large forms, many of which became adapted to Arctic conditions. Among these were the woolly mammoth, woolly rhinoceros, musk ox, moose, reindeer, and others that inhabited the cold periglacial areas. Large mammals that inhabited the more temperate zones included the elephant, mastodon, bison, hippopotamus, wild hog, deer, giant beaver, horse, and ground sloth. The evolution of these as well as of much smaller forms was affected in part by three factors: (1) a generally cooler, more arid climate subject to periodic fluctuations, (2) new migration routes resulting largely from the emergence of intercontinental connections during times of lower sea level, and (3) a changing geography due to the uplift of plateaus and mountain building.

Appearance of hominids

The most significant biological development was the appearance and evolution of the genus *Homo*. The oldest species, *H. habilis,* probably evolved from an australopithecine ancestor in the late Pliocene. The species was present in Africa by 2 million years ago and is known from sites as young as 1.5 million years old. Another extinct species, *H. erectus,* evolved in Africa, possibly from *H. habilis,* and is known from sites about 1.6 million years old. *H. erectus* spread to other parts of the Old World during the early Pleistocene and is known from northern China and Java by roughly 1 million years ago. Representatives of this group are known from many sites, and these beings constituted the dominant human species for more than a million years. The species *H. sapiens,* to which all modern humans belong, evolved in the later part of the middle Pleistocene, and early forms of the species are known from about 400,000 years ago. More modern forms of *H. sapiens,* the Neanderthals, appeared approximately 100,000 years ago during the last interglaciation and are known from many sites in Europe and western Asia. They disappeared about 35,000 to 30,000 years ago, and by then populations with fully modern skeletons had evolved and were widespread in the Old World. Exactly when modern *H. sapiens* entered the New World remains controversial. It appears that fully evolved humans had migrated as far as Alaska from Siberia via the Bering land bridge by 30,000 years ago, and large numbers presumably moved south down the Canadian plains corridor between the Cordilleran and Laurentide ice sheets when it opened near the end of the last glaciation some 12,000 years ago. Conflicting and not fully accepted evidence at a few sites in the United States and in southern South America, however, suggests occupation of the continental interior prior to 30,000 years ago. If such findings are valid, the group of earlier immigrants may have arrived by small ocean-going craft from the Pacific Islands.

Migration of plants and animals. Changing environments in response to climatic variation caused drastic disruptions of faunas and floras both on land and in the oceans. These disruptions were greatest near the former ice sheets that extended far to the south and caused the southward displacement of climatic and vegetation zones. In the temperate zones of central Europe and the United States where deciduous forests exist today, vegetation was open and most closely resembled the northern tundra, with grasses, herbs, and few trees during glacial intervals. Farther south, a broad region of boreal forests with varying proportions of spruce and pine or a combination of both extended almost to the Mediterranean in Europe and northern Louisiana in North America. The vegetation succession has been documented by studies of fossil pollen, which accumulated year by year with other sediments in lakes and bogs beyond the ice margin (see Figure 46). Although such floral migrations appear simple in concept, interpretation of the vegetation record is quite complicated because a number of the glacial pollen assemblages have no modern analogues—*i.e.,* they contain mixtures of forms from different present-day climatic environments. Similar relationships also occur with vertebrate faunas: more temperate forms commonly occur together with more Arctic forms. Such "disharmonious" faunas suggest that glacial climatic and environmental conditions in some cases were totally unlike those of any modern environment. One explanation is that climatic conditions may have been more equable during glacial times and may have lacked the seasonal extremes of modern climates in such areas. Although overall temperatures were significantly lower, summers probably were much cooler because of the influence of the ice sheet, and winters, except very near the ice margin, lacked severe cold spells, as the ice sheet formed a barrier to Arctic air masses that today bring freezing conditions far to the south. Thus, plants and animals whose geographic ranges would ordinarily be controlled by either

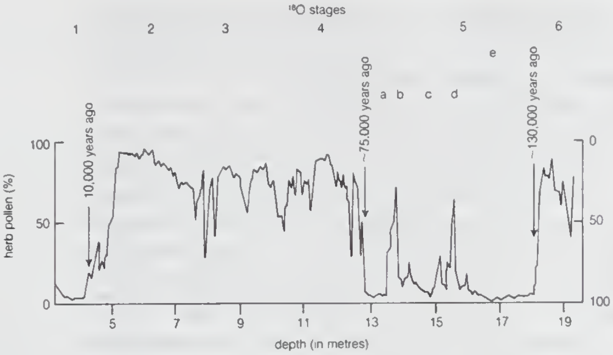

Figure 46: Relative proportions of herb and tree pollen from a core of a peat bog at Grande Pile, northwestern France. Correlative marine oxygen isotope stages are indicated. Vegetation varied from deciduous forest to tundra with abrupt changes in vegetation.

From G. Woillard (1979) in W S Broecker and G H Denton, *Geochimica et Cosmochimica Acta*, vol 33, © 1989 Pergamon Press

extreme seasonal warm or cold conditions were able to coexist during glacial times, and considerable community reorganization took place in response to climatic change during and following a glaciation.

Similar responses to changing environments are well known from life in the oceans. Marine organisms closely reflect the temperature, depth, and salinity of the water in which they live, and studies of the fossil succession from deep-sea cores have allowed detailed reconstructions of oceanic conditions for the late Pleistocene. Planktonic foraminifers are most useful for determining sea-surface conditions, and changes in the distribution of polar, subpolar, subtropical, and tropical faunas have been used to map changing oceanic conditions. Changes in the North Atlantic Ocean were most dramatic because of the direct influence of the ice sheets to the west, north, and east. During episodes of glaciation, polar faunas extended south to about 45° N latitude, whereas during interglaciations these faunas occurred mostly north of 70° and subtropical faunas extended far to the north under the influence of the Gulf Stream.

Displacement of marine forms

Megafaunal extinctions. The end of the Pleistocene was marked by the extinction of many genera of large mammals, including mammoths, mastodons, ground sloths, and giant beavers. The extinction event is most distinct in North America, where 32 genera of large mammals vanished during an interval of about 2,000 years, centred on 11,000 BP. On other continents, fewer genera disappeared, and the extinctions were spread over a somewhat longer time span. Nonetheless, they still appear to be more common near the end of the Pleistocene than at any other time during the epoch. Except on islands, small mammals, along with reptiles and amphibians, generally were not affected by the extinction process. The cause of the extinctions has been vigorously debated, with two main hypotheses being advanced: (1) the extinctions were the result of overpredation by human hunters; and (2) they were the result of abrupt climatic and vegetation changes during the last glacial–interglacial transition.

The first theory, the so-called overkill hypothesis, receives support from the coincidence in the timing of the mass extinction and the appearance of large numbers of human hunters, as evidenced by the Clovis complex, an ancient culture centred in North America. Clovis archaeological sites (concentrated in Arizona, New Mexico, and West Texas), with their distinctive projectile points, date between 10,000 and 12,000 years ago. Proponents of the hypothesis point out that these new immigrants from Eurasia were skilled hunters, that the North American fauna would not have been wary of this new group of predators, and that, once the number of large herbivores declined, large carnivores also would have been affected as their prey became extinct. In addition to direct slaughter, human disruption of the environment most likely contributed to the extinctions, particularly on other continents.

Abrupt climatic change also occurred at the time of the megafaunal extinctions, and so timing alone does not clearly differentiate one hypothesis from the other. The climatic-change hypothesis takes a number of forms but essentially focuses on the reorganization of vegetation, on the availability of food (including nutrient value), and on the general environmental disruption and stress that resulted as climates became more seasonal. It appears likely that the causes of extinction varied in different geographic areas under different conditions and that both climatic change and human activities played roles but of varying importance in different situations.

Cause of the climatic changes and glaciations. Pleistocene climates and the cause of the climatic cycles that resulted in the development of large-scale continental ice sheets have been a topic of study and debate for more than 100 years. Many theories have been proposed to account for Quaternary glaciations, but most are deficient in view of current scientific knowledge about Pleistocene climates. One early theory, the theory of astronomical cycles, seems to explain much of the climatic record and is considered by most to best account for the fundamental cause or driving force of the climatic cycles.

Astronomical theory

The astronomical theory is based on the geometry of the Earth's orbit around the Sun, which affects how solar radiation is distributed over the surface of the planet. The latter is determined by three orbital parameters that have cyclic frequencies: (1) the eccentricity of the Earth's orbit (*i.e.*, its departure from a circular orbit), with a frequency of about 100,000 years, (2) the obliquity, or tilt, of the Earth's axis away from a vertical drawn to the plane of the planet's orbit, with a frequency of 41,000 years, and (3) the precession, or wobble, of the Earth's axis, with frequencies of 19,000 and 23,000 years. Collectively these parameters determine the amount of radiation received at any latitude during any season; radiation curves have been calculated from them for different latitudes for the past 600,000 years. These curves vary systematically from the poles to the equator, with those in the higher latitudes being dominated by the 41,000-year tilt cycle and those in lower latitudes by the 19,000- and 23,000-year precession cycles. The astronomical theory places emphasis on summer insolation in the high-latitude areas of the Northern Hemisphere (about 55° N latitude). Glaciations are hypothesized to begin during times of low summer insolation when conditions should be most optimal for winter snow to last through the summer season.

Dating of the marine terraces in Barbados and New Guinea and, more importantly, determining the chronology of glaciations as inferred from the marine oxygen isotope record were milestones in testing the astronomical theory. Early spectral analysis of the oxygen isotope record of cores from the deep ocean showed frequencies of climatic variation at essentially the same frequencies as the orbital cycles—that is to say, at 100,000 years, 43,000 years, 24,000 years, and 19,000 years. These results (reported in 1976), along with those of more recent analyses, provide firm evidence of a tie between orbital cycles and the Earth's recent climatic record. The variations in the Earth's orbit are generally considered the "pacemaker" of the ice ages.

Although the planetary orbital cycles are the likely cause of the Pleistocene climatic cycles, the mechanisms and connections to the global climate are not fully understood, and important questions remain unanswered. The relatively small seasonal and latitudinal radiation variations alone cannot account for the magnitude of climatic change as experienced by the Earth during the Pleistocene. Clearly, feedback mechanisms must operate to amplify the insolation changes caused by the orbital parameters. One of these is albedo, the reflectivity of the Earth's surface. Increased snow cover in high-latitude areas would cause increased cooling. Another feedback mechanism is the decreased carbon dioxide content of the atmosphere during times of glaciation, as recorded in the bubbles of long ice cores. Variations in atmospheric carbon dioxide are essentially synchronous with global climatic change and thus in all likelihood played a significant role through the so-called greenhouse effect. (The latter phenomenon refers to the trapping of heat—that is to say, infrared radiation—in the lower levels of the atmosphere by carbon dioxide, water vapour, and certain other gases.) Another atmospheric effect is the increased amount of dust during glacial times, as borne out by ice core and loess records. All of these changes operate in the same direction, causing increased cooling during glacial times and warming during interglacial times.

Other problems remain with respect to the astronomical theory. One is the dominance of the 100,000-year cycle in the Pleistocene climatic record, whereas the eccentricity cycle is the weakest among the orbital parameters. Another is the cause of the asymmetrical pattern of the climatic record. Ice ages appear to start slowly and take a long time to build up to maximum glaciation, only to terminate abruptly and go from maximum glacial to full interglacial conditions in less than 10,000 years (see Figure 41). A third problem is the synchronous nature of the climatic record between the Northern and Southern hemispheres, which one would not expect from the orbital parameters because they operate in different directions in the two hemispheres.

Different approaches have been taken to explain these questions. Most of these suggest that the Northern Hemisphere with its enormous continental ice sheets was the controlling area and that the ice sheets themselves with their complex dynamics may explain the 100,000-year climatic cycle. Others propose that major reorganizations of the ocean–atmosphere system must be called upon to explain the climatic record. These reorganizations are concerned with the transport of salt through the oceans and water vapour through the atmosphere and revolve around the existence and strength of deep oceanic currents in the Atlantic Ocean.

Ongoing interdisciplinary research on Pleistocene paleoclimatology is focused on understanding the complex dynamics and interactions among the atmosphere, oceans, and ice sheets. Such research is expected to provide further insight into the cause of the climatic cycles, which is essential as scientists attempt to predict future climates in view of recent human-induced modifications of the climatic system. (W.H.J.)

HOLOCENE EPOCH

General considerations. The Holocene, also referred to as the Recent, is the latest interval of geologic time, covering approximately the last 10,000 years of Earth history (see Table 4). The sediments of the Holocene, both continental and marine, cover the largest area of the globe of any epoch in the geologic record, but the Holocene is unique because it is coincident with the late and post-Stone Age history of mankind. The influence of humans is of world extent and is so profound that it seems appropriate to have a special geologic name for this time. In 1833 Charles Lyell proposed the designation Recent for the period that has elapsed since "the earth has been tenanted by man." It is now known that humans have been in existence a great deal longer. The term Holocene was proposed in 1867 and was formally submitted to the International Geological Congress at Bologna, Italy, in 1885. It was officially endorsed by the U.S. Commission on Stratigraphic Nomenclature in 1969.

The Holocene is the latest division of the Quaternary and represents the most recent interglacial interval of the period. The preceding and substantially longer sequence of alternating glacial and interglacial ages is the Pleistocene Epoch (see above). Because there is nothing to suggest that the Pleistocene has actually ended, certain authorities prefer to extend the Pleistocene up to the present time; this approach tends to ignore humans and their impact, however. The Holocene forms the chronological framework for human history. Archaeologists use it as the time standard against which they trace the development of early civilizations.

Radiocarbon dating

Stratigraphy. *Chronology and correlation.* The Holocene is unique among geologic epochs because varied means of correlating deposits and establishing chronologies are available. One of the most important means is carbon-14 dating (see above *Carbon-14 dating and other cosmogenic methods*). Because the age determined by the carbon-14 method may be appreciably different from the true age in certain cases, it is customary to refer to such dates in "radiocarbon years." These dates, obtained from a variety of deposits, form an important framework for Holocene stratigraphy and chronology.

The limitations of accuracy of radiocarbon age determinations are expressed as ± a few tens or hundreds of years. In addition to this calculated error, there also is a question of error due to contamination of the material measured. For instance, an ancient peat may contain some younger roots and thus give a falsely "young" age unless it is carefully collected and treated to remove contaminants. Marine shells consist of calcium carbonate ($CaCO_3$), and in certain coastal regions there is upwelling of deep oceanic water that can be 500 to more than 1,000 years old. An "age" from living shells in such an area can suggest that they are already hundreds of years old.

Table 28 shows the comparative dates of radiocarbon years and those obtained by other means. Two sets of radiocarbon years are given because the half-life of carbon-14 was reassigned a value of 5,730 years by agreement of scientists. Many dates available in the literature, however, are based on the originally established half-life of 5,570 years.

*Wood from the tomb of the pharaoh Djoser at Saqqārah, Egypt, is dated historically at 4650 ± 75 BP in sidereal years, but according to multiple analyses by many laboratories it is about 4100 BP in radiocarbon years, or 550 years too young. The anomaly is most probably explained in terms of solar radiation, residence time of CO_2, and paleomagnetics. Tree-ring dating combined with ^{14}C measurements has confirmed this trend and provides a general curve for correcting Holocene ^{14}C dates. Almost all radiocarbon dates given are uncorrected. U.S. tree-ring chronology most closely resembles the sidereal dates; the Scandinavian varve chronology also is close to the astronomical chronology, subject to a 350 ± 200 year correction. †T_2 signifies half-life. ‡Dates older than 7450 BP are based on varve years, corrected by 350 ± 200 years. §Dates for varve years less than 6550 BP are extrapolated.

Varve chronology

In certain areas a varve chronology can be established. This involves counting and measuring thicknesses in annual paired layers of lake sediments deposited in lakes that undergo an annual freeze-up. Because each year's sediment accumulation varies in thickness according to the climatic conditions of the melt season, any long sequence of varve measurements provides a distinctive "signature" and can be correlated for moderate distances from lake basin to lake basin. The pioneer in this work was the Swedish investigator Baron Gerard De Geer, who developed a long chronology on which that shown in Table 28 is partly based.

In some relatively recent continental deposits, obsidian (a black glassy rock of volcanic origin) can be used for dating. Obsidian weathers slowly at a uniform rate, and the thickness of the weathered layer is measured microscopically and gauged against known standards to give a date in years. This has been particularly useful where arrowheads of obsidian are included in deposits.

As noted elsewhere in this article, paleomagnetism is another phenomenon used in chronology. The Earth's magnetic field undergoes a secular shift that is fairly well known for the last 2,000 years. The magnetized material to be studied can be natural, such as a lava flow; or it may be man-made, as, for example, an ancient brick kiln or smeltery that has cooled and thus fixed the magnetic orientation of the bricks to correspond to the geomagnetic field of that time.

Another form of dating is tephrochronology, so called because it employs the tephra (ash layers) generated by volcanic eruptions. The wind may blow the ash 1,500–3,000 kilometres, and, because the minerals or volcanic glass from any one eruptive cycle tend to be distinctive from those of any other cycle, even from the same volcano, these can be dated from the associated lavas by stratigraphic methods (with or without absolute dating). The ash layer then can be traced as a "time horizon" wherever it has been preserved. When the Mount Mazama volcano in Oregon exploded at about 6600 BP (radiocarbon-dated by burned wood), 70 cubic kilometres of debris were thrown into the air, forming the basin now occupied by Crater Lake. The tephra were distributed over 10 states, thereby providing a chronological marker horizon. A comparable eruption of Thera on Santorin in the Aegean Sea about 3,400 years ago left tephra in the deep-sea sediments and on adjacent land areas. Periodic eruptions of Mount Hekla in Iceland have been of use in Scandinavia, which lies downwind.

Tree-ring measurement and analysis

Finally, the measurement and analysis of tree rings (or dendrochronology) must be mentioned. The age of a tree that has grown in any region with a seasonal contrast in climate can be established by counting its growth rings. Work in this field by the University of Arizona's Laboratory of Tree-Ring Research, by selection of both living trees and deadwood, has carried the year-by-year chronology back more than 7,500 years. Certain pitfalls have been discovered in tree-ring analysis, however. Sometimes, as in a very severe season, a growth ring may not form. In certain latitudes the tree's ring growth correlates with moisture, but in others it may be correlated with temperature. From the climatic viewpoint these two parameters are often inversely related in different regions. Nevertheless, in experienced hands, just as with varve counting from adjacent lakes, ring measurements from trees with overlapping ages can extend chronologies back for many thousands of years. The bristlecone pine of the White Mountains in California has proved to be singularly long-lived and suitable for this chronology; some individuals still living are more than 4,000 years old, certainly the oldest living organisms. Wood from old buildings and even old paving blocks in western Europe and in Russia have contributed to the chronology. This technique not only offers an additional means of dating but also contains a built-in documentation of climatic characteristics. In certain favourable situations, particularly in the drier, low latitudes, tree-ring records sometimes document 11- and 22-year sunspot cycles.

The Pleistocene–Holocene boundary. Arguments can be presented for the selection of the lower boundary of the Holocene at several different times in the past. Some Russian investigators have proposed a boundary at the beginning of the Allerød, a warm interstadial age that began about 12,000 BP. Others, in Alaska, proposed a Holocene section beginning at 6000 BP. Marine geologists have recognized a worldwide change in the character of deep-sea sedimentation about 10,000–11,000 BP. In warm tropical waters, the clays show a sharp change at this time from chlorite-rich particles often associated with fresh feldspar grains (cold, dry climate indicators) to kaolinite and gibbsite (warm, wet climate indicators).

Pleistocene–Holocene boundary dates

Some of the best-preserved traces of the boundary are found in southern Scandinavia, where the transition from the latest glacial stage of the Pleistocene to the Holocene was accompanied by a marine transgression. These beds, south of Göteborg, have been uplifted and are exposed at the surface. The boundary is dated around 10,300 ± 200 years BP (in radiocarbon years). This boundary marks the very beginning of warmer climates that occurred after the latest minor glacial advance in Scandinavia. This advance built the last Salpausselkä moraine, which corresponds in part to the Valders substage in North America. The subsequent warming trend was marked by the Finiglacial retreat in northern Scandinavia, the Ostendian (early Flandrian) marine transgression in northwestern Europe.

Nature of the Holocene record. The very youthfulness of the Holocene stratigraphic sequence makes subdivision difficult. The relative slowness of the Earth's crustal movements means that most areas which contain a complete marine stratigraphic sequence are still submerged. Fortunately, in areas that were depressed by the load of glacial ice there has been progressive postglacial uplift (crustal rebound) that has led to the exposure of the nearshore deposits.

Character and fossil content of globigerina ooze

Deep oceanic deposits. The marine realm, apart from covering about 70 percent of the Earth's surface, offers far better opportunities than coastal environments for undisturbed preservation of sediments. In deep-sea cores, the boundary usually can be seen at a depth of about 10–30 centimetres, where the Holocene sediments pass downward into material belonging to the late glacial stage of the Pleistocene. The boundary often is marked by a slight change in colour. For example, globigerina ooze, common in the ocean at intermediate depths, is frequently slightly pinkish when it is of Holocene age because of a trace of iron oxides that are characteristic of tropical soils. At greater depth in the section, the globigerina ooze may be grayish because of greater quantities of clay, chlorite, and feldspar that have been introduced from the erosion of semiarid hinterlands during glacial time.

During each of the glacial epochs the cooling of the ocean waters led to reduced evaporation and thus fewer clouds, then to lower rainfall, then to reduction of vegetation, and so eventually to the production of relatively more clastic sediments (owing to reduced chemical weathering). Furthermore, the worldwide eustatic (glacially related) lowering of sea level caused an acceleration of erosion along the lower courses of all rivers and on exposed continental shelves, so that clastic sedimentation rates in the oceans were higher during glacial stages than during the Holocene. Turbidity currents, generated on a large scale during the low sea-level periods, became much less frequent following the rise of sea level in the Holocene.

Studies of the fossils in the globigerina oozes show that at a depth in the cores that has been radiocarbon-dated at about 10,000–11,000 BP the relative number of warm-water planktonic foraminiferans increases markedly. In addition, certain foraminiferal species tend to change their coiling direction from a left-handed spiral to a right-handed spiral at this time. This is attributed to the change from cool water to warm water, an extraordinary (and still not understood) physiological reaction to environmental stress (Figure 47). Many of the foraminiferans, however, responded to the warming water of the Holocene by migrating poleward by distances of as much as 1,000 to 3,000 kilometres in order to remain within their optimal temperature habitats.

Nannoplankton and oceanic circulation

In addition to foraminiferans in the globigerina oozes, there are nannoplankton, minute fauna and flora consisting mainly of coccolithophores. Research on the present coccolith distribution shows that there is maximum pro-

Adapted from G Wollin, D Ericson and M Ewing 'Late Pleistocene Climates Recorded in Atlantic and Pacific Deep-Sea Sediments,' in *Late Cenozoic Glacial Ages* (1971) Yale University Press, New Haven and London

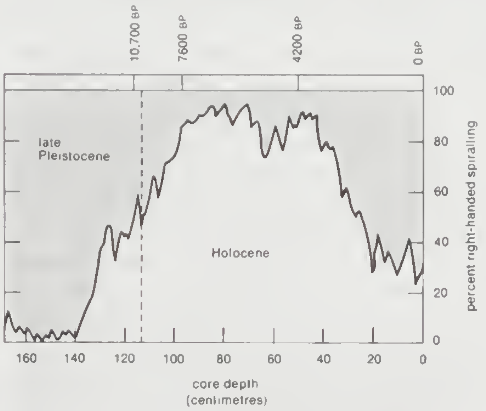

Figure 47: Climatic curve based on coiling direction of *Globoratalia truncatulinoides* obtained from deep-sea core at latitude 24°18′ N, longitude 75 55′ W (see text).

ductivity in zones of oceanic upwelling, notably at the subpolar convergence and the equatorial divergence. During the latest glacial stage the subpolar zone was displaced toward the equator, but with the subsequent warming of waters it shifted back to the borders of the polar regions.

The distribution of the carbonate plankton bears on the problem of rates of oceanic circulation. Is the Holocene rate higher or lower than during the last glacial stage? It has been argued that, because of the higher mean temperature gradient in the lower atmosphere from equator to poles during the last glacial period, there would have been higher wind velocities and, because of the atmosphere–ocean coupling, higher oceanic current velocities. There were, however, two retarding factors for glacial-age currents. First, the eustatic withdrawal of oceanic waters from the continental shelves reduced the effective area of the oceans by 8 percent. Second, the greater extent of floating sea ice would have further reduced the available air–ocean coupling surface, especially in the critical zone of the westerly circulation. According to climatic studies by the British meteorologist Hubert H. Lamb, the presence of large continental ice sheets in North America and Eurasia would have introduced a strong blocking action to the normal zonal circulation of the atmosphere, which then would be replaced by more meridional circulation. This in turn would have been appreciably less effective in driving major oceanic current gyres.

Continental shelf and coastal regions. It was recognized as early as 1842 that a logical consequence of a glacial age would be a large-scale withdrawal of ocean water. Consequently, deglaciation would produce a postglacial "glacioeustatic" transgression of the seas across the continental shelf. The trace of this Holocene rise of sea level was first discerned along the New England coast and along the coast of Belgium, where it was named the Flandrian Transgression by Georges Dubois in 1924.

Whereas the deep-sea Holocene sediments usually follow without interruption upon those of the Upper Pleistocene, on the continental shelf there is almost invariably a break in the sequence upon the continental formations there. As sea level rose, it paused or fluctuated at various stages, leaving erosional terraces, beach deposits, and other indicators of the stillstand. Brief regressions in particular permitted the growth of peat deposits that are of significance in the Holocene record because they can be dated by radiocarbon analysis. Dredging in certain places on the shelf, such as off eastern North America, also is useful because terrestrial fossils from the latest glacial period or early Holocene have been found; these range from mammoth and mastodon bones and tusks to human artifacts.

Sedimentary deposits and coral reefs

On about 70 percent of the world's continental shelves today the amount of sedimentary accumulation since the beginning of the Holocene is minimal, so that dredging or coring operations often disclose hard rock, with older formations at or very close to the surface. In other places, especially near the former continental ice fronts, the shelf is covered by periglacial fluvial sands (meltwater deposits), which, because of their unconsolidated nature, became extensively reworked into beaches and bars during the Holocene Transgression.

In warm coral seas the major pauses in the Holocene eustatic rise were long enough for fringing reefs to become established; and, when the rise resumed, the reefs grew upward, either in ribbonlike barriers or from former headlands as patch reefs or shelf atolls. Since coral generally does not colonize a sediment-covered shelf floor at depths of more than about 10 metres, those reefs now rising from greater depths must have been emplaced in the early Holocene or grown on foundations of ancient reefs.

The great ice-covered areas of the Quaternary Period included Antarctica, North America, Greenland, and Eurasia. Of these, Antarctica and Greenland have relatively high latitude situations and do not easily become deglaciated. Some melting occurs, but there is a very great melt-retardation factor in high-latitude ice sheets (high albedo or reflectivity, short melt season, and so forth). In the case of mid-latitude ice sheets, however, once melting starts, the ice disappears at a tremendous rate. The melt rate reached a maximum about 8000 BP, liberating 18 trillion (18×10^{12}) metric tons of meltwater annually. This corresponds to a rise in sea level of five centimetres per year. Hand in hand with melting, the sea level responded so that, as the ice began to retreat from its former terminal moraines, the sea began to invade the former coastlands.

As the sea level rose, the Earth's crust responded buoyantly to the removal of the load of ice, and at critical times the rate of rise of the water level was outstripped by the rate of rise of the land. In these places the highest ancient shoreline that is now preserved is known as the marine limit. The nearer the former centre of the ice sheet, the higher the marine limit. In northern Scandinavia, Ontario and northwestern Quebec, around Hudson Bay, and in Baffin Island, it reaches more than a 300-metre elevation. In central Maine and Spitsbergen it may exceed 100 metres, whereas in coastal Scotland and Northern Ireland it is rarely above 10–15 metres.

In addition to the marine-limit strandlines, there are row upon row of lower beach levels stretched out across Scandinavia, around Hudson Bay, and on other Arctic coasts. These strandlines are dated and distinctive and do not grade into each other. Each represents a specific period of time when the rising crust and rising sea level remained in place long enough to permit the formation of beaches, spits, and bars and sometimes the erosion of headlands ("fossil cliffs").

A complicating factor near the periphery of former ice sheets is the so-called marginal bulge. Reginald A. Daly, an American geologist, postulated that, if the ice load pressed down the middle of the glaciated area, then the Earth's crust in the marginal area tended to rise up slightly, producing a marginal bulge. With deglaciation the marginal bulge should slowly collapse. A fulcrum should develop between postglacial uplift and peripheral subsidence. In North America that fulcrum seems to run across Illinois to central New Jersey and then to swing northeastward, paralleling the coast and turning seaward north of Boston. In the Scandinavian region the fulcrum crosses central Denmark to swing around the Baltic Sea and then trends northeastward across the Gulf of Finland north of St. Petersburg, so that the southeastern Baltic and northwestern Germany are subsiding. The Netherlands area is subsiding also, but here the pattern is complicated by the long-term negative tectonic trend of the North Sea Basin and the Rhine delta.

It seems likely that this fulcrum shifted inward toward the former glacial centre during the early part of the Holocene. Passing inland, the lines of equal uplift (isobases) are positive, whereas seaward they are negative. The coastal area of southern New England is still slowly subsiding at the present time (1–3 millimetres per year).

The great deltas of the world, those of the Mississippi, Rhine, Rhône, Danube, Nile, Amazon, Niger, Tigris-Euphrates, Ganges, and Indus, all coincide with regions of tectonic subsidence. Because water-saturated sediment has a tendency to compact under further sediment loading, there is an additional built-in mechanism that adds to the subsidence in such areas.

Deltaic environment and sedimentary facies

In this deltaic setting Holocene sequences are found that are quite different from those in the postglacial uplifted regions. Whereas the Holocene beaches in the uplift areas extend horizontally across the country in concentric belts, the Holocene sequence in the deltaic regions is, for the most part, vertical in nature and can be studied only from well data.

In both the Mississippi and Rhine deltas, sediments that represent the earliest marine Holocene are missing. The sediments must lie seaward on the shelf margin, and the oldest marine layers are found to rest directly upon the late Pleistocene river silts and gravels. In a delta settling at around 0.5 to 3 millimetres per year, the rising sea of the Flandrian Transgression extended quickly across the river deposits to the inner margin (where there is a fulcrum comparable to that of the glaciated regions), marking the boundary between areas of downwarp and those of relative stability or gentle upwarp. The marine beds alternate with continental deposits that represent river or swamp environments. Six major fluctuations are recognizable in both the Mississippi and Rhine deltas. By radiocarbon

Table 29: Peat Building, Sea-Level Fluctuation, and the Holocene Record of the Mississippi Delta

Mississippi stage	years BP	international correlation (regression)	probable eustatic range
Balize Delta	300	Late Medieval	0 to −0.5 m
Plaquemines Delta	700	Paria	+0.5 to −1.5 m
Lafourche Delta	1500	pre-Dunkerquian III	0 to −1 m
Peat #1 (St. Bernard or La Loutre Delta)	1700–2100	Florida (Roman)	+1.5 to −2 m
Teche Delta	2800–3300	Pelham Bay	+2 to −2 m
Peat #2 (Cocodrie Delta)	4000–4300	Bahama	? +3 to −3 m
Peat #3 (Marinquin, Sale, or Cypremort Delta)	4700–5000	early Subboreal	? +3 to −3 m
Peat #4	6000–6500	Rhine Delta	−4 to −9 m
Peat #5	7000–7500	late Boreal	−12 to −22 m

dating the transgressive and regressive phases (Table 29) have been shown to be correlative in time.

Beaches, dunes, and peat deposits

On a subsiding coast there tends to be an alternation in importance between two types of associated sedimentary facies. During a regression of the sea the river distributaries are rejuvenated and there is an increase in the supply of sand and silt; beaches are widened and beach ridge dunes or cheniers may be formed. During a transgressive stage the saltwater wedge at river mouths causes a back-up, and the estuary becomes much more sluggish (thalassostatic).

In The Netherlands the basal Holocene is buried in the fluvial deposits of the lower Rhine. The postglacial eustatic rise had to traverse the North Sea Plain and advance up the English Channel several hundred kilometres before it reached the Netherlands area. At about 9000–8500 BP (Ancylus stage in the Baltic), the coastal beaches still lay seaward from the present shore. Subsequently, they became stabilized by a brief eustatic regression, while the high water table permitted the growth of the Lower Peat. This is contemporaneous with the late Boreal Peat that is widespread in northern Europe, as well as Peat #5 of the Mississippi delta (Table 29).

A further eustatic rise (of about 10–12 metres) ensued around 7750 BP, corresponding to a warming of the climate marked by the growth of oak forests in western Europe (the BAT, or "Boreal–Atlantic Transition"). In The Netherlands the barrier beaches re-formed close to the present coastline, and widespread tidal flats developed to the interior. These are known as the Calais Beds (or Calaisian) from the definition in Flanders by Dubois. In the protected inner margins, the peat continued to accumulate during and after the "Atlantic" time.

From evidence outside the areas of subsidence, it seems likely that the worldwide eustatic sea level rise reached its maximum sometime between 5500 and 2500 BP (many workers consider the date to be about 2000 BP). In The Netherlands, in spite of subsidence, the western coastline became more or less stabilized around 4000 BP with the beginning of the formation of the Older Dunes alternating with interdune soils. At the same time, in the tide flat areas the Calaisian was followed by the Dunkirk stage, or Dunkerquian.

The Younger Dune sequence of The Netherlands began with a dry climatic phase in the 12th century AD. With several fluctuations of cold continental climates, dune building continued until the 16th century. Only brief positive oscillations of sea level occurred until the 17th century, when the "modern" warming and eustatic rise started, accompanied also by dune stabilization.

Broadly comparable patterns occur in other areas, from France and Britain to Texas, Oregon, and Brazil. There is normally a threefold or fourfold subdivision in all the Holocene coastal dune belts, each extensively vegetated and consolidated before the successively younger dune belt was added. In a number of cases there is evidence from buried beach deposits that the foundations of the inner dunes are older strandlines that were established when the sea was somewhat higher than today. An important regressive phase seems to have initiated each new dune belt.

Other coastal regions. Besides regions of glacio-isostatic crustal adjustment, both positive and negative, and the deltaic or geosynclinally subsiding areas, there are many tens of thousands of kilometres of coastlines that are relatively stable and a smaller fraction that are tectonically active.

Holocene terraces and the eustatic curve

Most striking scenically are the coasts with Holocene terraces undergoing tectonic uplift. Terraces of this sort, backed in successive steps by Pleistocene terraces, are well developed in South America, the East Indies, New Guinea, and Japan. By careful surveys every few years the Japanese geodesists have been able to establish mean rates of crustal uplift (or subsidence) for many parts of the country and have been able to construct a residual eustatic curve that is comparable with those obtained elsewhere.

Besides uplifted coasts outside of glaciated areas there are also certain highly indented coasts that show clear evidence of Holocene "drowning." These coasts typically are characterized by the rias, or drowned estuaries, sculptured by fluvial action, but many of the valleys were cut 10 to 20 million years ago, and the Holocene history has been purely one of eustatic rise.

On the basis of the known climatic history of the Holocene, from the strandline record of Scandinavia and from the sedimentologic evolution of the Mississippi and Rhine deltas, an approximate chronology of Holocene eustasy can be worked out. The amplitudes of the fluctuations and the finite curve are less easily established. A first approximation of the oscillations was published in 1959 and in a more detailed way in 1961 (the so-called Fairbridge curve). Smoothed versions have been offered by several other workers (see Figure 48).

Holocene environment and biota. In formerly glaciated regions, the Holocene has been a time for the reinstitution of ordinary processes of subaerial erosion and progressive reoccupation by a flora and fauna. The latter expanded rapidly into what was an ecological vacuum, although with a very restricted range of organisms, because the climates were initially cold and the soil was still immature.

Floral change. The most important biological means of establishing Holocene climate involves palynology, the study of pollen, spores, and other microscopic organic particles. Pollen from trees, shrubs, or grasses is generated annually in large quantities and often is well preserved in fine-grained lake, swamp, or marine sediments. Statistical correlations of modern and fossil assemblages provide a

Adapted from N. Morner, *Sveriges Geologiska Undersokning*, Series C, no. 640 (1969)

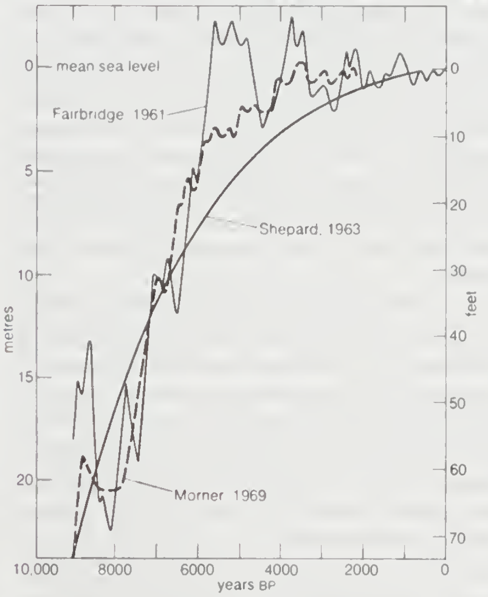

Figure 48: *Holocene sea level curves.*
The smooth curve of Shepard represents an average of many radiocarbon-dated shoreline indicators from both stable and subsiding areas; the oscillating curve of Mörner is based upon the isostatically emerged coast of western Sweden, corrected for uplift; and the oscillating curve of Fairbridge is based upon the geomorphology and radiocarbon dates of coastal features of the world, adjusted for crustal movements.

Table 30: Blytt–Sernander Framework

Blytt and Sernander divisions	archaeological periods in Scandinavia		absolute chronology|| years, sidereal	radiocarbon years, uncorrected BP (1950)
Sub-Atlantic	Historical time		AD 1950	0
	Viking time		AD 1000	1,050
	Iron Age		0	2,000
			600 BC	2,600
Subboreal	Bronze Age			
			1900 BC	3,600
	Neolithic Stone Age			
			4100 BC	5,100
Atlantic	Mesolithic Stone Age	Ertebølle Industry	6150 BC	7,750
Boreal		Maglemosian Industry	7100 BC	9,500
Preboreal		Klosterlund Industry	7700 BC	10,100

basis for estimating the approximate makeup of the local or regional vegetation through time. Even a crude subdivision into arboreal pollen (AP) and nonarboreal pollen (NAP) reflects the former types of climate. The tundra vegetation of the last glacial epoch, for example, provides predominantly NAP, and the transition to forest vegetation shows the climatic amelioration that heralded the beginning of the Holocene.

The first standard palynological stratigraphy was developed in Scandinavia by Axel Blytt, Johan Rutger Sernander, and E.J. Lennart von Post, in combination with a theory of Holocene climate changes. The so-called Blytt–Sernander system was soon tied to the archaeology and to the varve chronology of Gerard De Geer. It has been closely checked by radiocarbon dating, establishing a very useful standard. Every region has its own standard pollen stratigraphy, but these are now correlated approximately with the Blytt–Sernander framework (Table 30). To some extent this is even true for remote areas such as Patagonia and East Africa. Particularly important is the fact that the middle Holocene was appreciably warmer than today. In Europe this phase has been called the Climatic Optimum (zones Boreal to Atlantic), and in North America it has been called the hypsithermal (also altithermal and xerothermic).

Macro-botanical remains

Like pollen, macrobotanical remains by themselves do not establish chronologies. Absolute dating of these remains does, however, provide a chronology of floral changes throughout the Holocene. Recent discoveries of the dung deposits of Pleistocene animals in dry caves and alcoves on the Colorado Plateau, including those of mammoth, bison, horse, sloth, extinct forms of mountain goats, and shrub oxen, have provided floristic assemblages from which temperature and moisture requirements for such assemblages can be deduced in order to develop paleoenvironmental reconstructions tied to an absolute chronology. Macrobotanical remains found in the digestive tracts of late Pleistocene animals frozen in the permafrost regions of Siberia and Alaska also have made it possible to build paleoenvironmental reconstructions tied to absolute chronologies.

From these reconstructions, one can see warming and drying trends in the terminal Pleistocene (± 11,500 BP). Cold-tolerant, water-loving plants (*e.g.*, birch and spruce) retreated to higher elevations or higher latitudes (as much as 2,500 metres in elevation) within less than 11,000 years.

Alluvial deposits

Detailed studies of late Pleistocene and Holocene alluvium, tied to carbon-14 chronology, have provided evidence of cyclic fluctuations in the aggradation and degradation of Holocene drainage systems. Although it is still too early in the analysis to state with certainty, it appears from the work of several investigators that there is a regional, or semicontinental cycle, of erosion and deposition that occurs every 250–300, 500–600, 1,000–1,300, and possibly 6,000 years within the Holocene.

Faunal change. According to an analysis of multiple carbon-dated sites conducted in 1984 by James I. Mead and David J. Meltzer, 75 percent of the larger animals (those of more than 40 kilograms live weight) that became extinct during the late Pleistocene did so by about 10,800 to 10,000 years ago. Whether the cause of this decimation of Pleistocene fauna was climatic or cultural has been debated ever since another American investigator, Paul S. Martin, proposed the overkill hypothesis (see above *Pleistocene fauna and flora*) in the 1960s. Whatever the case, it seems appropriate on paleontological grounds to designate the beginning of a new epoch—the Holocene—at approximately 10,000 years ago.

Floral and faunal reconstructions tied to the physical evidence of fluvial, alluvial, and lacustrine sediments and to a radiocarbon chronology reflect a warming and drying trend (as contrasted with the Pleistocene) during the last 10,000 years. The drying trend apparently reached its peak about 5,500 to 7,500 years ago (referred to as Antev's Altithermal) and has ranged between that peak and the cold, wet conditions of the early Holocene since that time.

Nonmarine Holocene sediments are usually discontinuous, making exact correlations difficult. An absolute chronology provided by radiocarbon dating permits temporal correlation, even if the deposits are discontinuous or physically different. Analysis of Holocene deposits requires chronostratigraphic correlations of discontinuous and dissimilar deposits to allow an interpretation of local, regional, continental, and global conditions.

Analysis of microfauna from paleontological and archaeological sites of the late Pleistocene and Holocene of North America has aided in paleoenvironmental reconstructions. Micromammals (rodents and insectivores), as well as amphibians and insects, are paleoecologically sensitive. Comparisons of modern habitat and range of species to late Pleistocene and Holocene assemblages and distributions reveal disharmonious associations (*i.e.*, the occurrence of presently allopatric taxa that are presumed to be ecologically incompatible), especially in late Pleistocene assemblages. Tentative conclusions from micromammals and other environmental indicators suggest that the late Pleistocene supported an environment in which there coexisted plants and animals that are today separated by hundreds to thousands of kilometres (or considerable elevation differences). Stated in another way, the late Pleistocene climate was more equable than that of the present day, one in which seasonal extremes in temperature and effective moisture were reduced. The evolution of a modern biotic community, as opposed to one of the late Pleistocene, appears to be the consequence of intricate biological and biophysical interactions among individual species. Some researchers have theorized that the environmental changes that led to the formation of new biotic communities at the end of the Pleistocene resulted in the extinction of many of the Pleistocene faunal forms.

Holocene climatic trends and chronology. In the mid-latitudes and the tropics, the end of the last glacial period was marked by a tremendous increase in rainfall. The increased precipitation toward the end of the Pleistocene was marked by a vast proliferation of pluvial lakes in the Great Basin of western North America, notably Lake Bonneville and Lake Lahontan (enormous ancestors of present-day Great Salt Lake and Pyramid Lake). Two peaks of lake levels were reached at about 12,000 ± 500 BP (the beginning of the Allerød Warm stage) and approximately 9000 ± 500 BP (the early Boreal Warm stage). At Lake Balaton (in Hungary) high terrace levels also mark the Allerød and early Boreal Warm stages. Lake Victoria (in East Africa) exhibits the identical twin oscillation in its terrace levels.

In equatorial regions the same evidence of high solar radiation and high rainfall at the end of the Pleistocene and during the early Holocene is apparent in the record of the Nile sediments. The Nile, like the other great rivers of Africa (notably, the Congo, Niger, and Sénégal), became very reduced, if not totally blocked, by silt and desert sand during the low-precipitation, arid phases of the Pleistocene. An erroneous correlation between glacial phases and pluvial phases in the tropics has been widely accepted in the past, although cold ocean water means less precipitation, not more. The pluvial phases correspond to the high solar radiation states, the last maximum being about 10,000 years ago. Thus tremendous increases of Nile discharge are determined, by radiocarbon dating, to have occurred around 12,000 and 9,000 years ago, separated and followed by alluviation, indicating reduced runoff in the headwaters.

The expansion of monsoonal rains during the early Holocene in the tropical latitudes permitted an extensive spread of moist savanna-type vegetation over the Sahara in North Africa and the Kalahari in South Africa and in broad areas of Brazil, India, and Australia. Most of these areas had been dry savanna or arid during the last glacial period. Signs of late Paleolithic and Neolithic people can be seen throughout the Sahara today, and art is representative of the life and hunting scenes of the time. Lake deposits have been dated as young as 5000–6000 BP. Lake Chad covered a vast area in the very late Pleistocene and up to 5000 BP. The Dead Sea throughout the early Holocene shows a record of sedimentation from humid headwaters; there was a Neolithic settlement at Jericho around 9000–10,000 BP.

Dispersal of early humans

In the high to mid-latitudes after the early Holocene, with its remnants of ice-age conditions (tundra passing to birch forests), there was a transition to the mid-Holocene, marked by a progressive change to pine forest and then oak, beech, or mixed forest. The mean annual temperature reached 2.5° C above that of today. Neolithic humans pressed forward across Europe and Asia. In the Canadian Arctic and in Manitoba the mean temperature passed 4° C above present averages. It was a "milk-and-honey" period for early humans over much of the world, and in Europe it paved the way for the cultured races of the Bronze Age. Navigators started using the seaways to trade between the eastern Mediterranean, the British Isles, and the Baltic.

In the mid-latitude continental interiors there was still evidence of hot summers, but the winters were becoming colder and partly drier. There was an expansion of steppe or prairie conditions and their associated fauna and flora. Many lake levels showed a fall.

In Europe there was also the beginning of widespread deforestation as Bronze Age human communities started to use charcoal for smelting and extended agriculture to tilling and planting. As a consequence, soil erosion began almost immediately, hillsides developed lynchets (terracettes), and "anthropogenic sediments" began to accumulate on the lower floodplains.

At the corresponding latitudes in the Southern Hemisphere (approximately 30° to 35° S), pollen analysis indicates increasing desiccation during the Subboreal stage, with a maximum dryness about 3200 BP.

In the subtropical regions of Mesopotamia and the Nile valley, people had learned to harness water. The stationary settlements, advanced agriculture, and mild climates favoured a great flowering of human culture. It is surmised that, when the normal floods began to fail, human ingenuity rose to the occasion, as attested to by the development of irrigation canals and machinery.

The Sub-Atlantic stage (2200–0 BP) is the last major physical division of the geologic record. Historically its beginning coincides with the rise of the Roman Empire in Europe, the flowering of the classical dynasties of China, the Ptolemies in Egypt, the Olmec of central Mexico and Guatemala, and the pre-Incan Chavín cultures of Peru.

The record of solar activity is disclosed by documentation of auroras in ancient Chinese court records and later by sunspot numbers. Both phenomena reflect solar activity in general, but correlation with weather records in the higher latitudes is complicated. Other indicators of climate, such as tree-ring analysis and palynology, were previously mentioned, but many documentary indications are also useful: the time of the cherry blossom festival in Kyōto, Japan, the freezing of lakes, the incidence of floods, blizzards, or droughts, the economics of harvests, salt evaporation production, some disease statistics, and so on. The water levels of closed basins such as the Caspian Sea and particularly the evaporite basin of the Kara-Bogaz-Gol Gulf reflect runoff to the Volga. The Dead Sea bears witness to eastern Mediterranean precipitation.

The main trends of the Sub-Atlantic are identifiable as follows:

Classical Roman Period. This time interval is marked by the Florida or Roman emergence in the eustatic record about the BC–AD boundary and succeeded by a transgression.

The solar record is not complete, but indications are for low activity. Records of rainfall kept by the astronomer Ptolemy (fl. AD 127–145) in Alexandria noted thunderstorm activity in every summer month, in comparison with the totally dry summer today, which suggests a slightly wetter overall pattern in this latitude.

In northern Europe and in other high latitudes, in contrast, the cool stage at the beginning of the 1st century AD may have been drier and more continental, as evidenced by dune building.

Warming and desiccation trend

Late Roman Period. After the 1st century AD there is evidence of a progressive rise in sea level. Roman buildings and peat layers were covered by the marine transgression in the Netherlands, southern England, and parts of the Mediterranean. At the same time, drying and warming trends were associated with alluviation of streams and general desiccation in southern Europe and North Africa. Similar alluviation occurred in the American Southwest. This warming and desiccation trend is evident also in the subtropics of the Southern Hemisphere. The solar activity record indicates a mean intensity comparable to that of the mid-20th century.

Post-Roman and Carolingian Period. This period extends roughly from AD 400 to 1000. The important invasions of western Europe by the Huns and the Goths may have been generated by deteriorating climatic conditions in central Asia. Radiocarbon dating and studies of the ancient Chinese literature have disclosed that, when the glaciers of central Asia were large, the meltwaters fed springs, rivers, and lakes on the edge of the desert, and human communities flourished. When there was a warm phase, the water supply failed and the deserts encroached. Thus, in central Asia (and the Tarim Basin) during the cool Roman Period, the Old Silk Road permitted a regular trade between Rome and China, where the Han dynasty was flourishing. During the Ch'in, Wei, and Chou dynasties this trade declined. During the T'ang dynasty (AD 618–907) there was a reopening of the trade routes, and likewise during the Yüan dynasty (AD 1206–1368). Marco Polo passed this way in AD 1271. Radiocarbon dates of the 8.6-metre-high lake level at Sogo Nur showed overflow conditions from AD 1300 to 1450, after which gradual, fluctuating, but progressive desiccation followed, and today the area is almost total desert.

In North America the Post-Roman-Carolingian Period was marked by warm temperatures in the northern parts, with mean paleotemperatures in central Canada about 1° C above the present. In the semiarid southwestern United States, the arroyos, washes, and ephemeral river valleys were filling slowly with alluvium (younger "Tsegi alluvium"), an indication that stream energy was generated by the summer flash floods. There were marginal retreats in almost all the mountain glacier regions of the world from the Alps to Patagonia.

In the tropical region of Central America there was the unexplained decline of the coastal Mayan people (Mexico and Guatemala) about the 10th century AD. The mountain Mayas continued to flourish, however, and it is possible that the high precipitation of this warming period introduced critical ecological limits to continued occupation of the (now) swampy coastal jungles.

The Viking-Norman Period. Approximately AD 1000–1250 the worldwide warm-up that culminated in the 10th century and has been called the early Medieval Warm Period or the "Little Climatic Optimum," continued for two more centuries, although there was a brief drop in mean solar activity in the period around 1030–70. During the 8th to 10th centuries the Vikings had extended as far afield as the Crimea and exploited coastal salt pans, the existence of which speak for seasonally high evaporation conditions and eustatic stability.

In the Arctic regions during the 10th, 11th, and 12th centuries there was widespread navigation by the Vikings. Partly in response to reduced sea-ice conditions and milder climates they were able to establish settlements in Iceland, southern Greenland (Erik the Red, *c.* 985), and in eastern North America (Vinland; Leif Eriksson, *c.* 1000). In Alaska, from tree-ring evidence, the mean temperature was 2° to 3° C warmer in the 11th century than today. Eskimos had settled in Ellesmere Island about AD 900. Records of sea ice off Iceland show negligible severity from 865–1200. Often the westerly storm tracks must have passed north of Europe altogether.

After a brief interval of cold winters in Japan, the cherry blossoms returned to early blooming in the 12th century. In the semiarid southwestern United States there appears to have been increased precipitation, leading to a spread of vegetation and agriculture. Pueblo campsites dated AD 1100–1200 are found on top of the youngest Tsegi Alluvium. The snow line in the Rocky Mountains was about 300 metres higher than today. Similar trends are recorded in the Southern Hemisphere, notably in Australia and Chile. The first immigration of Maori peoples into New Zealand probably occurred at this mild time.

The so-called little ice ages

"Medieval" Cool Period. This interval, extending roughly from AD 1250 to 1500, corresponds to the Paria Emergence in the eustatic record and has been called one of the "little ice ages" by certain authors. Solar activity records show a decline from 1250 to 1350, a brief rise from 1350 to 1380, and then a phenomenal low that lasted until 1500. Pollen records in northern Europe reveal rather consistently cool conditions, and smoothed mean temperature curves show a cumulative drop during this period. Stalactite studies in a karst cave in France showed a travertine growth peak (indicating cool, moist conditions) in 1450. In North America cool, moist conditions were widespread at first, becoming dry later. The arroyos and washes became filled with the Naha Alluvium, and the human population decreased markedly. There is pollen evidence of a temperature drop of about 1° C. This is the period of the "Great Drought." In the upper Mississippi valley the Indian cultures began a general decline, accompanied by a transfer from agriculture to hunting. It was similar in the western prairies, and it was this hunting culture that the first Spanish explorers encountered.

In the Canadian north the mean temperatures had dropped about two degrees below the previous high. In the Sierra Nevada, the Rockies, and Alaska there were glacial readvances, with evidence of a 2° C temperature drop. In the Arctic regions, the Eskimo economy underwent a marked change to adjust to these more extreme conditions, which amounted to about 5° or 6° C below the mean of the climatic optimum.

The Norse settlements in Greenland were abandoned altogether as the permafrost advanced. Pollen studies at Godthåb indicate a shift from a maritime climate to a cold, dry continental regime. The sea ice off Iceland reveals an extraordinary growth in severity, from zero coverage before the year 1200 to eight-week average cover in the 13th century, rising to 40 weeks in the 19th century, and dropping again to eight weeks in the 20th century. In Japan there were glacial readvances and a mean winter temperature drop of 3.5° C. Summers were marked by excessive rains and bad harvests.

The equatorial regions now began a marked desiccation, with a drop in level of all the great African lakes. The Nile suffered a decreased flow and alluviation.

South of the equator in the temperate belts there occurred a general return to cooler and wetter conditions that have continued (with oscillations) until the present time in southern Chile, Patagonia, southernmost Africa, southwestern Australia, and New Zealand.

Little Ice Age. Throughout most of what is commonly called the Little Ice Age (1500–1850) the mean solar activity was quite low, but positive fluctuations occurred around 1540–90 and 1770–1800. The main westerly storm belts shifted about 500 kilometres to the south, and for much of the time the northern latitudes came under cool continental conditions. Observed temperature series in Europe from Paris to Leningrad show large fluctuations until 1850.

Glacier advances are recorded in the Alps, in the Sierra Nevada, and in Alaska. Corresponding low sea levels are recorded by early tide gauge records in The Netherlands and Germany. Even in equatorial latitudes there are traces of mountain glacier advances (as in the Andes of Colombia).

Impact of technology

The Industrial Age (AD 1850–1950). The year 1850 started a brief warming trend that persisted for 100 years. It also approximates a critical turning point in climatic, sea level, glacial, and sedimentologic records. In many regions of central and southern Europe "anthropogenic" sediments (or cultural layers) began to appear in Neolithic times (early to mid-Holocene). Elsewhere in the world (*e.g.,* in North America, Australia, South Africa), however, this type of sedimentation began around the middle of the 19th century, depending on soil erosion stimulated by mechanized (disk) plowing, large-scale deforestation, and engineering activity. Thus independently of natural climatic change, the century 1850–1950, marked by anthropogenic aridification, proved to be a time of man-made deserts.

The Earth now is on a long-term cooling trend of the glacial-interglacial cycles and is likely to continue so for several thousand years, but there are numerous modulating influences, meteorologic, geologic, and man-made. These may accelerate or reverse the general trend, and from the point of view of human history they can well play a critical role. (R.W.F./L.D.A.)

BIBLIOGRAPHY

General works. Overviews are presented in CLAUDE C. ALBRITTON, JR., *The Abyss of Time, Changing Conceptions of the Earth's Antiquity After the Sixteenth Century* (1980); DON L. EICHER, *Geologic Time,* 2nd ed. (1976); WILLIAM B.N. BERRY, *Growth of a Prehistoric Time Scale: Based on Organic Evolution,* rev. ed. (1987); HENRY FAUL and CAROL FAUL, *It Began with a Stone: A History of Geology from the Stone Age to the Age of Plate Tectonics* (1983); ROBERT H. DOTT, JR., and ROGER LYMAN BATTEN, *Evolution of the Earth,* 4th ed. (1988); and REED WICANDER and JAMES S. MONROE, *Historical Geology: Evolution of the Earth and Life Through Time* (1989). A. HALLAM, *Great Geological Controversies,* 2nd ed. (1989), traces the development of the history of geology and of various, often contradictory, concepts. For the early recognition of the geologic cycle and the promulgation of uniformitarianism, see the classics themselves: JAMES HUTTON, *Theory of the Earth, With Proofs and Illustrations,* 2 vol. (1795, reissued 1972); JOHN PLAYFAIR, *Illustrations of the Huttonian Theory of the Earth* (1802, reprinted 1964); and CHARLES LYELL, *Principles of Geology,* 3 vol. (1830–33), available also in many later editions. Relevant developments in modern geologic sciences are discussed in DONALD R. PROTHERO, *Interpreting the Stratigraphic Record* (1989); RUTH E. MOORE, *Man, Time, and Fossils: The Story of Evolution,* 2nd rev. ed. (1961); MARTIN J.S. RUDWICK, *The Meaning of Fossils: Episodes in the History of Palaeontology,* 2nd rev. ed. (1976, reprinted 1985); W. LEE STOKES, *Essentials of Earth History: An Introduction to Historical Geology,* 4th ed. (1982); DON L. EICHER and A. LEE MCALESTER, *History of the Earth* (1980); and DON L. EICHER, A. LEE MCALESTER, and MARCIA L. ROTTMAN, *The History of the Earth's Crust* (1984). (G.D.J.)

Relative and absolute dating. Surveys of methodologies of ascertaining geologic time include FREDERICK E. ZEUNER, *Dating the Past: An Introduction to Geochronology,* 4th rev. ed. (1958, reissued 1972); PATRICK M. HURLEY, *How Old Is the Earth?* (1959, reprinted 1979); E.I. HAMILTON, *Applied Geochronology* (1965); G. BRENT DALRYMPLE and MARVIN A. RALPH (eds.), *Dating Techniques for the Archaeologist* (1971). Stratigraphic geology as the basis of relative age measurement is discussed in W.B. HARLAND, A. GILBERT SMITH, and B. WILCOCK (eds.), *The Phanerozoic Time-Scale* (1964); JOHN W. HARBAUGH, *Stratigraphy and the Geologic Time Scale,* 2nd ed. (1974); ARTHUR HOLMES, *Holmes Principles of Physical Ge-*

ology, 3rd ed. rev. by DORIS L. HOLMES (1978); N.J. SNELLING (ed.), *The Chronology of the Geological Record* (1985); DEREK V. AGER, *The Nature of the Stratigraphical Record,* 2nd ed. (1981); and GILLES S. ODIN (ed.), *Numerical Dating in Stratigraphy,* 2 vol. (1982). The development of methods of absolute age measurement is examined in HENRY FAUL (ed.), *Nuclear Geology* (1954); HENRY FAUL, *Ages of Rocks, Planets, and Stars* (1966); the collected symposium papers published as *Radioactive Dating* (1963); ROBERT L. FLEISCHER, P. BUFORD PRICE, and ROBERT M. WALKER, *Nuclear Tracks in Solids: Principles and Applications* (1975); E. JÄGER and J.C. HUNZIKER (eds.), *Lectures in Isotope Geology* (1979); GUNTER FAURE, *Principles of Isotope Geology,* 2nd ed. (1986); and ROBERT BOWEN, *Isotopes in Earth Sciences* (1988). (T.E.Kr.)

Geologic history of the Earth. Reviews of Earth history based on information provided by the record of geologic processes include PRESTON CLOUD, *Oasis in Space: Earth History from the Beginning* (1988); L.R.M. COCKS (ed.), *The Evolving Earth* (1981); KENT C. CONDIE, *Plate Tectonics & Crustal Evolution,* 3rd ed. (1989); L.A. FRAKES, *Climates Throughout Geologic Time* (1979), a survey of all glaciations in Earth history; W.B. HARLAND *et al., A Geologic Time Scale* (1982), a well-documented account with many time charts; HAROLD L. LEVIN, *The Earth Through Time,* 3rd ed. (1988), with emphasis on sediments and fossils; R.J. O'CONNELL and W.S. FYFE (eds.), *Evolution of the Earth* (1981); CARL K. SEYFERT and LESLIE A. SIRKIN, *Earth History and Plate Tectonics: An Introduction to Historical Geology,* 2nd ed. (1979), with emphasis on the Phanerozoic Eon; STEVEN M. STANLEY, *Earth and Life Through Time,* 2nd ed. (1989); and BRIAN F. WINDLEY, *The Evolving Continents,* 2nd ed. (1984). Summaries of the geologic history of individual continents and countries include DEREK V. AGER, *The Geology of Europe: A Regional Approach* (1980); L. CAHEN and N.J. SNELLING, *The Geochronology and Evolution of Africa* (1984); ARTHUR ESCHER and W. STUART WATT (eds.), *Geology of Greenland* (1976); CHARLES S. HUTCHISON, *Geological Evolution of South-East Asia* (1989); D.V. NALIVKIN, *Geology of the U.S.S.R.* (1973; originally published in Russian, 1962); A.J. TANKARD *et al., Crustal Evolution of Southern Africa: 3.8 Billion Years of Earth History* (1982); and YANG ZUNYI, CHENG YUGI, and WANG HONGZHEN (TSUN-I YANG, YÜ-CH'I CHE'NG, and HUNG-CHEN WANG), *The Geology of China* (1986).

Precambrian Era. L.D. AYRES *et al., Evolution of Archean Supracrustal Sequences* (1985), presents good overviews of worldwide occurrences. KENT C. CONDIE, *Archean Greenstone Belts* (1981), offers a detailed synthesis. D.R. HUNTER (ed.), *Precambrian of the Southern Hemisphere* (1981), includes authoritative accounts of Australia, southern Africa, and South America. ALFRED KRÖNER and REINHARD GREILING (eds.), *Precambrian Tectonics Illustrated* (1984), reviews classic occurrences. S. MAHMOOD NAQVI and JOHN J.W. ROGERS, *Precambrian Geology of India* (1987), is a succinct review. Other surveys of Archean and Proterozoic stratigraphy and paleontology include those by E.G. NISBET, *The Young Earth: An Introduction to Archaean Geology* (1987); and by J. WILLIAM SCHOPF (ed.), *Earth's Earliest Biosphere: Its Origin and Evolution* (1983). (B.F.W.)

Paleozoic Era. Summaries of Paleozoic history and life are found in many of the general works cited in the beginning sections of this bibliography.

Cambrian Period: C.H. HOLLAND (ed.), *Cambrian of the New World* (1971), *Cambrian of the British Isles, Norden, and Spitsbergen* (1974), *Lower Palaeozoic of the Middle East, Eastern and Southern Africa, and Antarctica* (1981), and *Lower Palaeozoic of North-Western and West-Central Africa* (1985), are detailed surveys of Lower Paleozoic rocks. Correlation charts, explanatory notes on rocks and faunas, and extensive references are found in REINHARD WOLFART, *The Cambrian System in the Near and Middle East* (1983); J.H. SHERGOLD *et al., The Cambrian System in Australia, Antarctica, and New Zealand* (1985); W.T. CHANG, *The Cambrian System in Eastern Asia* (1988); KAISA MENS, JAN BERGSTRÖM, and KASIMIERA LENDZION, *The Cambrian System on the East European Platform* (1990); and VLADIMIR A. ASTASHKIN *et al., The Cambrian System on the Siberian Platform* (1991). MICHAEL E. TAYLOR (ed.), *Short Papers for the Second International Symposium on the Cambrian System, 1981* (1981), contains research reports from many parts of the world. Descriptions of Cambrian life-forms and those of succeeding geologic periods are found in RAYMOND C. MOORE *et al.* (eds.), *Treatise on Invertebrate Paleontology* (1953–), a comprehensive multivolume work; part A contains a discussion of Cambrian biostratigraphy. STEPHEN JAY GOULD, *Wonderful Life: The Burgess Shale and the Nature of History* (1989), analyzes a famous Cambrian biota and its significance in the history of life. (R.A.R.)

Ordovician Period: In addition to relevant sections of the general surveys cited above, discussions of the development of knowledge of Ordovician time correlations, climates, sea-level changes, and life are offered in R.J. ROSS, JR., "The Ordovician System, Progress and Problems," *Annual Review of Earth and Planetary Sciences,* 12:307–335 (1984); and in a collection of essays by DAVID L. BRUTON (ed.), *Aspects of the Ordovician System* (1984). (W.B.N.B.)

Silurian Period: C.H. HOLLAND and M.G. BASSETT (eds.), *A Global Standard for the Silurian System* (1989), provides working definitions for systemic, series, and stage boundaries at stratotypes in the United Kingdom and the Czech Republic, summaries of other reference localities, and reviews of the major index fossils. ANDERS MARTINSSON (ed.), *The Silurian-Devonian Boundary* (1977), applies the "golden spike" concept in defining a chronostratigraphic boundary. JAMES A. SECORD, *Controversy in Victorian Geology: The Cambrian-Silurian Dispute* (1986), presents a historical treatment of Murchison's development of the Silurian system and the conflict that arose therein. A.M. ZIEGLER *et al.,* "Silurian Continental Distributions, Paleogeography, Climatology, and Biogeography," *Tectonophysics,* 40(1–2):13–51 (1977), offers an especially thorough treatment of Silurian weather systems that remains valid despite minor revisions in paleogeography. A thorough review of issues related to tectonics, paleogeography, sea-level events, reef development, and sedimentary patterns is found in *Special Papers in Palaeontology,* no. 44 (1990), the whole issue being devoted to the papers of the first international symposium on the Silurian System that took place in early 1989. (M.E.Jo.)

Devonian Period: For the Devonian rocks, environment, and life-forms, see D.L. DINELEY, *Aspects of a Stratigraphic System: The Devonian* (1984); M.R. HOUSE, C.T. SCRUTTON, and M.G. BASSETT (eds.), *The Devonian System: A Palaeontological Association International Symposium* (1979); W.S. MCKERROW and C.R. SCOTESE (eds.), *Palaeozoic Palaeogeography and Biogeography* (1990); and N.J. MCMILLAN, A.F. EMBRY, and D.J. GLASS (eds.), *Devonian of the World: Proceedings of the Second International Symposium on the Devonian System,* 3 vol. (1988). (M.R.H.)

Carboniferous Period: Discussions of the period are included in general texts on historical geology, such as COLIN W. STEARN, ROBERT L. CARROLL, and THOMAS H. CLARK, *Geological Evolution of North America,* 3rd ed. (1979). The results of ongoing research in the field are presented at congresses and published as INTERNATIONAL CONGRESS ON CARBONIFEROUS STRATIGRAPHY AND GEOLOGY, *Compte rendu* (irregular), including materials in French, English, and German. The Decade of North American Geology project of the Geological Society of America includes works on Carboniferous geology in many of its series of publications. Another series, undertaken by the International Union of Geological Sciences, summarizes the Carboniferous geology of all continents: Carlos Martinez Diaz (ed.), *The Carboniferous of the World* (1983–). (W.L.Ma.)

Permian Period: In addition to the general texts cited above, specific references include CHARLES A. ROSS and JUNE R.P. ROSS, "Permian," in *Treatise on Invertebrate Paleontology,* part A, *Introduction—Fossilization (Taphonomy), Biogeography, and Biostratigraphy* (1979), pp. 291–350, and "Late Paleozoic Sea Levels and Depositional Sequences," in CHARLES A. ROSS and DREW HAMAN (eds.), *Timing and Depositional History of Eustatic Sequences: Constraints on Seismic Stratigraphy* (1987), pp. 137–149; CHARLES A. ROSS, "Paleozoic Evolution of Southern Margin of Permian Basin," *Geological Society of America Bulletin,* 97(5):536–554 (1986); L.L. SLOSS (ed.), *Sedimentary Cover, North American Craton, U.S.* (1988); and GARRY D. MCKENZIE (ed.), *Gondwana Six: Stratigraphy, Sedimentology, and Paleontology* (1987). (J.R.P.R./Ch.A.R.)

Mesozoic Era. For a survey of the era, see the general texts on historical geology cited at the beginning of this bibliography, especially CARL K. SEYFERT and LESLIE A. SIRKIN, *Earth History and Plate Tectonics: An Introduction to Historical Geology,* 2nd ed. (1979), which develops important aspects of Mesozoic plate divergence, mountain building, geosynclines, and life-forms and extinction events. JOHN D. COOPER, RICHARD H. MILLER, and JACQUELINE PATTERSON, *A Trip Through Time: Principles of Historical Geology,* 2nd ed. (1990), incorporates a narrative review of Earth history by eras. (L.Si.)

Triassic Period: A. LOGAN and L.V. HILLS (eds.), *The Permian and Triassic Systems and Their Mutual Boundary* (1973), includes papers of an international conference on the subject. Information on the fauna and flora of the period, as well as its paleogeography, is found in N.J. SILBERLING and E.T. TOZER, *Biostratigraphic Classification of the Marine Triassic in North America* (1968); E.T. TOZER, *A Standard for Triassic Time* (1967), "Triassic Time and Ammonoids: Problems and Proposals," *Canadian Journal of Earth Sciences,* 8:983–1031 (1971), and *The Trias and Its Ammonoids: The Evolution of a Time Scale* (1984); and A. HALLAM (ed.), *Patterns of Evolution as Illustrated by the Fossil Record* (1977). (A.Lo.)

Jurassic Period: Discussions of notable geologic features of the period include DAVID G. HOWELL, "Terranes," *Scientific American,* 253(5):116–126 (November 1985), a treatment of the origin and nature of microplates, with an analysis of western North American terranes that provides evidence of ancient oceanic crust; JOHN C. LORENZ, *Triassic-Jurassic Rift-Basin Sedimentology: History and Methods* (1988), an overview of basin research from the 19th century to the present, emphasizing the Hartford Basin in Connecticut; and JOHN MCPHEE, *Basin and Range* (1981), a discussion of the basin and range structure of North America. The results of significant stratigraphic research are presented in RALPH W. IMLAY, *Correlation of the Jurassic Formations of North America, Exclusive of Canada* (1952), a clarification of the biostratigraphic basis for the correlations. Life-forms of the period are addressed in the appropriate sections of the *Treatise on Invertebrate Paleontology* cited above; RAYMOND C. MOORE, CECIL G. LALICKER, and ALFRED G. FISCHER, *Invertebrate Fossils* (1952), dealing with the biology, morphology, ecology, classification, and biostratigraphy of the invertebrate phyla; ROBERT T. BAKKER, *The Dinosaur Heresies: New Theories Unlocking the Mystery of the Dinosaurs and Their Extinction* (1986); and JOHN H. OSTROM, "A New Look at Dinosaurs," *National Geographic,* 154(2):152–185 (August 1978), intended to dispel old myths about dinosaur evolution and to substitute an ecosystem-based extinction scenario for the formerly proposed climatic, volcanic, dietary, or extraterrestrial explanations. (L.Si.)

Cretaceous Period: Studies of the stratigraphy of the period include T. BIRKELUND *et al.*, "Cretaceous Stage Boundaries: Proposals," *Bulletin of the Geological Society of Denmark,* 33(1–2):3–20 (1984); J.M. HANCOCK and E.G. KAUFFMAN, "The Great Transgressions of the Late Cretaceous," *Journal of the Geological Society of London,* 136:175–186 (1979), comparing the transgressions in Europe, North America, and other areas; T. MATSUMOTO, "Inter-regional Correlation of Transgressions and Regressions in the Cretaceous Period," *Cretaceous Research,* 1(4):359–373 (1980), comparing the stable areas and relationships to tectonically active areas; and RICHARD A. REYMENT and PETER BENGTSON (compilers), *Events of the Mid-Cretaceous: Final Report on Results Obtained by IGCP Project* (1986), surveying mid-Cretaceous studies worldwide. Cretaceous rocks and environmental features are the subject of W.G.E. CALDWELL (ed.), *The Cretaceous System in the Western Interior of North America* (1975), a series of papers on a Cretaceous epicontinental sea; C.R. LLOYD, "The Mid-Cretaceous Earth: Paleogeography, Ocean Circulation and Temperature, Atmospheric Circulation," *Journal of Geology,* 90(4):393–413 (1982), providing quantitative and qualitative synthesis of climate, circulation, and temperatures; and WALTER KEGEL CHRISTENSEN, *Upper Cretaceous Belemnites from the Vomb Trough in Scania, Sweden* (1986), focusing on the biostratigraphy and biogeography of boreal Europe. Life-forms are examined by NORMAN F. SOHL, "Cretaceous Gastropods: Contrasts Between Tethys and the Temperate Provinces," *Journal of Paleontology,* 61(6):1085–1111 (1987), a comparative faunal history; C.F. KOCH and N.F. SOHL, "Preservational Effects in Paleoecological Studies: Cretaceous Mollusc Examples," *Paleobiology,* 9:26–34 (1983); and S.M. STANLEY, *Earth and Life Through Time,* 2nd ed. (1989). (C.F.K.)

Cenozoic Era. *Tertiary Period:* In addition to general geologic histories, other sources include STEPHEN JAY GOULD, *Time's Arrow, Time's Cycle: Myth and Metaphor in the Discovery of Geological Time* (1987); MAURICE GIGNOUX, *Stratigraphic Geology* (1955; originally published in French, 4th ed., 1950); M.J. HAMBREY and W.B. HARLAND (eds.), *Earth's Pre-Pleistocene Glacial Record* (1981); A.M. SPENCER (ed.), *Mesozoic-Cenozoic Orogenic Belts* (1974); and WILLIAM J. FRAZIER and DAVID R. SCHWIMMER, *Regional Stratigraphy of North America* (1987). Studies of the environment of this interval of Earth history include JOHN M. ARMENTROUT, MARK R. COLE, and HARRY TERBEST, JR., *Cenozoic Paleogeography of the Western United States* (1979); B.M. FUNNELL and W.R. RIEDEL (eds.), *The Micropalaeontology of Oceans* (1971); and KOTORA HATAI, *Tertiary Correlations and Climatic Changes in the Pacific* (1967). Flora and fauna of the period are studied in CHARLES B. BECK (ed.), *Origin and Early Evolution of Angiosperms* (1976); W.B. HARLAND *et al.* (eds.), *The Fossil Record* (1967); DONALD E. SAVAGE and DONALD E. RUSSELL, *Mammalian Paleofaunas of the World* (1983); and R.J.G. SAVAGE, *Mammal Evolution: An Illustrated Guide* (1986). (W.A.Be.)

Quaternary Period: General summaries of the physical and biological record of the Pleistocene Epoch are found in RICHARD F. FLINT, *Glacial and Quaternary Geology* (1971); TAGE NILSSON, *The Pleistocene: Geology and Life in the Quaternary Ice Age* (1983); and V. ŠIBRAVA, D.Q. BOWEN, and G.M. RICHMOND (eds.), *Quaternary Glaciations in the Northern Hemisphere* (1986). Regional surveys include W.F. RUDDIMAN and H.E. WRIGHT, JR. (eds.), *North America and Adjacent Oceans During the Last Deglaciation* (1987); STEPHEN C. PORTER and H.E. WRIGHT, JR. (eds.), *Late-Quaternary Environments of the United States,* 2 vol. (1983); N.J. SHACKLETON, R.G. WEST, and D.Q. BOWEN (eds.), *The Past Three Million Years: Evolution of Climatic Variability in the North Atlantic Region* (1988); and A.A. VELICHKO, H.E. WRIGHT, JR., and C.W. BARNOSKY (eds.), *Late Quaternary Environments of the Soviet Union,* trans. from Russian (1984). R.S. BRADLEY, *Quaternary Paleoclimatology: Methods of Paleoclimatic Reconstruction* (1985), is a well-written reference source. A historical account of the development of the glacial theory, the Quaternary climatic record, and hypotheses of climatic change is given in JOHN IMBRIE and KATHERINE PALMER IMBRIE, *Ice Ages: Solving the Mystery* (1979, reissued 1986). Megafaunal extinctions at the end of the Pleistocene are explored in PAUL S. MARTIN and RICHARD G. KLEIN (eds.), *Quaternary Extinctions: A Prehistoric Revolution* (1984). The biological record is emphasized in ANTONY J. SUTCLIFFE, *On the Track of Ice Age Mammals* (1985); and MICHAEL O. WOODBURNE (ed.), *Cenozoic Mammals of North America: Geochronology and Biostratigraphy* (1987). (W.H.J.)

A chronological survey of the Holocene Epoch is provided by ERNST ANTEVS, "Geologic-Climatic Dating in the West," *American Antiquity,* 20(4):317–335 (April 1955). O.K. DAVIS *et al.*, "The Pleistocene Dung Blanket of Bechan Cave, Utah," in H.H. GENOWAYS and M.R. DAWSON (eds.), *Contributions in Quaternary Vertebrate Paleontology* (1984), pp. 267–282; RUSSELL W. GRAHAM, HOLMES A. SEMKEN, JR., and MARY ANN GRAHAM (eds.), *Late Quaternary Mammalian Biogeography and Environments of the Great Plains and Prairies* (1987); and J.I. MEAD *et al.*, "Dung of Mammuthus in the Arid Southwest, North America," *Quaternary Research* 25(1):121–127 (1986), are paleoecological and paleontological studies. Human ecology is the subject of NEIL ROBERTS, *The Holocene: An Environmental History* (1989); and IAN TATTERSALL, ERIC DELSON, and JOHN VAN COUVERING (eds.), *Encyclopedia of Human Evolution and Prehistory* (1988). (L.D.A.)

Geography

Geography is the study of the surface of the Earth. The word is derived from the Greek words *geō* ("the Earth") and *graphein* ("to write"). The surface of the Earth is the interface of the atmosphere, lithosphere, hydrosphere, and biosphere. It provides the habitat, or environment, in which humans are able to live. This habitable zone has a number of special characteristics. One of the most important is the complex interaction among many physical, biologic, and human elements of the Earth, such as land surface, climate, water, soil, vegetation, agriculture, and urbanization. Another characteristic is the high variability of the environment from place to place—hot tropics to cold polar regions, dry deserts to humid equatorial forests, vast level plains to rugged mountains, and uninhabited ice caps to densely settled metropolitan areas. Yet another is the consistency with which significant patterns occur, which makes possible generalizations about distributions; obvious examples are measurements of temperature and rainfall, which are the most important climatic elements affecting farming and many other human activities. Geographic study is particularly concerned with location, with areal patterns, with the interrelationships of phenomena (especially of the relationship between human society and the land, as in ecology), with regionalization, and with ties among areas. Typical areas of inquiry include where people live; in what sort of patterns they are distributed over the Earth's surface; what factors of environment, resources, culture, and economic development account for this distribution; whether or not significant regions can be recognized by types of population, livelihood, and culture; and what types of movements and relations occur among places.

For coverage of related topics in the *Macropædia* and *Micropædia*, see the *Propædia*, sections 10/33 and 10/36, and the *Index*.

This article is divided into the following sections:

ORIGIN AND DEVELOPMENT OF GEOGRAPHY

Early history. Human beings are inherently curious. They wonder how other lands and peoples differ from their own home and folk. The first recorded knowledge of such differences came mainly from the accounts of travelers. The 5th-century-BC Greek writer Herodotus was an outstanding early example of one who carefully recorded his personal observations made during many years of extensive travel. The Greek perception of the Earth was highly advanced: the philosophers Pythagoras and Aristotle believed it to be a sphere, and the Pythagorean Philolaus taught that it revolved around a central fire. In the 3rd century BC Eratosthenes of Cyrene, whose *Geographica* was the first work to have the word geography as its title, employed ingenious reasoning and measurements to produce a remarkably accurate calculation of the circumference of the Earth. He had observed that at Syene (modern Aswān, Egypt) at noon on the summer solstice the Sun was directly overhead, while at Alexandria it cast a shadow. By calculating the angle of the shadow and using the distance between Syene and Alexandria, Eratosthenes arrived at a figure of 250,000 stadia (or stades) for the Earth's circumference. The length of the stadium unit that he used is not known, but the range of modern estimates for the unit indicate that his figure exceeded the actual circumference at the Equator by about 15 percent or less. Eratosthenes' figure, however, subsequently was rejected by classical geographers, such as Ptolemy—who calculated, erroneously, that the Earth was much smaller—and centuries would pass before a more accurate calculation would be made and generally accepted.

The ancient Greeks

In his 17-volume work written at about the time of Christ, the Greek geographer and historian Strabo provided the most detailed summary and review of the classical knowledge of geography. The first two books were devoted to a wide-ranging discussion of the aims and methods of geography and to a review of earlier writings; many early works of Greek or Roman authors have disappeared or have survived only in fragments, and they are known today only through Strabo's critical comments in these books. The other 15 books written by Strabo provided regional descriptions. The great contribution of the 2nd-century-AD astronomer and geographer Ptolemy was the concept of the tabulation of latitude and longitude of places; these tabulations could give precision to locations, but Ptolemy's data again contained errors that were to plague geographers for centuries.

With the breakup of the Roman Empire in the West, most of the geographic knowledge of the Greeks gradually was lost in Europe, but during the 11th and 12th centuries it was preserved, revised, and enlarged by Arab geographers. Geographic study in Europe was stimulated anew by contact with Muslim learning during the Crusades, although in their reacquaintance with Greek ideas—particularly those of Ptolemy—European thinkers generally ignored the additions and corrections of the Arabs. Thus, the errors of Ptolemy were perpetuated in the West until the voyages of the 15th and 16th centuries started bringing back to Europe detailed and more accurate information on the rest of the world.

The Arabs

An important figure of the new learning was the German scholar Bernhardus Varenius (Bernhard Varen), whose *Geographia generalis* (1650; *General Geography*) was revised numerous times and remained a standard reference work for a century or more. Unlike many earlier writers, Varenius included ideas based on direct observations and original measurements. In the century before Varenius, the Flemish cartographer Abraham Ortelius prepared a world map in sections and bound them together in book form in his *Theatrum orbis terrarum* (1570; *Epitome of the Theatre of the World*), the first atlas. The first use of the term atlas, however, was by Ortelius' contemporary Gerardus Mercator (Gerhard de Cremer) and is said to be derived from the representation of Atlas supporting the heavens that formed a frontispiece to early atlases. Mercator, who also came from Flanders, was the leading cartographer of the 16th century.

The four generations of the Cassini family of astronomers and surveyors in France were preeminent in developing methods for accurately surveying the land surface. In work extending from the late 17th to the late 18th century, the Cassinis made the first detailed topographic survey of a large country, and this was used as the basis for a national atlas of France published in 1791. In the 18th century James Cook set new standards in accuracy and skill in navigation. Furthermore, his voyages had scientific missions. On his famous second voyage (1772–75), which circumnavigated the globe at high southern latitudes, he was accompanied by Johann and Georg Forster, the father and son who made botanical collections and climatological observations. Georg Forster later influenced Alexander von Humboldt to study geography.

Contributions of Humboldt

Like many before him Humboldt was determined to see for himself what other parts of the world were like, but he was distinguished by the range of his curiosity, by the careful preparation for his trips, by the range and precision of his observations and measurements, by his mental acuity in suggesting and evaluating possible interrelationships, and by his utilization of carefully recorded notes and observations over many years for reflective analysis and publication. He purchased, learned to use, and made extensive measurements with the measuring instruments of his time. During his travels in South and Central America (1799–1804) Humboldt located places with accurate latitudes and reasonably close longitudes. Through his detailed observations in the Andes he was able to provide the first systematic description of the interrelations of altitude, temperature, vegetation, and agriculture in low-latitude mountains and to provide a clear picture of vertical zonation. He plotted his data on maps and coined the term isotherm for a line joining points with the same temperatures. In his regional monograph on the economic geography of New Spain (Mexico), Humboldt presented data on population, production, trade, utilization of resources, and their interconnections.

Emergence of the modern discipline. Humboldt thus laid the groundwork for modern geography, with its emphasis on direct field observation and accurate measurements as the basis for generalizations. Three institutional innovations in the 19th century also played important roles in the development of the modern discipline: a new type of university, the rise of geographic societies, and organized government surveys of natural conditions and resources. In 1809 Humboldt's brother Wilhelm, with the support of Frederick William III of Prussia, founded the University of Berlin (now the Humboldt University of Berlin), without requirements to either faculty or students to adhere to a particular creed. Although universities had existed since the Middle Ages, many had come to be viewed primarily as defenders of Christianity rather than as centres of free inquiry. The flowering of universities gave rise to specialists in many academic disciplines, including geography, who besides teaching carried out programs of original research that created great bodies of new knowledge.

In his *Kritik der reinen Vernunft* (1781; *Critique of Pure Reason*) the 18th-century German philosopher Immanuel Kant had already provided a reasoned statement of the place of geography among the fields of learning, noting that geography dealt with phenomena associated in space just as history dealt with events occurring together in time. Both Kant and Alexander von Humboldt lectured on physical geography, the latter at the University of Berlin. Carl Ritter, a contemporary of Humboldt, also taught at the university, occupying the first chair of geography ever established at a modern university.

Founding of geographic societies

As the number of teachers and specialists grew, they created professional associations. Geographic societies began to play an important role in the diffusion of geographic knowledge. The Société de Géographie de Paris was founded in Paris in 1821, the Gesellschaft für Erdkunde zu Berlin in Berlin in 1828, the Royal Geographical Society in London in 1830, the Imperial Russian Geographical Society in St. Petersburg (modern Leningrad) in 1845, and the American Geographical Society in New York City in 1851. These associations and others provided a forum for reporting on new geographic knowledge by sponsoring lectures and discussions and by publishing periodicals, monographs, and maps.

The rise of governmental surveys of resources, natural features, and possibilities for settlement was particularly important in the large continental expanses of the United States and the Russian Empire. In the United States Thomas Jefferson, who had a keen sense of geography, dispatched the Lewis and Clark Expedition (1804–06) to explore the newly acquired lands of the Louisiana Purchase and beyond. In the second half of the 19th century a number of expeditions to the West surveyed routes for a transcontinental railroad, explored possibilities for settlement, determined the extent of mineral resources, and mapped the basic characteristics of the terrain. The Russian tsar Peter I the Great recognized the importance of exact geographic knowledge in the landward expansion of his country and thus supported expeditions and geographic publications. In 1727 Ivan Kirilov produced the first systematic geographic and economic description of Russia and in 1734 published the first atlas of the Russian Empire. Many geographic expeditions were sponsored by the government and by geographic societies. The establishment of networks for systematic geographic observation aided mapping of many physical phenomena. At the suggestion of Humboldt, a network of weather stations was established throughout Russia, and Humboldt later was able to utilize data from these stations in his studies of continental climates. While he was in charge of the U.S. Navy's Depot of Charts and Instruments (later the U.S. Naval Observatory), the pioneer hydrographer Matthew Fontaine Maury distributed special logbooks to sea captains for the recording of information on winds and currents. From these observations he was able to prepare maps of the Earth's major wind patterns, which enabled vessels to shorten considerably the time of voyages. In 1855 Maury published *The Physical Geography of the Sea,* the first work of modern oceanography.

Geography as an academic discipline—*i.e.,* as a field of advanced study and research in universities—became well-established in Germany in the 1870s. In 1874 the Prussian government decreed that a chair of geography (to be occupied by a professor) would be established in each of the Prussian universities, and by 1880 10 such professors had been appointed. Other universities in Germany, as well as in France and other European countries, quickly followed suit. Among the leaders during this period of expansion and definition of the field was the German geographer and geologist Ferdinand Paul Wilhelm, Freiherr von Richthofen, who wrote a monumental five-volume study of Chinese geography and was influential in the development of geographic methodology in Germany and elsewhere. Another German, Friedrich Ratzel, wrote pioneering works in the fields of human and political geography.

Rise of opposing schools

The rise of a considerable body of geographers with advanced academic training in the discipline led to the emergence of differing beliefs on the nature of geography. One school thought of geography as the study of the interrelationships of phenomena that occur together in space, specifically of the relationships of man and nature. In one form this was conceived as the influence that natural conditions exercise on humans—a sort of environmental determinism. The reverse of this was man's effect on nature, first examined by the American diplomat and scholar George Perkins Marsh in *Man and Nature, or Physical Geography as Modified by Human Action* (1864). A second school, founded on ideas of Richthofen and elaborated by the German Alfred Hettner, conceived of geography as areal differentiation. This concept was further expanded by the American geographer Richard Hartshorne in *The Nature of Geography* (1939). Yet a third school considered the proper object of geographic inquiry to be the visual landscape (either alone or in association with nonvisual elements). In this tradition an attempt was made to reconstruct the "original landscape" (*Urlandschaft*) of Earth before the advent of humans; this landscape was distinct from the cultural landscape, transformed by human agency. Other geographers interpreted landscapes mainly on the basis of vegetation types of the world and associated phenomena. Although differing in viewpoint and emphasis, each of these schools was concerned with the variations of human, physical, and biologic phenomena over space on the Earth's surface and the interrelationships or associations of these phenomena in specific places or regions.

The rise of modern geography in France was led by Paul Vidal de La Blache. Vidal de La Blache defined the field of regional geography, emphasizing the study of small, relatively homogeneous areas that he called *pays*. He also concentrated on the interrelationship of man and environment, which he termed "possibilism": within limits, nature offers possibilities to humans, who in utilizing these possibilities—expressed by such means as culture and technology—modify nature. In 1898 Vidal de La Blache became the first occupant of the chair in geography at the Sorbonne whose academic training was in geography. There he trained a large and able group of students, who themselves were named to professorships at other French universities and who wrote a distinguished series of works on the regions of France. Vidal de La Blache had planned a mammoth series of regional geographies to cover the entire world but died before the plan could be realized; the 23-volume *Géographie universelle* (1927–48), completed mostly under the direction of his student Lucien Gallois, has remained the most successful world regional geography ever published.

In Great Britain a report by the Royal Geographical Society, in which British scholarship in geography was compared unfavourably with that in the countries of continental Europe, prompted the appointment of geographers at the universities of Oxford and Cambridge in 1887 and 1888, respectively. Halford (later Sir Halford) J. Mackinder, who became the chair at Oxford, had a grand sweep of both history and geography. His principal work, *Britain and the British Seas* (1902; 2nd ed. 1930), included an imaginative and broad interpretation of the rise of Britain and of British sea power in relation to the maritime resources and protection from invasion provided by the surrounding seas. He later developed the concept of a landlocked heartland in Eurasia inaccessible to sea power and a rimland easily accessible from the ocean and of the relations between the two regions. This concept was further developed after World War I in his *Democratic Ideals and Reality* (1919); and still later it found ultimate expression in the creation of the North Atlantic Treaty Organization and the Warsaw Pact political and military blocs. Others who contributed to the rise of geography in Britain include Hugh Robert Mill, who studied the part played by water in the world economy; George G. Chisholm, whose *Handbook of Commercial Geography* (1889; many subsequent editions) provided a meticulous, detailed worldwide survey of commercial products and conditions of their production and trade; and A.J. Herbertson, who succeeded Mackinder at Oxford and who proposed a framework of natural regions for the study of world geography.

Work of Mackinder

In prerevolutionary Russia four individuals played key roles in the development of geography in the late 19th century: P.P. Semyonov, who wrote a seminal five-volume study of Russian geography; A.I. Voyeykov, who investigated climate, particularly in relation to agriculture; V.V. Dokuchayev, who made pioneering studies in soil geography; and D.N. Anuchin, who in 1885 became the head of the new department of geography at the University of Moscow and who trained many of the geographers who later occupied key positions in the Soviet Union.

Geography in the 20th century. At the end of the 19th century geography was a subject of original research and teaching mainly in the universities of Germany, France, and nearby continental countries and, to a lesser extent, in the major universities of Great Britain. The flowering of geography in these countries, coupled with the excitement of the great surveys of the American West, had a strong impact on geographic studies at the universities in the United States. During the first half of the 20th century geography became well-established in the United States, as well as in Great Britain. A key figure in the United States was William Morris Davis, who contributed to physical geography—especially to the branch called geomorphology—by developing the concept of the erosion cycle. Many of his students became distinguished contributors to geography. An important event in the rise of academic geography in the United States was the creation in 1903 at the University of Chicago of a department of geography devoted to graduate instruction and research. It trained many of the geographers who were among the earliest professors and leaders in the development of the modern discipline in American universities. Also important was the Department of Geography and Industry at the University of Pennsylvania, Philadelphia, where J. Russell Smith wrote the influential *Industrial and Commercial Geography* (1913), a highly readable regional geography of North America that in many revisions remained a major textbook for half a century. The teaching of geography was cultivated in many teachers' colleges, among which Michigan State Normal College (now Eastern Michigan University), in Ypsilanti, was outstanding.

Geography in the United States

After World War II, particularly in the 1950s and '60s, geographic studies underwent considerable expansion in the United States and Great Britain and spread widely in the universities of Canada, Australia, and Japan. In eastern Europe, particularly in what was then the Soviet Union, Poland, and Hungary, important research institutes were established within the framework of academies of sciences. Scandinavia became a centre of study of the spatial diffusion of innovation: particularly influential was the work of Torsten Hägerstrand, who studied the impact of the growing use of automobiles and telephones in Sweden. Contrasts of geographic work among countries resulted from varied national traditions, differing needs, and unequal receptivity to change.

International ties among geographers were greatly strengthened by three factors: active programs sponsored by the International Geographical Union, which has members from some 90 countries who participate in international congresses and contribute to the work of commissions; the evolving role of English as a common language of international communication and conferences and its supplementary use in geographic periodicals in other languages or as a basic language of scientific publications in many non-Anglophone countries; and the speed and ease of international travel, facilitating frequent personal contacts.

During the 20th century the discipline has evolved rapidly, with many new concepts and methodologies. At first geomorphology was the exciting field, with the generalizing power of Davis' theories. Until mid-century the focus was particularly on regional geography and the great diversity of the lands and peoples of the world. After World War II regional geographers often were associated with the implementation of economic programs in less-developed areas. In the 1960s attention turned to the development of quantitative methods and the building of models of both physical and human systems. In the late 1960s and the 1970s active environmental concerns came once again to the fore after a period of relative neglect that had resulted from a reaction to an earlier, crude environmental determinism. In the 1970s and '80s the rise of quantitative models based on large bodies of data from censuses and other surveys came to be perceived by some geographers as dealing too much with abstract space and not enough with terrestrial place. Calls were made for a behavioral approach involving individual perceptions and choices and for a more humanistic geography. Still others called for more radical approaches. But throughout these changes ran a common thread of intense interest in human beings and their societies, in the physical and biologic environment, in areal patterns of occurrence on the surface of the Earth, and in associations and interrelationships in specific places and regions, whether viewed from an ecological or systems perspective. Better statistical sources became available, especially in many new national censuses. Aerial photography offered a new tool, but even more exciting and powerful have been the possibilities of remote sensing from artificial satellites and of using computers to handle masses of data and their analysis.

Impact of human occupation

The very object of geographic study—the surface of the Earth—has changed rapidly, particularly under the impact of humans, in the second half of the 20th century. Geographers, in common with scientists and scholars in many fields, increasingly have become concerned with a number of problems: desertification, whether caused by recurring droughts or by human actions; the hasty clearing of equatorial forests, which upset delicate biological balances; the threat of natural disasters of many kinds and also of man-made accidents, particularly nuclear ones; environmental pollution, as with acid rain in North America and Europe or air pollution in cities; the high rates of population increase that pose special problems of survival in some developing countries with limited resources; the persisting problems of enormous regional variations in resource use, productivity, wealth, and welfare; and the spectre of hunger and starvation in fragile environments, often exacerbated by economic and political problems. Among the potential developments have been exploitation of the mineral and other resources of the oceans and ocean floors, the use of biogenetic engineering to increase agricultural productivity and to solve problems created by the pests that inhibit expansion of farming in many regions of the world, and the perfection of superconductivity to overcome the inefficient transfer of electrical energy. All of these problems and potentials include geographic attributes—since they involve natural and human factors in a spatial setting—and they present continuing frontiers for research and study.

GEOGRAPHIC METHODS

Map location and measurement. The map is the distinctive data bank of the geographer. Since geography deals particularly with locations, distributions, areal associations, and interrelationships of phenomena in space, accurate observation and measurement of the surface of the Earth and the recording and displaying of location on maps are of prime importance.

Latitude and longitude

Latitude and longitude are commonly utilized for plotting locations on the surface of the globe. Fairly accurate measurements of latitude were made in antiquity by Greek scholars. Measurements of longitude remained rough, however, because of the difficulty in measuring differences in solar time (the Sun "moves" westward at the mean rate of one degree each four minutes). The perfection of the chronometer solved this problem, but for long each country had its own system for numbering the meridians. Finally, by an international agreement reached in 1884, an imaginary line from pole to pole through Greenwich, near London, was recognized as the prime meridian (*i.e.,* 0° longitude). Measurement of direction, or bearing, was aided considerably by use of the magnetic compass, but as Christopher Columbus noted in crossing the Atlantic, the direction in which the compass pointed varied with longitude.

The measurement of distances overland could be counted in days of journey on foot, by camel, by horse, or by other means. More accurate measurements of short distances were obtained by using a chain, and the chain as a unit of length (66 feet) is still a traditional surveying measure in English-speaking countries. Later, the chain itself was replaced by a steel tape, and still later electronic instruments came into use. A practical measurement of distances at sea was developed in the 16th century: a log was thrown overboard and the amount of time it took the stationary log to play out a certain distance on a line marked off with knots was measured. Navigation by means of satellites is now available, but a ship's speed is still measured in knots and records are kept in a logbook. After the adoption of the metre as a standard unit in France in the late 18th century, it gradually replaced older local and national measures of distance over much of the world during the 19th and 20th centuries.

Maps of small areas—topographic maps, for example—can be made by a method called triangulation. A baseline is measured with chains or other devices, and by using this base as one side of a triangle the other sides are calculated from the angles at the two ends of the baseline. Angles can be measured more easily and accurately than distances, and from the points on the corners of the original triangle, a network of points joined by triangles can be established. Triangulation was known to the ancient Egyptians and Greeks; with improved instruments, especially the theodolite, this method was utilized in the great national surveys of Europe and America from the 18th to the 20th century. How to represent the entire, spherical Earth or large areas of it on maps remained a problem. In 1492 the German navigator and geographer Martin Behaim completed the construction of a terrestrial globe. Ships following straight lines on flat maps, however, did not arrive at expected points. Mercator devised a map projection—which became known as the Mercator projection—on which ships following straight lines would arrive at the plotted points. Although the projection was excellent for navigation, it was poor for many geographic comparisons, since the size of areas in the higher latitudes becomes grossly exaggerated; Greenland, for example, appears to be larger than South America, though in fact it is less than one-eighth as large. The Earth cannot be shown accurately in all respects on a flat piece of paper since either bearing (angle), distance, or scale must be distorted. Modern geographers use maps drawn in what is called the equal-area projection, but even this projection distorts shapes or distances, particularly toward the edges of the map.

Map projections

With the increasing specialization of knowledge, measuring the shape of the Earth developed into the discipline of geodesy, plotting land positions for detailed maps became the province of surveying, and constructing numerous types of maps with appropriate projections grew into the field of cartography. Maps have remained as the basic tools in geography for plotting and analyzing a vast range of physical, biologic, historical, economic, political, and social data. Geography and cartography are closely associated: many geographers are cartographers and a significant number of cartographers are geographers, and cartographic training is widely available in departments of geography in universities and colleges.

Aerial photography and remote sensing. During the 20th century immense strides have been made in observing features on the Earth's surface, first by the development of aerial photography and later by satellite imagery. Aerial photography was first used extensively during World War I for reconnaissance. A new profession of photographic interpretation evolved in which the identification of both natural and man-made features became a special skill. After the war aerial photographs quickly proved their usefulness in mapping landforms, land uses, types of forest, vegetation, and the limits of the built-up areas of cities; in locating archaeological sites; and, in the United States, in measuring the size of farm fields and crop acreages in agricultural programs of the federal government and as the basis for county soil surveys. The perfection of stereoscopic plotting from overlapping aerial photographs greatly improved contour mapping in the production of topographic maps. The development of side-looking airborne radar made possible rapid surveys of large tracts of land, particularly in areas of economically underdeveloped countries that were not easily accessible by other means. Colour photographic film and infrared imagery also increased the potential for measurement of many aspects of land use or of physical processes.

Use of satellites

Even more revolutionary was the rapid evolution from the late 1950s of remote sensing using artificial satellites. Simultaneous, or synoptic, worldwide patterns could be viewed for the first time. The first weather satellite, called Nimbus, was launched in 1964. The advances in meteorology provide a particularly vivid example. Although humans had been observing the weather for countless ages and all major countries had dense networks of weather stations, satellites finally made it possible to clearly recognize many cloud patterns, such as the huge spiral cloud formations of major weather systems. By using weather satellites in combination with communication satellites, cloud and rainfall patterns could be presented almost instantaneously to worldwide television audiences. The rapid advances in space technology and multiband remote sensing allowed for a wide range of physical and man-made features to be observed, mapped, and studied with a comprehensiveness not previously possible. Data from geodetic satellites gave a much more exact determination of the shape of the Earth and revealed many irregularities not previously recognized. With the advent of navigation satellites locations could be determined with much greater precision. When astronauts traveled to the Moon people saw for the first time the whole terrestrial globe as a unity (though, of course, only half could be seen at one time).

Mathematical and statistical analysis. Although the use of mathematics in geography is ancient, the extensive and fundamental utilization of quantitative and statistical methods in modern geography arose mainly in the second half of the 20th century. The methodologies are similar to or identical with those used in the physical, biological, and social sciences, except that special attention is given to the problems of place-specific or area-specific data, in which the recognition and description of spatial patterns require special techniques. Model building, probability theory, and simulation techniques have proved to be of special value. Torsten Hägerstrand, for example, utilized an excellent data base in his native Sweden to make his seminal studies of the geographic diffusion of innovations. The development of electronic computers greatly expanded the power to analyze geographic problems. Computers can store immense amounts of data, and they greatly accelerate the speed at which complicated statistical and mathematical problems can be solved. They have become particularly valuable for their ability to handle such programs as those that measure spatial contiguity, spatial diffusion through time, and locational patterns, as well as for their use in network analysis, node accessibility indexes, map projections, and the display of cartographic data.

Importance of direct observation

There is a long-standing tradition in geography of placing special value on direct field observation and mapping. Much geographic knowledge is based on observations, if not by a research investigator directly then by others who write about observations revealed in oral interviews, in census enumerations, or in the interpretation of remote sensing images, aerial photographs, or maps. The questions others ask may not be formulated in such a way as to reveal the locational characteristics and spatial patterns so important to the geographer. Census information, for example, often fails to be broken into units small enough to permit satisfactory areal analysis. Thus, geographers often need to gather their own data.

FIELDS OF MODERN GEOGRAPHY

Geography is divided into systematic fields and regional specializations, which can be grouped under three main headings: physical geography, human geography, and regional geography.

Physical geography. The principal activities of the physical geographer—observing, measuring, and describing the surface of the Earth—are those aspects of the larger discipline of geography that are the most recognizable to the layperson. Even so, the growing complexity of geographic inquiry has resulted in increased specialization within the field. The principal branches of physical geography are geomorphology, climatology, biogeography, and soil geography. As human activity has become more able to affect the landscape and ecology of the world, two more branches have emerged: resource management and environmental studies.

Geomorphology. Geomorphology is the study of the forms of the land's surface and of the processes that mold them. As the branch has developed, landforms increasingly have been described with quantitative measures. The processes of weathering, erosion, transport, and deposition are analyzed. Fluvial, glacial and periglacial, coastal, and eolian processes are recognized and are often the subjects of specialized study. Slopes have received detailed consideration. In the branch called climatic geomorphology, the special landforms developed in deserts, in humid tropical conditions, and in the glacial and periglacial conditions of polar areas (or in relicts from the ice ages in other areas) are examined. Landforms are also changed by human activity, either directly (such as by constructing cities, excavating mines, or modifying hydrology by the building of dams and reservoirs) or indirectly by modifying vegetation (clearing forests, cultivation, and overgrazing), which then may accelerate geomorphologic processes by increasing runoff and causing severe gullying and soil erosion.

Applied geomorphology

Applied geomorphology increasingly is being utilized in environmental management. Engineering measures sometimes have unanticipated environmental consequences that may intensify rather than reduce the problems that they mean to correct, as in some projects to control coastal erosion and flooding; understanding the complexity and interrelatedness of environmental conditions is the object of much of the newer research in geomorphology.

Climatology. Climatology is concerned with the prevailing state of the atmosphere, including average climatic values, seasonal and diurnal rhythms, extreme values, the frequency of values within stated ranges, weather types and their characteristics, and the explanation and distribution of both climatic elements and general climatic types. Of particular geographic interest are the interrelationships of climatic elements and types with other physical and biologic features and with human activities. Examples include the effect of insolation at the Earth's surface on temperature, atmospheric pressure, winds, and precipitation; the effect of the distribution of land and water on climatic elements; and the effect of climate on vegetation, soils, and agriculture. Because climates show extreme variations over the face of the globe—from equatorial regions to the poles and from oceanic areas to continental interiors—and are associated with many other features, they have high geographic interest. Many human activities also are affected by weather, from heating and cooling requirements in buildings to transportation (especially by air). Extreme weather conditions can cause great damage either directly by such phenomena as ice, hail, or wind (cyclones or typhoons) or indirectly through flooding caused by heavy or prolonged rain, especially if associated with spring thaws and melting snow. Unseasonable frosts may damage specialty fruit areas.

Three branches

Biogeography. Biogeography encompasses three different paths of geographic inquiry, although it is not uncommon for the distinctions among them to become blurred. As phytogeography or zoogeography, biogeography refers to the spatial distribution, past and present, of individual categories of plants or animals and of attempts to explain this distribution. Biogeography may refer to the interrelationships of plants and animals with one another and with environmental conditions, particularly within regional types of continental scale (called biomes) or within smaller areas of individual plant and animal communities, as in ecology. It is also sometimes used to refer to the study of the effects of human activity on plants and animals in the biosphere. Particularly fruitful to the growth of the field were the studies in the ecology of high mountains by the German geographer Carl Troll and his students.

Soil geography. Soil geography is concerned with the areal distribution of soil types over the land, the principal factors in formation of different types of soil, the plant and animal world as the source of the organic matter in the soil, horizons in a vertical profile of the soil, and the moisture, drainage, and erosional conditions that underlie the chain, or catena, of soil differences along the horizontal profile of a slope, from well-drained relatively flat upper surfaces down steeper slopes to low-lying relatively flat surfaces. Of special concern are the role of soils in agricultural systems and the impact of human activity on the improvement, erosion, degradation, or reclamation of soils.

Resource management and environmental studies. The broad fields of resource management and of environmental studies are of particular interest to geographers, for they involve both physical and biologic systems on the one hand and human systems on the other, and they typically have specific spatial patterns on the surface of the Earth.

Emphases of the two branches

Resource management tends to emphasize human direction in the utilization of natural resources for the benefit of humans, usually on a sustained-yield or long-range basis, as, for example, in the development of the water resources of a stream for multiple purposes (power, irrigation, and recreation). Environmental studies tend to focus on the plant and animal worlds and on the threats to them posed by human activities; on the degradation of the atmosphere, hydrosphere, and lithosphere by pollution of many types; or on the interaction of these two aspects, as by acid rain created from the production of energy from hydrocarbons or by the potential depletion of the ozone layer in the upper atmosphere through the use of chlorofluorocarbons. In all of these studies geographers generally take into account alternative technologies, relative costs, impacts on other systems, perceptions of dangers and gains, policy alternatives, and the spatial range of the benefit or problem.

Specific man-made environmental problems that have been studied geographically include accelerated soil erosion through crop intertilling, overgrazing, and deforestation; the human impact on stream regimen and quality; the environmental impact of modern agricultural technologies through the increased use of fertilizers, pesticides, and herbicides; the impoverishment of natural species directly or indirectly through human actions; and the environmental impact of urbanization.

Early research in the utilization of water resources, for example, was concerned mainly with engineering studies for the construction of large dams, but later studies were expanded to include alternative programs for conserving water in irrigation or for conserving energy use. The initial emphasis in flood control was on building levees—which concentrate flood flows in restricted channels—permitting unrestricted construction in natural floodplains; later studies have included analyzing land-use regulation in floodplains, improving flood-warning systems, waterproofing buildings in areas subject to flood, and other measures in an effort to reduce flood damage and losses at far less cost and with greater effectiveness. The role of water quality in maintaining environmental systems also has received increased emphasis. The American geographer Gilbert F. White has played a leading international role in studies of the management of resources and of environmental hazards.

Human geography. One of the central problems in human geography is to explain the distribution and characteristics of people—this is the province of population geography. But this distribution can be understood only if attention is paid to how people satisfy their needs and make a living, the field of economic geography; to their cultural and social values, tools, and organization, which are the fields of cultural and social geography; to their concentrations in cities and metropolitan areas, the object of urban geography; to their political organization, examined by political geography; to their health and to the diseases that affect them, the field of medical geography; and to the evolution of their present patterns, the subject of historical geography.

Focus on distribution

Population geography. Population geography examines particularly the distribution of population in relation to its various characteristics, such as growth, number, density, age, sex, fertility, mortality, natural increase, and occupations; division into rural and urban, ethnic, linguistic, or religious groupings; and migrations. Typically geographers are not satisfied with national averages or aggregates, since they often conceal sharp regional contrasts, and instead attempt to measure and depict these regional and local variations. In desert areas, for example, most of the population is concentrated in a few oases, which occupy a tiny fraction of the area. Minority ethnic, linguistic, or religious groups often show marked clustering, sometimes being concentrated in relatively homogeneous subregions. Some regions increase in population while others decline, these shifts often being accompanied by substantial migration flows. Some geographic studies are concerned mainly with spatial distribution, spatial mobility, or spatial diversity in relationship to environments or resources, all of which are often depicted on maps. Other studies are more concerned with fertility, mortality, population growth, and forecasting through the use of demographic models. Still others address questions of population policy. Interest in population geography in the second half of the 20th century has been heightened by the sharp and growing contrast between the economically developed countries—which have long experienced a demographic transition from high to low birth and death rates and thus to low rates of population increase—and the less-developed countries—in which death rates have declined dramatically but birth rates have remained high, resulting in rapid population growth that has posed extremely difficult problems.

Rural–urban shift in emphasis

The emphasis in human-geography studies has shifted to reflect how much less people are bound to the land as a result of the transformation in agriculture, increased industrialization, improved transportation and trade, changes in sources and forms of energy, urbanization, and the expansion of service industries. Location, accessibility, transportation and communication, life-styles, and economic and cultural factors increasingly have been recognized as key factors in the distribution of population. The diffusion of research in population geography from its early centres in Europe and North America to the world as a whole has emphasized greater culture-specific orientation in population studies and the contrasts in national policies between those advocating population limitation and others promoting rapid population increase. In the late 20th century large-scale studies of continental dimensions increasingly have given way to studies of small areas and even of individuals through household surveys, as the immense complexity and diversity of the processes of population growth and distribution have been recognized.

The field of population geography has developed mainly in the second half of the 20th century. Since 1956 the International Geographical Union has supported a special commission devoted to this field. Symposia have contributed greatly to international participation and progress. One of the reports in *Geography and Population* (1984), edited by John I. Clarke, noted the need to look at specific population problems of individual countries. Examples cited include the problems of decentralizing and de-urbanizing the population and of a growing proportion of the population that is very old (aged 75 and over) in some economically developed countries, the massive redistribution of population associated with settlement regroupings in Mozambique and Tanzania, the large influx of foreign migrant workers into the oil-producing countries of the Middle East, high population pressure and growth in the precarious deltaic environment of Bangladesh, high-mountain population pressure and out-migration in Nepal, the huge concentration of population in the capital of Mexico, the impact on population redistribution of development projects in The Sudan and of political polarization in Korea, the effects of pluralism and of a rapidly changing demographic pattern in many islands in the Pacific and Indian oceans and the Caribbean, the effectiveness of transmigration policies in Indonesia, and the out-migration of the labour force in Poland.

Economic geography. Basic to understanding the distribution of population is an awareness of how people make a living. The modern field of economic geography evolved out of the older commercial geography, which flourished in western Europe and North America in the late 19th and early 20th centuries with the growing interest in international trade. Economic geography, however, is far more complex than the earlier field in analyzing the characteristics of, differences among, and movements between areas in the production, exchange, and consumption of goods and services. Of special geographic interest are the localizations of economic activity as they have evolved historically within specific cultural and technological contexts, based on particular combinations of physical, biologic, and human resources, economic and political conditions, and interregional ties and movements. In studying how centres of a nation's iron and steel industry arose, for example, consideration must be given not only to the location and availability of raw materials—such as iron ore, coking coals, other fuels, limestone for flux, and scrap—but also such factors as the availability, qualifications, and cost of labour; distances and costs of reaching markets; effect of inertia in the form of past capital investments in plant and in social overhead (*e.g.,* transportation and communication systems); plant obsolescence; changing competitive positions through the introduction of new technologies; and even changes in foreign-exchange rates among the currencies of competing countries.

Classification of economic activities

Economic activities traditionally are classified as being either primary, secondary, or tertiary in nature. Primary production involves those activities that make direct use of natural resources and that are located close to such resources. They include agriculture, livestock raising, forestry, fishing and hunting, and mining and quarrying.

Secondary production involves processing primary products by manufacturing and related activities. Tertiary production refers to services—such as banking, marketing, and accounting—rather than to the production of goods. In advanced economies tertiary activities form an increasing portion of employment, as evidenced by the increasing percentage of people employed in services and by the growing number of office buildings in all of the world's larger cities. In addition to general works in economic geography—often devoted to a particular world region, country, or even individual city—many studies examine the principal subfields: agricultural geography, manufacturing (or industrial) geography, transportation, and trade (from the international movement of goods to retail trade in a single urban neighbourhood).

Five themes of cultural geography

Cultural and social geography. Five major themes characterize cultural geography: culture, culture area, cultural landscape, cultural history, and cultural ecology. The cultural geographer studies the distribution in space and time of cultures and the elements of culture, such as artifacts and tools, techniques, attitudes, customs, languages, and religious beliefs; cultural complexes in their spatial organization; the cultural landscape—*i.e.*, the association of human, biologic, and physical features on the surface of the Earth (especially as perceived visually), ranging from the natural landscape unaffected by humankind to the landscape as thoroughly transformed by human action; the evolution and succession of cultures and cultural elements, including the history of cultural origins and their areal diffusion; and the complex interrelationships and areal associations of culture and nature. The American geographer Carl O. Sauer was particularly creative in working the concepts and teaching of anthropology, archaeology, and sociology into geography.

Whereas the focus of cultural geography is more on traditional societies (though it is not restricted to them), social geography is more oriented toward urban problems in countries with advanced economies. Social geographers have been concerned particularly with the spatial aspects of disadvantaged groups (such as minorities, women, the aged, and the poor), of such social pathologies as crime and mental illness, and of inequality, social welfare, and housing.

Urban geography. Urban geography generally takes a much broader scope than cultural geography; it is a major field in the countries with well-developed economies and high levels of urbanization—western Europe, North America, Australia, and Japan. Among topics investigated are factors affecting the location of individual cities, urban systems as networks of settlement points, regional differences in urbanization, cities in relation to their tributary areas or spheres of influence, the hierarchy of central places, the characteristics of city-size regularities (such as the rule of ranking cities according to size), functional types of cities (economic classification), expansion of metropolitan areas, internal spatial structure of land use, urban transportation and areal patterns of commuting, social problems in cities, housing, and cities as growth poles. One of the seminal contributions to the discipline was made by the German geographer Walter Christaller, who in the first half of the 20th century studied the urban centres of southern Germany and demonstrated that there existed a hierarchy among these centres as well as spacing and size regularities in tributary areas.

Increased importance in the 20th century

Cities are often the locus of studies for many branches of geography—economic, social, or political. The relative role of urban geography has increased dramatically during the 20th century, as the proportion of the population living in urban areas has risen and as interest in the field of geography has shifted from the concern with agricultural geography (and its emphasis on physical factors, such as rainfall, temperature, and soil) to a focus on the burgeoning urban agglomerations as centres of economic, political, and social development and problems. Symbolic of this shift have been studies undertaken of the function of cities as office centres, in which offices are concentrated in skyscrapers that are packed together in central business districts for maximum accessibility to financial, legal, and marketing services both inside and outside the city. Although the development of high-speed express highways and of regional airports has tended to diffuse activities within metropolitan areas from central cities to suburban fringes—housing, manufacturing, and retail trade in particular have exhibited this tendency—the growth of business service activities and of office functions has tended to maintain high daytime populations in central areas, with workers often commuting from suburban communities and metropolitan fringes.

Political geography. Studies in political geography at the international level have been concerned with the organization of the world into states; with their larger political groupings into regional alliances on the one scale and their subordinate division into political-administrative units on another; with the functions, delimitation, and demarcation of boundaries; with the selection of capital sites; with the relation of core areas and peripheral areas; with metropolitan powers and colonies; with the bases of political power in terms of population, production, organization, and policy; with the relations among states, including international trade and aid; with international organizations; and with territorial waters, maritime boundaries, and the law of the sea. At the national scale, studies have been concerned with regionalism, including separatist movements and their bases, and increasingly with the areal analysis of voting patterns as they reflect regional interests. At the metropolitan level studies have been devoted to the political fragmentation of metropolitan areas into hundreds and even thousands of separate political bodies and to the rise of new organizational forms of metropolitan-wide bodies with taxing powers, such as water districts, transportation authorities, and voluntary planning associations.

Three areas of investigation

Medical geography. Three quite different types of investigations are included under the broad umbrella of medical geography. First, there are studies of the diffusion of infectious diseases from their centres of occurrence by specific pathways through space and time. These studies include the mapping of distribution of a certain disease (such as sleeping sickness in Africa) in relation to vectors in the transmission of the disease (such as the tsetse fly) or a series of geographic studies on the areal diffusion of infectious diseases, such as successive waves of a disease following particular outbreaks. An early classic study of the second type was made by the English physician John Snow, who plotted on a map the cases of cholera from an outbreak in 1854 in London and found that all had used water from a centrally placed public well that he determined was being contaminated by nearby latrines. Second are studies of the ecology of malnutrition in relation to medical problems. These include analyses of dietary deficiencies as they are related to general poverty or to specific inadequacies of the food supply, such as of proteins or vitamins. Third are surveys of health-care facilities—their optimum spatial location and allocation compared to their actual distribution—as, for example, the lack of facilities in certain districts of a city or in regions of a country or for disadvantaged segments of the population.

As it came to be recognized that the construction of man-made lakes was also creating unanticipated health hazards, researchers in medical geography have been called upon to determine how these problems arose and how they can be prevented in the future. The impoundment of Lake Volta in Ghana, for example, caused a precipitous rise in the number of cases of schistosomiasis among those who settled on the lakeshore; and this rise was then linked to the increase of the disease-carrying snail population along the shoreline. Atlases have come to provide useful summaries of the distribution of diseases and other causes of mortality.

Historical geography. Given the rich history of Europe, the successive transformations of the landscape, and changing geographic relationships through time, it is not surprising that interest in historical geography has a long record. The stages in the transformation of the natural landscape to the cultural landscape have been studied in many of the countries of western, southern, and eastern Europe. The famous Domesday Book—the survey of England taken in 1086 on the orders of William I the Conqueror to inventory the lands and resources of the

The Domesday Book

country—has become the most thoroughly investigated early geographic record. The British geographer H. Clifford Darby's monumental seven-volume geographic analysis of this inventory, published between 1952 and 1977, was a landmark in research in historical geography.

Historical geography is concerned with the geography of past periods or dates or with changes over time as the landscape evolves. The first aspect is a horizontal consideration of the areal patterns during specific periods in time; the other entails a vertical analysis of the process of change through time. The field of historical geography expanded significantly in the latter half of the 20th century as graduate training of a considerable number of specialists emerged, particularly those trained by Darby at the University of Cambridge and by the Canadian geographer Andrew H. Clark at the University of Wisconsin, Madison, as well as by their students and successors.

Regional geography. In contrast to the systematic fields of geography, which view particular categories of physical, biologic, or human phenomena as distributed over the globe, regional geography is concerned with the associations within regions of all or some of these elements, particularly in regard to their interrelationships and as they have evolved historically. The particular elements that give distinctive character to regions differ from place to place. High altitudes and steep slopes are the distinctive features of the Himalayas or Andes; forests are the features of the Amazon Basin, Siberia, and northern Canada; dryness and scanty vegetation, of the Sahara, the interior of Australia, and Central Asia; highly intensive agriculture, of the rice-producing areas of monsoonal Asia; commercial agriculture and livestock production, of the American Midwest; urbanized landscapes dotted with industries and connected by transport lines, of the belt from southern England through the Low Countries to the Ruhr district in Germany, of the manufacturing belt of the northeastern United States and adjacent Canada, and of the Pacific coast of Japan; ice sheets, of Greenland and Antarctica; and extensive grasslands used for grazing, of the dry margins of agriculture in the western United States, the interior of Argentina, southeastern Australia, and the steppes of Ukraine, Russia, and Central Asia. The distinguishing element may be surface configuration, ice and snow, climate, vegetation, or type of human activity—*i.e.,* pastoral, agricultural, industrial, or commercial.

Rise of the modern discipline

Although interest in how countries differ dates to the geographic studies of antiquity, systematic modern study of regional characteristics and differences dates from the late 19th and early 20th centuries and the pioneering work of Hettner in Germany, who emphasized the physical basis of regions, Vidal de La Blache in France, who appreciated especially the historical element in the evolution of a sense of region by its inhabitants, and Herbertson in England, who suggested the concept of natural regions. Throughout much of the 20th century regional geography has been extensively pursued, though at times it clearly has been subordinated to research in systematic branches of geography. The attempt to recognize and map ever smaller units of land that were homogeneous in some respect has led to minute regional subdivisions, particularly by scholars studying intensively their own countries or regions. The American Robert S. Platt was the first to make a sharp distinction between homogeneous regions, in which significant elements, either physical or human, were relatively uniform (such as the wheat belts of Canada, Argentina, and Australia), and regions of organization, where the unity derives from dynamic organizational forces from a centre (such as a political unit or the tributary area of a city).

One major question is how the world should be divided for regional treatment. For a long time the continents were considered to be the appropriate units. Regions of cultural similarity have gained increasing recognition over the years, the major divisions including Latin America, the Middle East and North Africa, the Mediterranean, Scandinavia, monsoonal Asia, and Central Asia. Vegetation and climatic belts display a close relationship with agricultural types and human activities and thus are also useful for many purposes.

BIBLIOGRAPHY

History of geography: PRESTON E. JAMES and GEOFFREY J. MARTIN, *All Possible Worlds: A History of Geographical Ideas,* 2nd ed. (1981), is a general history of the rise of the discipline of geography, with emphasis on the modern period. ROBERT E. DICKINSON and O.J.R. HOWARTH, *The Making of Geography* (1933, reprinted 1976), though dated in some respects, is still useful. GEORGE KISH (ed.), *A Source Book in Geography* (1978), is a handy annotated anthology. RICHARD HARTSHORNE, *The Nature of Geography* (1939, reprinted 1976), and *Perspective on the Nature of Geography* (1959, reissued 1968), provide a detailed examination of writings on the subject. J. OLIVER THOMSON, *History of Ancient Geography* (1948, reissued 1965), is a well-documented review of knowledge and theories. J.N.L. BAKER, *A History of Geographical Discovery and Exploration,* rev. ed. (1936, reissued 1967), remains the best single-volume summary of geographic explorations. See also the valuable bibliographies in *Geographers: Biobibliographical Studies* (irregular). For the modern period, see, for French and German work up to the 1960s, ROBERT E. DICKINSON, *The Makers of Modern Geography* (1969); on British geography, T.W. FREEMAN, *A History of Modern British Geography* (1980); on French geography, PAUL CLAVAL, *La Pensée géographique* (1972); on Soviet geography, I.P. GERASIMOV (ed.), *Soviet Geography,* trans. from Russian (1962); and on geography in the United States, PRESTON E. JAMES and CLARENCE F. JONES (eds.), *American Geography* (1954). Developments in 11 countries or regions in the latter part of the 20th century are discussed in R.J. JOHNSTON and PAUL CLAVAL (eds.), *Geography Since the Second World War* (1984).

Methodology: A standard introduction to cartography is ARTHUR H. ROBINSON *et al., Elements of Cartography,* 5th ed. (1984). Various aspects of cartography are covered in J.B. HARLEY and DAVID WOODWARD (eds.), *The History of Cartography* (1987–), an outstanding work, with one of six planned volumes published. More specialized are PHILLIP C. MUEHRCKE and JULIANA O. MUEHRKE, *Map Use: Reading, Analysis, and Interpretation,* 2nd ed. (1986); and MARK S. MONMONIER, *Computer-Assisted Cartography: Principles and Prospects* (1982). *The Times Atlas of the World,* 7th ed. (1985); RAND MCNALLY, *The New International Atlas* (1980, reissued 1987); and *National Geographic Atlas of the World,* 5th ed. (1981), are all examples of excellent cartography. Aerial photography is treated in C.P. LO, *Geographical Applications of Aerial Photography* (1976). Introductions to remote sensing are provided by BENJAMIN F. RICHASON, JR. (ed.), *Introduction to Remote Sensing of the Environment,* 2nd ed. (1983); and ROBERT K. HOLZ (ed.), *The Surveillant Science: Remote Sensing of the Environment,* 2nd ed. (1985). ROBERT N. COLWELL (ed.), *Manual of Remote Sensing,* 2nd ed., 2 vol. (1983), is advanced and comprehensive. Pioneering and influential volumes on quantitative methods include TORSTEN HÄGERSTRAND, *Innovation Diffusion as a Spatial Process* (1967; originally published in Swedish, 1953), a classic study; RICHARD J. CHORLEY and PETER HAGGETT (eds.), *Models in Geography* (1967); and PETER HAGGETT, ANDREW D. CLIFF, and ALLAN FREY, *Locational Analysis in Human Geography,* 2nd ed. (1977). See also JOHN F. LOUNSBURY and FRANK T. ALDRICH, *Introduction to Geographic Field Methods and Techniques,* 2nd ed. (1986).

Physical geography: (*General*): CUCHLAINE A.M. KING, *Physical Geography* (1980), provides coverage at local, regional, and continental scales. TOM L. MCKNIGHT, *Physical Geography: A Landscape Appreciation,* 2nd ed. (1987), is a succinct review. ARTHUR N. STRAHLER and ALAN H. STRAHLER, *Elements of Physical Geography,* 3rd ed. (1984), is comprehensive and well illustrated. MICHAEL J. CLARK, KENNETH J. GREGORY, and ANGELA M. GORNELL (eds.), *Horizons in Physical Geography* (1987), offers overviews of issues in the field.

(*Geomorphology*): KARL W. BUTZER, *Geomorphology from the Earth* (1976), is generally nontechnical. B.W. SPARKS, *Geomorphology,* 3rd ed. (1986), stresses deficiencies in theory. ARTHUR L. BLOOM, *Geomorphology: A Systematic Analysis of Late Cenozoic Landforms* (1978), is a thorough introduction. Works devoted to special processes include LUNA B. LEOPOLD, M. GORDON WOLMAN, and JOHN P. MILLER, *Fluvial Processes in Geomorphology* (1964); CLIFFORD EMBLETON and CUCHLAINE A.M. KING, *Glacial and Periglacial Geomorphology,* 2nd ed., 2 vol. (1975); CUCHLAINE A.M. KING, *Beaches and Coasts,* 2nd ed. (1972); and JULIUS BÜDEL, *Climatic Geomorphology* (1982; originally published in German, 1977).

(*Climatology*): Nontechnical introductions include HOWARD J. CRITCHFIELD, *General Climatology,* 4th ed. (1983); JOHN E. OLIVER and JOHN J. HIDORE, *Climatology* (1984); GLENN T. TREWARTHA and LYLE H. HORN, *An Introduction to Climate,* 5th ed. (1980); and ROGER G. BARRY and RICHARD J. CHORLEY, *Atmosphere, Weather, and Climate,* 5th ed. (1987). A comprehensive analysis is H.E. LANDSBERG (ed.), *World Survey of Climatology* (1969–), a multivolume series.

(*Biogeography*): Introductions are provided by JAMES H. BROWN and ARTHUR C. GIBSON, *Biogeography* (1983), with broad coverage and many references; PIERRE DANSEREAU, *Biogeography: An Ecological Perspective* (1957); I.G. SIMMONS, *Biogeography: Natural and Cultural* (1979), which focuses on human influence in the biosphere; and JOY TIVY, *Biogeography: A Study of Plants in the Ecosphere*, 2nd ed. (1982), which includes environmental and historical influences on plant distributions. Advanced specialized studies are contained in CARL TROLL (ed.), *Geo-Ecology of the Mountainous Regions of the Tropical Americas* (1968), and *Geoecology of the High-Mountain Regions of Eurasia* (1972).

(*Soil geography*): Brief introductions to the field include ROBERT M. BASILE, *A Geography of Soils* (1971); and DONALD STEILA, *The Geography of Soils: Formation, Distribution, and Management* (1976).

(*Resource management and environmental studies*): Good general introductions, with extensive bibliographies on environmental studies, include IAN R. MANNERS and MARVIN W. MIKESELL (eds.), *Perspectives on Environment* (1974); and KENNETH A. HAMMOND, GEORGE MACINKO, and WILMA B. FAIRCHILD (eds.), *Sourcebook on the Environment: A Guide to the Literature* (1978). The seminal contributions of Gilbert F. White to resource management and essays on related themes are contained in ROBERT W. KATES and IAN BURTON (eds.), *Geography, Resources, and Environment*, 2 vol. (1986). Other valuable works include ANDREW GOUDIE, *The Human Impact on the Natural Environment*, 2nd ed. (1986); GILBERT F. WHITE (ed.), *Natural Hazards* (1974); IAN BURTON, ROBERT W. KATES, and GILBERT F. WHITE, *The Environment as Hazard* (1978); ROBERT W. KATES, *Risk Assessment of Environmental Hazard* (1978); ANNE V. WHYTE and IAN BURTON (eds.), *Environmental Risk Assessment* (1980); THOMAS F. SAARINEN, DAVID SEAMON, and JAMES L. SELL (eds.), *Environmental Perception and Behavior* (1984); J.T. COPPOCK and B.S. DUFFIELD, *Recreation in the Countryside* (1975); and STEPHEN SMITH, *Recreation Geography* (1983).

Human geography: (*General*): General introductions to the field include PETER HAGGETT, *Geography*, rev. 3rd ed. (1983), emphasizing ecological and spatial approaches; JAN O.M. BROEK and JOHN W. WEBB, *A Geography of Mankind*, 3rd ed. (1978), a cultural and economic approach; and RHOADS MURPHEY, *Patterns on the Earth: An Introduction to Geography*, 4th ed. (1978), a historical and cultural approach within a regional framework.

(*Population geography*): A good international summary of approaches is JOHN I. CLARKE (ed.), *Geography and Population* (1984). Useful general reviews of the field include GEORGE A. SCHNELL and MARK S. MONMONIER, *The Study of Population* (1983), with world maps showing countries scaled by population size; and HUW R. JONES, *A Population Geography* (1981), with an extensive bibliography. Population pressures in relation to resources and resource depletion are treated in GARY L. PETERS and ROBERT P. LARKIN, *Population Geography*, 2nd ed. (1983); and WILBUR ZELINSKY, LESZEK A. KOSÍNSKI, and R. MANSELL PROTHERO (eds.), *Geography and a Crowding World* (1970), papers from a symposium on population pressures on physical and social resources in the developing lands. Population in relation to development is considered in PHILIP M. HAUSER (ed.), *World Population and Development* (1979). Migration is reviewed in LESZEK A. KOSÍNSKI and R. MANSELL PROTHERO (eds.), *People on the Move: Studies on Internal Migration* (1975).

(*Economic geography*): Brief introductions include HAROLD H. MCCARTY and JAMES B. LINDBERG, *A Preface to Economic Geography* (1966); and ROBERT B. MCNEE, *A Primer on Economic Geography* (1971). General treatments include RICHARD S. THOMAN and PETER B. CORBIN, *The Geography of Economic Activity*, 3rd ed. (1974); and JAMES O. WHEELER and PETER O. MULLER, *Economic Geography*, 2nd ed. (1986), with a North American orientation. Somewhat more advanced and theoretical are BRIAN J.L. BERRY, EDGAR C. CONKLING, and D. MICHAEL RAY, *The Geography of Economic Systems* (1976); PETER E. LLOYD and PETER DICKEN, *Location in Space: A Theoretical Approach to Economic Geography*, 2nd ed. (1977); and THOMAS J. WILBANKS, *Location and Well-Being: An Introduction to Economic Geography* (1980).

(*Cultural and social geography*): General treatments include PHILIP L. WAGNER and MARVIN W. MIKESELL (eds.), *Readings in Cultural Geography* (1962); J.E. SPENCER and WILLIAM L. THOMAS, *Introducing Cultural Geography*, 2nd ed. (1978); and TERRY G. JORDAN and LESTER ROWNTREE, *The Human Mosaic: A Thematic Introduction to Cultural Geography*, 4th ed. (1986). Two important collections of papers are WILLIAM L. THOMAS (ed.), *Man's Role in Changing the Face of the Earth* (1956, reissued in 2 vol., 1970); and JOHN LEIGHLY (ed.), *Land and Life: A Selection from the Writings of Carl Ortwin Sauer* (1963, reprinted 1974). General introductions to social geography include DAVID LEY, *A Social Geography of the City* (1983); and PAUL KNOX, *Urban Social Geography: An Introduction*, 2nd ed. (1987).

(*Urban geography*): Major works on worldwide urbanization include BRIAN J.L. BERRY, *Comparative Urbanization*, rev. and enl. 2nd ed. (1981); L.S. BOURNE, R. SINCLAIR, and K. DZIEWÓNSKI (eds.), *Urbanization and Settlement Systems* (1984); and STANLEY D. BRUNN and JACK F. WILLIAMS (eds.), *Cities of the World: World Regional Urban Development* (1983). North American cities are treated in TRUMAN ASA HARTSHORN, *Interpreting the City: An Urban Geography* (1980); STANLEY D. BRUNN and JAMES O. WHEELER (eds.), *The American Metropolitan System* (1980); RISA PALM, *The Geography of American Cities* (1981); MAURICE YEATES and BARRY GARNER, *The North American City*, 3rd ed. (1980); and PETER O. MULLER, *Contemporary Suburban America* (1981). JEAN GOTTMANN, *Megalopolis: The Urbanized Northeastern Seaboard of the United States* (1961, reissued 1969), is a classic study. A similar study for Canada is MAURICE YEATES, *Main Street: Windsor to Quebec City* (1975). British cities are more fully treated in HAROLD CARTER, *The Study of Urban Geography*, 3rd ed. (1981); and DAVID T. HERBERT and COLIN J. THOMAS, *Urban Geography* (1982). WALTER CHRISTALLER, *Central Places in Southern Germany* (1966; originally published in German, 1933), is a widely influential study.

(*Political geography*): ALAN D. BURNETT and PETER J. TAYLOR (eds.), *Political Studies from Spatial Perspectives: Anglo-American Essays on Political Geography* (1981), is an influential collection of papers; more diverse is PETER J. TAYLOR and JOHN HOUSE (eds.), *Political Geography* (1984). MARTIN IRA GLASSNER and HARM J. DE BLIJ, *Systematic Political Geography*, 3rd ed. (1980), is a widely used text. Special topics are treated by J.R.V. PRESCOTT, *Boundaries and Frontiers* (1978), and *The Political Geography of the Oceans* (1975); PETER J. TAYLOR and R.J. JOHNSTON, *The Geography of Elections* (1979); and JEAN GOTTMANN (ed.), *Centre and Periphery: Spatial Variation in Politics* (1980).

(*Medical geography*): Good introductions to medical geography include ANDREW T.A. LEARMONTH, *Patterns of Disease and Hunger* (1978); GERALD F. PYLE, *Applied Medical Geography* (1979); and the older but still valuable L. DUDLEY STAMP, *The Geography of Life and Death* (1964). Studies of infectious diseases are summarized in JACQUES M. MAY, *The Ecology of Human Disease* (1958); and JACQUES M. MAY (ed.), *Studies in Disease Ecology* (1961). For analyses of spatial aspects of health-care delivery systems, see JOHN EYLES and KEVIN J. WOODS, *The Social Geography of Medicine and Health* (1983), international in scope; DAVID R. PHILLIPS, *Contemporary Issues in the Geography of Health Care* (1981), a comparison of the British and American systems; and GARY W. SHANNON and G.E. ALAN DEVER, *Health Care Delivery: Spatial Perspectives* (1974), primarily American in focus. Diverse aspects are presented in the following conference papers or collected volumes: ANDREW T.A. LEARMONTH (ed.), *The Geography of Health* (1981); NEIL D. MCGLASHAN and JOHN R. BLUNDEN (eds.), *Geographical Aspects of Health* (1983); MELINDA S. MEADE (ed.), *Conceptual and Methodological Issues in Medical Geography* (1980); and GERALD F. PYLE (ed.), *New Directions in Medical Geography* (1979).

(*Historical geography*): An international overview of work in historical geography during the period 1945–70 is provided by ALAN R.H. BAKER (ed.), *Progress in Historical Geography* (1972). Research methods are discussed in ALAN R.H. BAKER and MARK BILLINGE (eds.), *Period and Place: Research Methods in Historical Geography* (1982); WILLIAM NORTON, *Historical Analysis in Geography* (1984); and ALAN R.H. BAKER and DEREK GREGORY (eds.), *Explorations in Historical Geography* (1984). H.C. DARBY (ed.), *A New Historical Geography of England* (1973); and R.A. DODGSHON and R.A. BUTLIN (eds.), *An Historical Geography of England and Wales* (1978), are valuable summaries. D.W. MEINIG, *The Shaping of America: A Geographical Perspective on 500 Years of History*, vol. 1, *Atlantic America, 1492–1800* (1986), is an important synthesis. JAMES R. GIBSON (ed.), *European Settlement and Development in North America* (1978); and ROBERT D. MITCHELL and PAUL A. GROVES (eds.), *North America: The Historical Geography of a Changing Continent* (1987), contain many valuable studies. See also RONALD E. GRIM, *Historical Geography of the United States: A Guide to Information Sources* (1982), which provides admirable coverage; and R. COLE HARRIS and JOHN WARKENTIN, *Canada Before Confederation: A Study in Historical Geography* (1974), which covers the early period in Canada. Prehistory is discussed in KARL W. BUTZER, *Environment and Archeology* (1971), and *Archaeology as Human Ecology* (1982).

Regional geography: Some useful treatments covering the large regions of the world include C. LANGDON WHITE, EDWIN J. FOSCUE, and TOM L. MCKNIGHT, *Regional Geography of Anglo-America*, 6th ed. (1985); J.H. PATERSON and CLARENCE W. OLMSTEAD, *North America: A Geography of Canada and the United*

States, 7th ed. (1984); J. WREFORD WATSON, *North America,* 2nd ed. (1968); *Studies in Canadian Geography,* 6 vol. (1972); PRESTON E. JAMES, C.W. MINKEL, and EILEEN W. JAMES, *Latin America,* 5th ed. (1986); ROBERT C. WEST and JOHN P. AUGELLI, *Middle America,* 2nd ed. (1976); GEORGE W. HOFFMAN (ed.), *A Geography of Europe,* 5th ed. (1983); PAUL E. LYDOLPH, *Geography of the U.S.S.R.: Topical Analysis* (1979); R.J. JOHNSTON and J.C. DORNKAMP (eds.), *The Changing Geography of the United Kingdom* (1982); WILLIAM A. HANCE, *The Geography of Modern Africa,* 2nd ed. (1975); R.J. HARRISON CHURCH *et al., Africa and the Islands,* 4th ed. (1977); A.T. GROVE, *Africa,* 3rd ed. (1978); W.B. FISHER, *The Middle East: A Physical, Social, and Regional Geography,* 7th ed. rev. (1978); NORTON GINSBURG, *The Pattern of Asia* (1958); J.E. SPENCER and WILLIAM L. THOMAS, *Asia, East by South: A Cultural Geography,* 2nd ed. (1971); O.H.K. SPATE and ANDREW T.A. LEARMONTH, *India and Pakistan: A General and Regional Geography,* 3rd ed. rev. (1967); and D.N. JEANS (ed.), *Australia: A Geography* (1977).

Bibliographic guides: Further bibliographic information may be found in STEPHEN GODDARD (ed.), *A Guide to Information Sources in the Geographical Sciences* (1983); J. GORDON BREWER, *The Literature of Geography: A Guide to Its Organisation and Use,* 2nd ed. (1978), textual discussion with some emphasis on British works; and CHAUNCY D. HARRIS, *Bibliography of Geography,* pt. 1, *Introduction to General Aids* (1976), and pt. 2, *Regional,* vol. 1, *The United States of America* (1984). CHAUNCY D. HARRIS *et al.* (eds.), *A Geographical Bibliography for American Libraries* (1985), focuses on the period 1970–84, though earlier works are also included; while GORDON R. LEWTHWAITE, EDWARD T. PRICE, JR., and HAROLD A. WINTERS (comps. and eds.), *A Geographical Bibliography for American College Libraries,* rev. ed. (1970), is particularly useful for the period before 1970. *Geographical Abstracts* (monthly), is the fullest bibliography in English and is especially strong in systematic fields of geography. *Current Geographical Publications* (monthly) concentrates on American publications. *Bibliographie Géographie Internationale* (quarterly) is international in scope and the best bibliography on regional geography.

Periodicals: Leading international journals in English include *Annals of the Association of American Geographers* (quarterly); *Canadian Geographer/Geographe Canadien* (quarterly); *Geographical Journal* (3/yr.); *Geographical Review* (quarterly); and *Transactions of the Institute of British Geographers* (quarterly). See also CHAUNCY D. HARRIS, *Annotated World List of Selected Current Geographical Serials,* 4th ed. (1980), which annotates 443 of the most valuable current serials from 72 countries.

Dictionaries: AUDREY N. CLARK, *Longman Dictionary of Geography: Human and Physical* (1985), offers good brief definitions of terms in all fields. R.J. JOHNSTON (ed.), *The Dictionary of Human Geography,* 2nd ed. (1986), includes advanced, signed definitions. ANDREW GOUDIE *et al., The Encyclopaedic Dictionary of Physical Geography* (1985), is authoritative, with a focus on concepts.

(C.D.H.)

Geometry

Geometry is the branch of mathematics concerned with the shape of individual objects, spatial relationships among various objects, and the properties of surrounding space. It is one of the oldest branches of mathematics. The earliest known unambiguous examples of written records—dating from Egypt and Mesopotamia about 3100 BC—demonstrate that ancient peoples had already begun to devise mathematical rules and techniques useful for surveying land areas, constructing buildings, and measuring storage containers. Beginning about the 6th century BC, the Greeks gathered and extended this practical knowledge and from it generalized the abstract subject now known as geometry, from the combination of the Greek words *geo* ("Earth") and *metron* ("measure") for the measurement of the Earth. Thales of Miletus (fl. *c.* 600 BC), one of the legendary Seven Wise Men from ancient Greece, is credited with fashioning the first geometric, or even mathematical, proofs—that is, employing logical reasoning to think about idealized, or abstract, entities in order to establish general, or theoretical, results—in contrast to earlier "recipes" that applied to specific examples from direct experience. Over the following centuries, various Greeks refined and developed the subject until, by the time of Plato and Aristotle in the 4th century BC, geometry had become the model for reasoning, influencing first the development of logic and eventually all of science.

While Greek mathematical knowledge all but disappeared from Europe during the Middle Ages, the Islāmic world preserved Greek results and made further mathematical progress, particularly in trigonometry and algebra. As ancient Greek and Islāmic mathematics filtered back into Europe at the end of the Middle Ages, it was realized that geometry need not be limited to the study of flat surfaces (plane geometry) and rigid three-dimensional objects (solid geometry) but that even the most abstract thoughts and images might be represented and developed in geometric terms. In particular, algebra was combined with geometry in 17th-century France to create analytic geometry. In addition to applying algebraic notation and techniques to common geometric figures, it revealed the hitherto unknown "shape" of mathematical expressions, including expressions that contain higher powers on the variable, or multivariable, terms. Such work led directly to the discovery of differential calculus and, from the mid-18th century to the early 19th century, to the development of differential geometry. Seventeenth-century France also saw the creation of projective geometry, although it was then rather neglected until the 19th century.

This article begins with an extensive historical treatment. In addition to describing some of the achievements of the ancient Greeks, this historical overview examines some applications of geometry to astronomy, cartography, and painting from classical Greece through the Islāmic world to Renaissance Europe and beyond. It concludes with a brief discussion of non-Euclidean geometries. The article then proceeds to descriptions of the origins, fundamental concepts, and distinctive procedures of the major branches of geometry. Additional information about the development and history of geometry can be found in MATHEMATICS, THE FOUNDATIONS OF; MATHEMATICS, THE HISTORY OF; ALGEBRA; ANALYSIS; and TRIGONOMETRY.

For coverage of related topics in the *Macropædia* and *Micropædia,* see the *Propædia,* sections 10/21, 10/22, and 10/23, and the *Index.*

This article is divided into the following sections:

HISTORY OF GEOMETRY

Ancient geometry: practical and empirical

The origin of geometry lies in the concerns of everyday life. The traditional account, preserved in Herodotus's *History* (5th century BC), credits the Egyptians with inventing surveying in order to reestablish property values after the annual flood of the Nile. Similarly, eagerness to know the volumes of solid figures derived from the need to evaluate tribute, store oil and grain, and build dams and pyramids. Even the three abstruse geometrical problems of ancient times—to double a cube, trisect an angle, and square a circle, all of which are discussed below—probably arose from practical matters, from religious ritual, timekeeping, and construction, respectively, in pre-Greek societies of the Mediterranean. And the main subject of later Greek geometry, the theory of conic sections, owed its general importance, and perhaps also its origin, to its application to optics and astronomy.

While many ancient individuals, known and unknown, contributed to the subject, none equaled the impact of Euclid and his *Elements* of geometry, a book now 2,300 years old and the object of as much painful and painstaking study as the Bible. Much less is known about Euclid, however, than about Moses. In fact, the only thing known with a fair degree of confidence is that Euclid taught at the Library of Alexandria during the reign of Ptolemy I (323–285/83 BC). Euclid wrote not only on geometry but also on astronomy and optics and perhaps also on mechanics and music. Only the *Elements,* which was extensively copied and translated, has survived intact.

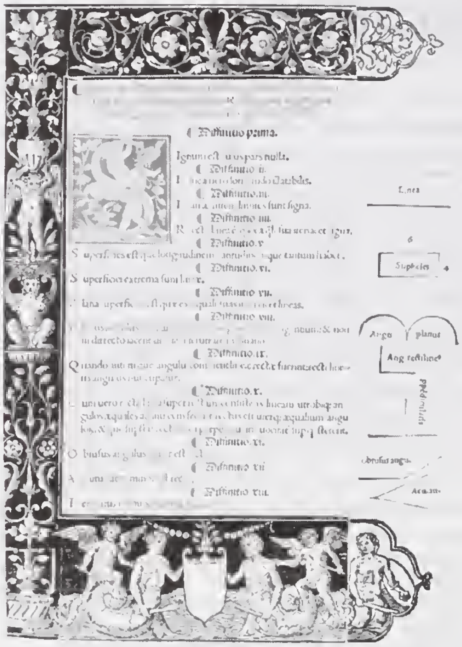

Figure 2: A page from a printed edition of Euclid's *Elements.*
Art Resource New York

Euclid's *Elements* was so complete and clearly written that it literally obliterated the work of his predecessors. What is known about Greek geometry before him comes primarily from bits quoted by Plato and Aristotle and by later mathematicians and commentators. Among other precious items they preserved are some results and the general approach of Pythagoras (*c.* 580–*c.* 500 BC) and his followers. The Pythagoreans convinced themselves that all things are, or owe their relationships to, numbers. The doc-

This map spans a millennium of prominent Greco-Roman mathematicians, from Thales of Miletus (*c.* 600 BC) to Hypatia of Alexandria (*c.* AD 400).

trine gave mathematics supreme importance in the investigation and understanding of the world. Plato developed a similar view, and philosophers influenced by Pythagoras or Plato often wrote ecstatically about geometry as the key to the interpretation of the universe. Thus ancient geometry gained an association with the sublime to complement its earthy origins and its reputation as the exemplar of precise reasoning.

FINDING THE RIGHT ANGLE

Egyptian rope pullers

Ancient builders and surveyors needed to be able to construct right angles in the field on demand. The method employed by the Egyptians earned them the name "rope pullers" in Greece, apparently because they employed a rope for laying out their construction guidelines. One way that they could have employed a rope to construct right triangles was to mark a looped rope with knots so that, when held at the knots and pulled tight, the rope must form a right triangle. The simplest way to perform the trick is to take a rope that is 12 units long, make a knot 3 units from one end and another 5 units from the other end, and then knot the ends together to form a loop, as shown in Figure 3. However, the Egyptian scribes have not left us instructions about these procedures, much less any hint that they knew how to generalize them to obtain the Pythagorean theorem: the square on the line opposite the right angle equals the sum of the squares on the other two sides. Similarly, the Vedic scriptures of ancient India contain sections called *sulvasutras,* or "rules of the rope," for the exact positioning of sacrificial altars. The required right angles were made by ropes marked to give the triads (3, 4, 5) and (5, 12, 13).

Ends of the rope are knotted. Rope is pulled taut along entire length, to create a right triangle.

Figure 3. Egyptian rope pullers constructing a right triangle.

In Babylonian clay tablets (*c.* 1700–1500 BC) modern historians have discovered problems whose solutions indicate that the Pythagorean theorem and some special triads were known more than a thousand years before Euclid. A right triangle made at random, however, is very unlikely to have all its sides measurable by the same unit—that is, every side a whole-number multiple of some common unit of measurement. This fact, which came as a shock when discovered by the Pythagoreans, gave rise to the concept and theory of incommensurability.

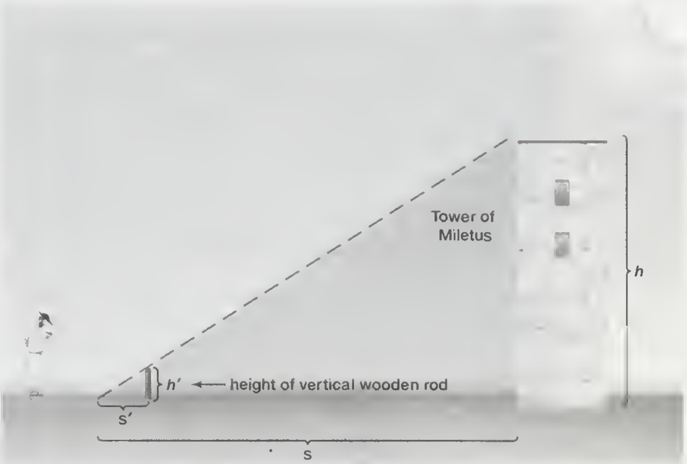

Figure 4: *Caricature of Thales measuring the height of a tower in Miletus.*
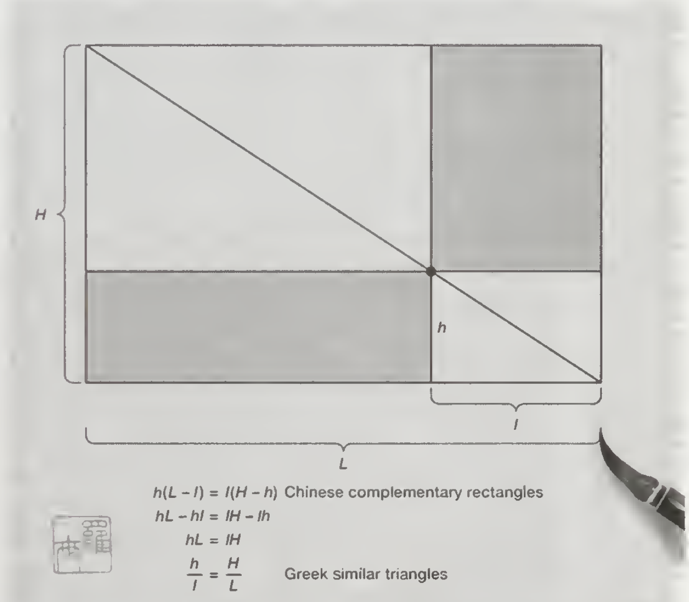
By aligning the shadows cast by the tower and the rod, the large triangle with sides *s* and *h* is similar to the small triangle with corresponding sides *s′* and *h′*. Hence, the ratio of *h* to *s* is equal to the ratio of *h′* to *s′*. The lengths of *s*, *s′*, and *h′* can be measured and used to calculate *h*, the height of the tower.

LOCATING THE INACCESSIBLE

By ancient tradition, Thales of Miletus, who lived before Pythagoras in the 6th century BC, invented a way to measure inaccessible heights (see Figure 4), such as the Egyptian pyramids. Although none of his writings survives, Thales may well have known about a Babylonian observation that for similar triangles (triangles having the same shape but not necessarily the same size) the length of each corresponding side is increased (or decreased) by the same multiple. The ancient Chinese arrived at measures of inaccessible heights and distances by another route, using "complementary" rectangles, as seen in Figure 5, which can be shown to give results equivalent to those of the Greek method involving triangles.



H

ESTIMATING THE WEALTH

Early estimates of π

A Babylonian cuneiform tablet written some 3,500 years ago treats problems about dams, wells, water clocks, and excavations. It also has an exercise on circular enclosures with an implied value of $\pi = 3$. The contractor for King Solomon's swimming pool, who made a pond 10 cubits across and 30 cubits around (1 Kings 7:23), used the same value. However, the Hebrews should have taken their π from the Egyptians before crossing the Red Sea, for the Rhind papyrus (*c.* 2000 BC; our principal source for ancient Egyptian mathematics) implies a more accurate value: $\pi = 3.1605$.

Knowledge of the area of a circle was of practical value to the officials who kept track of the pharaoh's tribute as well as to the builders of altars and swimming pools. Ahmes, the scribe who copied and annotated the Rhind papyrus (*c.* 1650 BC), has much to say about cylindrical granaries and pyramids, whole and truncated. He could calculate their volumes, and, as appears from his taking the Egyptian *seked,* the horizontal distance associated with a vertical rise of one cubit, as the defining quantity for the pyramid's slope, he knew something about similar triangles.

Ancient geometry: abstract and applied

THE THREE CLASSICAL PROBLEMS

Euclidean construction tools

In addition to proving mathematical theorems, ancient mathematicians constructed various geometrical objects. Euclid arbitrarily restricted the tools of construction to a straightedge (an unmarked ruler) and a compass. The restriction made three problems of particular interest (to double a cube, to trisect an arbitrary angle, and to square a circle) very difficult—in fact, impossible. Various methods of construction using other means were devised in the classical period, and efforts, always unsuccessful, using straightedge and compass persisted for the next 2,000 years. In 1837 the French mathematician Pierre Laurent Wantzel proved that doubling the cube and trisecting the angle are impossible, and in 1880 the German mathematician Ferdinand von Lindemann showed that squaring the circle is impossible, as a consequence of his proof that π is a transcendental number.

Doubling the cube. The Vedic scriptures made the cube the most advisable form of altar for anyone who wanted to supplicate in the same place twice. The rules of ritual required that the altar for the second plea have the same shape but twice the volume of the first. If the sides of the original and derived altars are a and b, respectively, then $b^3 = 2a^3$. The problem came to the Greeks together with its ceremonial content. An oracle disclosed that the citizens of Delos could free themselves of a plague merely by replacing an existing altar by one twice its size. The Delians applied to Plato. He replied that the oracle did not mean that the gods wanted a larger altar but that they had intended "to shame the Greeks for their neglect of mathematics and their contempt for geometry." With this blend of Vedic practice, Greek myth, and academic manipulation, the problem of the duplication of the cube took a leading place in the formation of Greek geometry.

Hippocrates of Chios, who wrote an early *Elements* about 450 BC, took the first steps in cracking the altar problem. He reduced the duplication to finding two mean proportionals between 1 and 2, that is, to finding lines x and y in the ratio $1{:}x = x{:}y = y{:}2$. After the intervention of the Delian oracle, several geometers around Plato's Academy found complicated ways of generating mean proportionals.

A few generations later, Eratosthenes of Cyrene (*c.* 276–*c.* 194 BC) devised a simple instrument with moving parts that could produce approximate mean proportionals.

Trisecting the angle. The Egyptians told time at night by the rising of 12 *asterisms* (constellations), each requiring on average two hours to rise. In order to obtain more convenient intervals, the Egyptians subdivided each of their *asterisms* into three parts, or *decans*. That presented the problem of trisection. It is not known whether the second celebrated problem of archaic Greek geometry, the trisection of any given angle, arose from the difficulty of the *decan,* but it is likely that it came from some problem in angular measure.

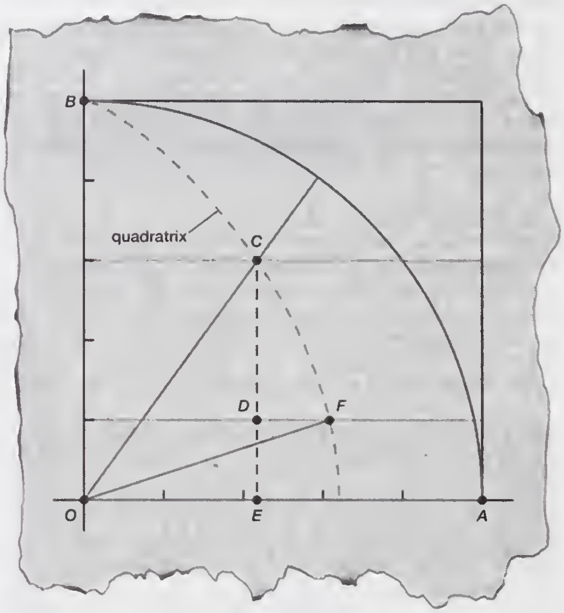

Figure 6: Quadratrix of Hippias.

Quadratrix. Several geometers of Plato's time tried their hands at trisection. Although no one succeeded in finding a solution with straightedge and compass, they did succeed with a mechanical device and by a trick. The mechanical device, perhaps never built, creates what the ancient geometers called a quadratrix. Invented by a geometer known as Hippias of Elis (fl. 5th century BC), the quadratrix is a curve traced by the point of intersection between two moving lines, one rotating uniformly through a right angle, the other gliding uniformly parallel to itself, as shown in Figure 6. Starting from a horizontal position, a line segment (OA) is rotated at a constant rate through a right angle around one of its endpoints (O) at the same time the segment (OA) also glides uniformly through a vertical distance equal to the segment's length. Because both the angle rotation and the vertical displacement are produced by uniform motion, each moves through the same fraction of its entire journey in the same time. Hence, finding some proportion (say one-third) for a given angle (here $\angle COA$) is simple: find the equal proportion for vertical displacement of the point on the quadratrix at which the two segments intersect (C), locate the point (F) on the quadratrix at that height (one-third of the original height in this example), and then draw the new angle ($\angle FOA$) through that point.

Neusis. The trick for trisection is an application of what the Greeks called *neusis*, a maneuvering of a measured length into a special position to complete a geometrical figure. A late version of its use, ascribed to Archimedes (*c.* 285–212/211 BC), exemplifies the method of angle trisection. (See Figure 7.)

1. Given $\angle AOB$, draw the circle with centre at O through the points A and B. Thus, OA and OB are radii of the circle and $OA = OB$.

2. Extend the ray AO indefinitely.

3. Now take a straightedge marked with the length of the circle's radius and maneuver it (this is the *neusis*) into position to draw a line segment from B through a point C on the circle to a point D on the ray AO such that CD is equal to the circle's radius; that is, $CD = OC = OB = OA$.

Bridge of Asses

4. By the "Bridge of Asses" (described below), $\angle CDO = \angle COD$ and $\angle OCB = \angle OBC$.

5. $\angle AOB = \angle ODC + \angle OBC$, because $\angle AOB$ is an angle external to ΔDOB and an external angle equals the sum of the opposite interior angles ($\angle AOB + \angle BOD = 180° = \angle BOD + \angle ODB + \angle DBO$).

6. $\angle OBC = \angle OCB$ (by step 4) $= \angle ODC + \angle COD$ (by step 5) $= 2\angle ODC$ (by step 4).

7. Substituting $2\angle ODC$ for $\angle OBC$ in step 5 and simplifying, $\angle AOB = 3\angle ODC$. Hence $\angle ODC$ is one-third the original angle, as required.

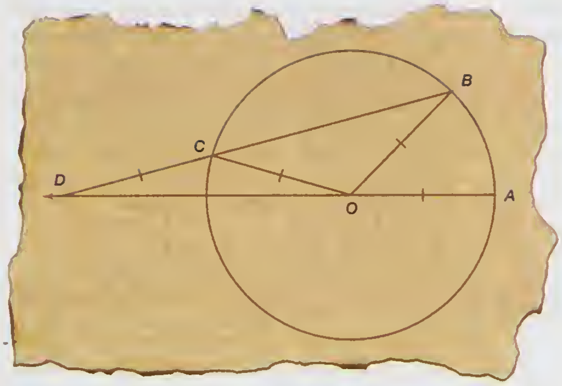

Figure 7: Archimedes' method of angle trisection.

Squaring the circle. The pre-Euclidean Greek geometers transformed the practical problem of determining the area of a circle into a tool of discovery. Two approaches can be distinguished: Hippocrates' dodge of substituting one problem for another; and the technique known in modern times as the "method of exhaustion" and attributed by its greatest practitioner, Archimedes, to Plato's student Eudoxus of Cnidus (*c.* 390–*c.* 340 BC).

Quadrature of lunes. While not able to square the circle, Hippocrates did demonstrate the quadratures of lunes; that is, he showed that the crescent moon-shaped area between two intersecting circular arcs could be expressed exactly as a rectilinear area, or quadrature. In the following simple case, shown in Figure 8, two lunes developed around the sides of a right triangle have a combined area equal to that of the triangle.

1. Starting with the right ΔABC, draw a circle whose diameter coincides with AB (side c), the hypotenuse. Because any right triangle drawn with a circle's diameter for its hypotenuse must be inscribed within the circle, C must be on the circle.

2. Draw semicircles with diameters AC (side b) and BC (side a).

3. Label the resulting lunes L_1 and L_2 and the resulting segments S_1 and S_2, as indicated in the figure.

4. Now the sum of the lunes (L_1 and L_2) must equal the sum of the semicircles ($L_1 + S_1$ and $L_2 + S_2$) containing them minus the two segments (S_1 and S_2). Thus, $L_1 + L_2 = (\pi/2)(b/2)^2 - S_1 + (\pi/2)(a/2)^2 - S_2$ (since the area of a circle is π times the square of the radius).

5. The sum of the segments (S_1 and S_2) equals the area of the semicircle based on AB minus the area of the triangle. Thus, $S_1 + S_2 = (\pi/2)(c/2)^2 - \Delta ABC$.

6. Substituting the expression in step 5 into step 4 and factoring out common terms, $L_1 + L_2 = (\pi/8)(a^2 + b^2 - c^2) + \Delta ABC$.

7. Since $\angle ACB = 90°$, $a^2 + b^2 - c^2 = 0$, by the Pythagorean theorem. Thus, $L_1 + L_2 = \Delta ABC$.

Hippocrates managed to square several sorts of lunes, some on arcs greater and less than semicircles, and he intimated, though he may not have believed, that his method could square an entire circle. At the end of the classical age, Boethius (*c.* AD 470–524), whose Latin translations of snippets of Euclid would keep the light of geometry flickering for half a millennium, mentioned that someone had accomplished the squaring of the circle. Whether the unknown genius used lunes or some other method is not known, since for lack of space Boethius did not give the demonstration. He thus transmitted the challenge of the quadrature of the circle together with fragments of geometry apparently useful in performing it. Europeans kept at the hapless task well into the Enlightenment. Finally, in 1775, the Paris Academy of Sciences, fed up with the task of spotting the fallacies in solutions submitted to it, refused to have anything further to do with circle squarers.

Circle
squares

Method of exhaustion. The method of exhaustion as developed by Eudoxus approximates a curve or surface by using polygons with calculable perimeters and areas. As the number of sides of a regular polygon inscribed in a circle increases indefinitely, its perimeter and area "exhaust," or take up, the circumference and area of the circle to within any assignable error of length or area, however small. In Archimedes' usage, the method of exhaustion produced upper and lower bounds for the value of π, the ratio of any circle's circumference to its diameter. This he accomplished by inscribing a polygon within a circle, and circumscribing a polygon around it as well, thereby bounding the circle's circumference between the polygons' calculable perimeters (see Figure 9). He used polygons with 96 sides and thus bound π between 310/71 and 31/7.

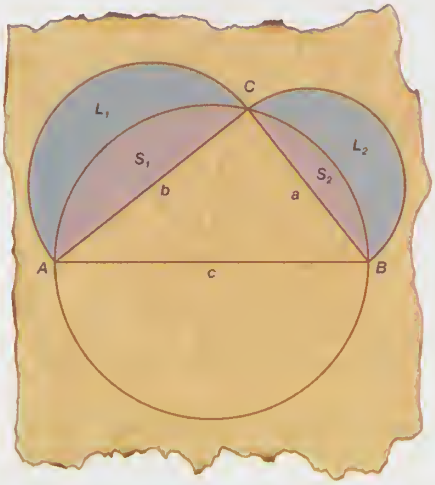

Figure 8: Quadrature of the lune.

IDEALIZATION AND PROOF

The last great Platonist and Euclidean commentator of antiquity, Proclus (*c.* AD 410–485), attributed to the inex-

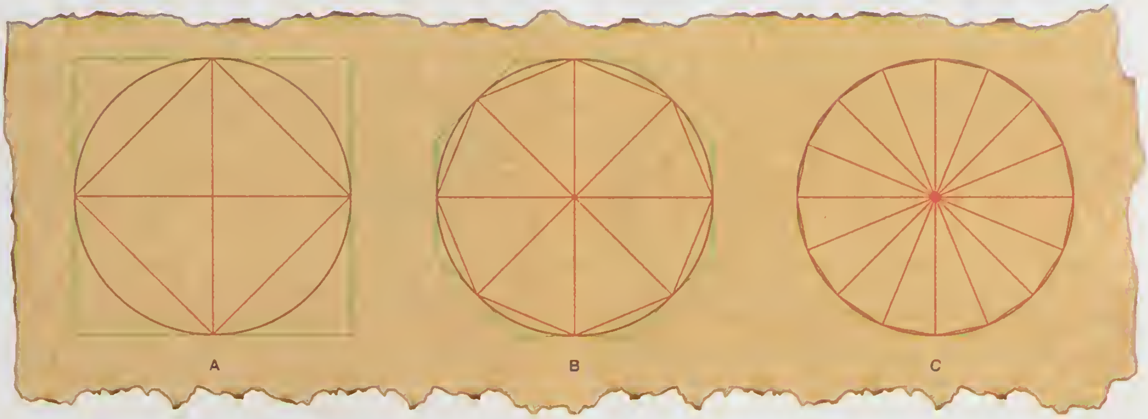

Figure 9: *Method of exhaustion.*
Archimedes' method of approximating the value of π is illustrated for polynomials with 4, 8, and 16 sides, respectively.

haustible Thales the discovery of the far-from-obvious proposition that even apparently obvious propositions need proof. Proclus referred especially to Thales' theorem that in an isosceles triangle the angles opposite the equal sides are equal—Euclid's fifth proposition in the first book of his *Elements*. In the Middle Ages the theorem was named the Bridge of Asses (Latin: Pons Asinorum), possibly for students who, clearly not destined to cross over into more abstract mathematics, had difficulty understanding the proof—or even the need for the proof. An alternative name was *Elefuga*, which Roger Bacon, writing circa AD 1250, derived from Greek words indicating "escape from misery." Medieval schoolboys did not usually go beyond the Bridge of Asses, which thus marked their last obstruction before liberation from the *Elements*.

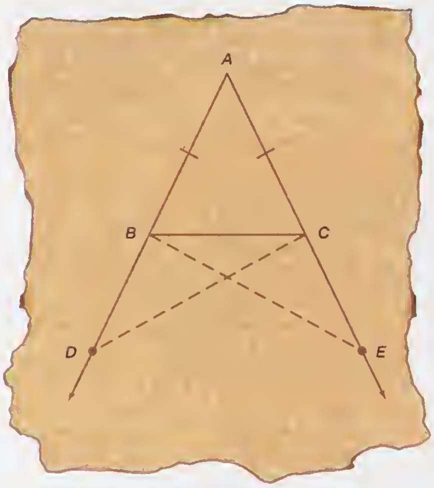

Figure 10: Bridge of Asses.

As shown in Figure 10, the Bridge of Asses may also have received its name from the figure described by Euclid for his proof:

1. We are given that ΔABC is an isosceles triangle—that is, that $AB = AC$.

2. Extend sides AB and AC indefinitely away from A.

3. With a compass centred on A and open to a distance larger than AB, mark off AD on AB extended and AE on AC extended so that $AD = AE$.

4. $\angle DAC = \angle EAB$, because it is the same angle.

5. Therefore, $\Delta DAC \cong \Delta EAB$; that is, all the corresponding sides and angles of the two triangles are equal. By imagining one triangle to be superimposed on another, Euclid argued that the two are congruent if two sides and the included angle of one triangle are equal to the corresponding two sides and included angle of the other triangle (known as the side-angle-side theorem).

6. Therefore, $\angle ADC = \angle AEB$ and $DC = EB$, by step 5.

7. Now $BD = CE$ because $BD = AD - AB$, $CE = AE - AC$, $AB = AC$, and $AD = AE$, all by construction.

8. $\Delta BDC \cong \Delta CEB$, by the side-angle-side theorem of step 5.

9. Therefore, $\angle DBC = \angle ECB$, by step 8.

10. Hence, $\angle ABC = \angle ACB$ because $\angle ABC = 180° - \angle DBC$ and $\angle ACB = 180° - \angle ECB$.

The ancient Greek geometers soon followed Thales over the Bridge of Asses. In the 5th century BC the philosopher-mathematician Democritus (*c.* 460–*c.* 370 BC) declared that his geometry excelled all the knowledge of the Egyptian rope pullers because he could prove what he claimed. By the time of Plato, geometers customarily proved their propositions. Their compulsion and the multiplication of theorems it produced fit perfectly with the endless questioning of Socrates and the uncompromising logic of Aristotle. Perhaps the origin, and certainly the exercise, of the peculiarly Greek method of mathematical proof should be sought in the same social setting that gave rise to the practice of philosophy—that is, the Greek *polis*. There citizens learned the skills of a governing class, and the wealthier among them enjoyed the leisure to engage their minds as they pleased, however useless the result, while slaves attended to the necessities of life. Greek society could support the transformation of geometry from a practical art to a deductive science. Despite its rigour, however, Greek geometry does not satisfy the demands of the modern systematist. Euclid himself sometimes appeals to inferences drawn from an intuitive grasp of concepts such as point and line or inside and outside, uses superposition, and so on. It took more than 2,000 years to purge the *Elements* of what pure deductivists deemed imperfections.

The first deductive science

THE EUCLIDEAN SYNTHESIS

Euclid, in keeping with the self-conscious logic of Aristotle, began the first of his 13 books of the *Elements* with sets of definitions ("a line is breadthless length"), common notions ("the whole is greater than the part"), and axioms, or postulates ("all right angles are equal"). Of this preliminary matter, the fifth and last postulate, which states a sufficient condition that two straight lines meet if sufficiently extended, has received by far the greatest attention. In effect it defines parallelism. Many later geometers tried to prove the fifth postulate using other parts of the *Elements*. Euclid saw farther, for coherent geometries (known as non-Euclidean geometries) can be produced by replacing the fifth postulate with other postulates that contradict Euclid's choice.

The first six books contain most of what Euclid delivers about plane geometry. Book I presents many propositions doubtless discovered by his predecessors, from Thales' theorem (Euclid's fifth proposition), discussed above, to the Pythagorean theorem, with which the book effectively ends.

Book VI applies the theory of proportion from Book V to similar figures and presents the geometrical solution to quadratic equations. As usual, some of it is older than Euclid. Books VII–X, which concern various sorts of numbers, especially primes, and various sorts of ratios, are seldom studied now, despite the importance of the masterful Book X, with its elaborate classification of incommensurable magnitudes, to the later development of Greek geometry.

Books XI–XIII deal with solids: XI contains theorems about the intersection of planes and of lines and planes and theorems about the volumes of parallelepipeds (solids with parallel parallelograms as opposite faces); XII applies the method of exhaustion introduced by Eudoxus to the volumes of solid figures, including the sphere; XIII, a three-dimensional analogue to Book IV, describes the Platonic solids. Among the jewels in Book XII is a proof of the recipe used by the Egyptians for the volume of a pyramid.

The Pythagorean theorem

Euclid's clever demonstration of the Pythagorean theorem in Book I became famous as the Windmill proof. The Pythagorean theorem states that the sum of the squares on the legs of a right triangle is equal to the square on the hypotenuse (the side opposite the right angle)—in familiar algebraic notation, $a^2 + b^2 = c^2$. The Babylonians and Egyptians had found some integer triples (a, b, c) satisfying the relationship. Pythagoras or one of his followers may

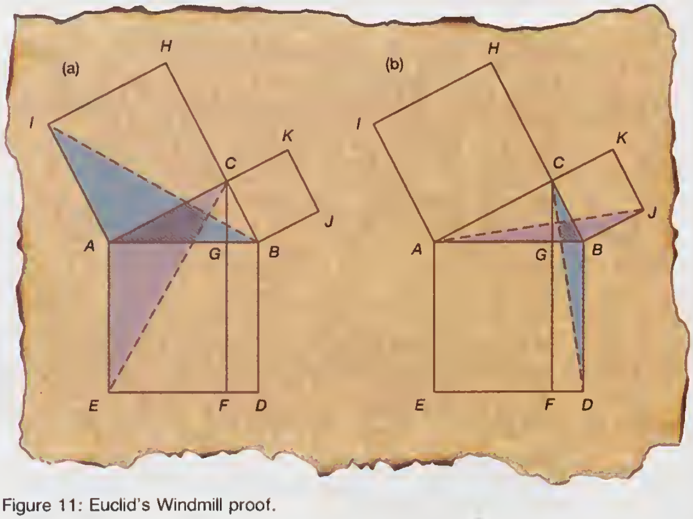

Figure 11: Euclid's Windmill proof.

have been the first to prove the theorem that bears his name. Euclid's proof, which generated the famous Windmill diagram (see Figure 11), is as follows:

1. Draw squares on the sides of the right ΔABC.
2. BCH and ACK are straight lines because $\angle ACB = 90°$
3. $\angle EAB = \angle CAI = 90°$, by construction.
4. $\angle BAI = \angle BAC + \angle CAI = \angle BAC + \angle EAB = \angle EAC$, by 3.
5. $AC = AI$ and $AB = AE$, by construction.
6. Therefore, $\Delta BAI \cong \Delta EAC$, by the side-angle-side theorem, as highlighted in part (a) of the figure.
7. Draw CF parallel to BD.
8. Rectangle $AGFE = 2\Delta ACE$. This remarkable result derives from two preliminary theorems: (a) the areas of all triangles on the same base, whose third vertex lies anywhere on an indefinitely extended line parallel to the base, are equal; and (b) the area of a triangle is half that of any parallelogram (including any rectangle) with the same base and height.
9. Square $AIHC = 2\Delta BAI$, by the same parallelogram theorem as in step 8.
10. Therefore, rectangle $AGFE$ = square $AIHC$, by steps 6, 8, and 9.
11. $\angle DBC = \angle ABJ$, as in steps 3 and 4.
12. $BC = BJ$ and $BD = AB$, by construction as in step 5.
13. $\Delta CBD \cong \Delta JBA$, as in step 6 and highlighted in part (b) of the figure.
14. Rectangle $BDFG = 2\Delta CBD$, as in step 8.
15. Square $CKJB = 2\Delta JBA$, as in step 9.
16. Thus, rectangle $BDFG$ = square $CKJB$, as in step 10.
17. Square $ABDE$ = rectangle $AGFE$ + rectangle $BDFG$, by construction.
18. Therefore, square $ABDE$ = square $AIHC$ + square $CKJB$, by steps 10 and 16.

GNOMONICS AND THE CONE

During its daily course above the horizon the Sun appears to describe a circular arc. Supplying in his mind's eye the missing portion of the daily circle, the Greek astronomer could imagine that his real eye was at the apex of a cone, the surface of which was defined by the Sun's rays at different times of the day and the base of which was defined by the Sun's apparent diurnal course. Our astronomer, using the pointer of a sundial, known as a gnomon, as his eye, would generate a second, shadow cone spreading downward. The intersection of this second cone with a horizontal surface, such as the face of a sundial, would give the trace of the Sun's image (or shadow) during the day as a plane section of a cone. (The possible intersections of a plane with a cone, known as the conic sections, are the circle, ellipse, point, straight line, parabola, and hyperbola; see Figure 12.)

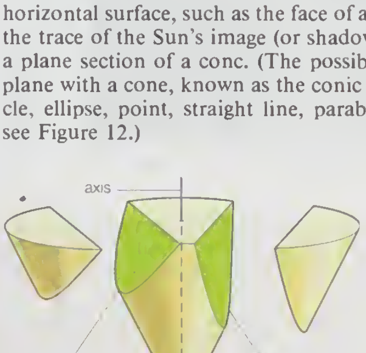

Figure 12: *Conic sections.*
The conic sections result from intersecting a plane with a double cone. There are three distinct families of conic sections: the ellipse (including the circle); the parabola (with one branch); and the hyperbola (with two branches).

However, the doxographers ascribe the discovery of conic sections to a student of Eudoxus, Menaechmus (mid-4th century BC), who used them to solve the problem of duplicating the cube. His restricted approach to conics—he worked with only right circular cones and made his sections at right angles to one of the straight lines composing their surfaces—was standard down to Archimedes' era. Euclid adopted Menaechmus's approach in his lost book on conics, and Archimedes followed suit. Doubtless, however, both knew that all the conics can be obtained from the same right cone by allowing the section at any angle.

The reason that Euclid's treatise on conics perished is that Apollonius of Perga (*c.* 262–*c.* 190 BC) did to it what Euclid had done to the geometry of Plato's time. Apollonius reproduced known results much more generally and discovered many new properties of the figures. He first proved that all conics are sections of any circular cone, right or oblique. Apollonius introduced the terms ellipse, hyperbola, and parabola for curves produced by intersecting a circular cone with a plane at an angle less than, greater than, and equal to, respectively, the opening angle of the cone.

ASTRONOMY AND TRIGONOMETRY

Calculation. In an inspired use of their geometry, the Greeks did what no earlier people seems to have done: they geometrized the heavens by supposing that the Sun, Moon, and planets move around a stationary Earth on a rotating circle or set of circles, and they calculated the speed of rotation of these supposititious circles from observed motions. Thus they assigned to the Sun a circle eccentric to the Earth to account for the unequal lengths of the seasons.

The Ptolemaic system

Ptolemy (fl. AD 127–145 in Alexandria, Egypt) worked out complete sets of circles for all the planets. In order to account for phenomena arising from the Earth's motion around the Sun, the Ptolemaic system included a secondary circle known as an epicycle, whose centre moved along the path of the primary orbital circle, known as the deferent. Ptolemy's *Great Compilation,* or *Almagest* after its Arabic translation, was to astronomy what Euclid's *Elements* was to geometry. Contrary to the *Elements,* however, the *Almagest* deploys geometry for the purpose of calculation. Among the items Ptolemy calculated was a table of chords, which correspond to the trigonometric sine function later introduced by Indian and Islāmic mathematicians. The table of chords assisted the calculation of distances from angular measurements as a modern astronomer might do with the law of sines.

Epistemology. The application of geometry to astronomy reframed the perennial Greek pursuit of the nature of truth. If a mathematical description fit the facts, as did Ptolemy's explanation of the unequal lengths of the seasons by the eccentricity of the Sun's orbit, should the description be taken as true of nature? The answer, with increasing emphasis, was "no." Astronomers remarked that the eccentric orbit representing the Sun's annual motion could be replaced by a pair of circles, a deferent centred on the Earth and an epicycle the centre of which moved along the circumference of the deferent. That gave two observationally equivalent solar theories based on two quite different mechanisms. Geometry was too prolific of alternatives to disclose the true principles of nature. The Greeks, who had raised a sublime science from a pile of practical recipes, discovered that in reversing the process, in reapplying their mathematics to the world, they had no securer claims to truth than the Egyptian rope pullers.

Ancient geometry: cosmological and metaphysical

PYTHAGOREAN NUMBERS AND PLATONIC SOLIDS

The Pythagoreans used geometrical figures to illustrate their slogan that all is number—thus their "triangular numbers" ($n(n-1)/2$), "square numbers" (n^2), and "altar numbers" (n^3), some of which are shown in Figure 13. This principle found a sophisticated application in Plato's creation story, the *Timaeus*, which presents the smallest particles, or "elements," of matter as regular geometrical figures. Since the ancients recognized four or five elements at most, Plato sought a small set of uniquely defined

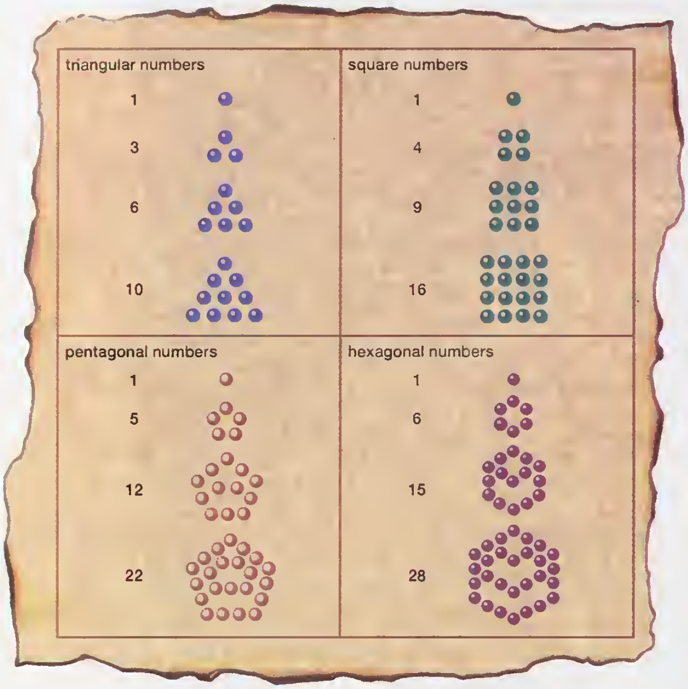

Figure 13: *Polygonal numbers.*
The ancient Greeks generally thought of numbers in concrete terms, particularly as measurements and geometric dimensions. Thus, they often arranged pebbles in various patterns to discern arithmetical, as well as mystical, relationships between the numbers. A few such patterns are indicated here.

geometrical objects to serve as elementary constituents. He found them in the only three-dimensional structures whose faces are equal regular polygons that meet one another at equal solid angles. As shown in Figure 14, they are: the tetrahedron, or pyramid (with 4 triangular faces); the cube (with 6 square faces); the octahedron (with 8 equilateral triangular faces); the dodecahedron (with 12 pentagonal faces); and the icosahedron (with 20 equilateral triangular faces).

The cosmology of the *Timaeus* had a consequence of the first importance for the development of mathematical astronomy. It guided Johannes Kepler (1571–1630) to his discovery of the laws of planetary motion. Kepler deployed the five regular Platonic solids not as indicators of the nature and number of the elements but as a model of the structure of the heavens. In 1596 he published *Prodromus Dissertationum Mathematicarum Continens Mysterium Cosmographicum* ("Cosmographic Mystery"), in which each of the known six planets revolved around the Sun on spheres separated by the five Platonic solids, as shown in Figure 15. Although Tycho Brahe (1546–1601), the world's greatest observational astronomer before the invention of the telescope, rejected the Copernican model of the solar system, he invited Kepler to assist him at his new observatory outside of Prague. In trying to resolve discrepancies between his original theory and Brahe's observations, Kepler made the capital discovery that the planets move in ellipses around the Sun as a focus.

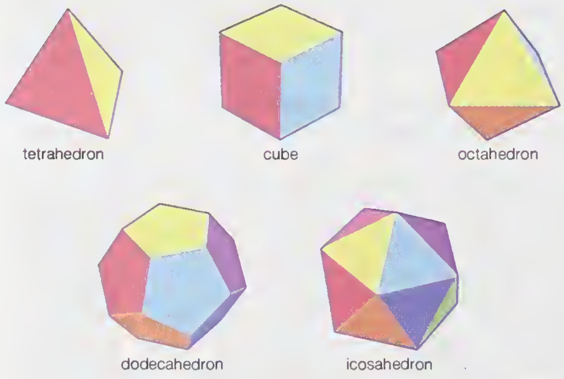

Figure 14: The five Platonic solids.

MEASURING THE EARTH AND THE HEAVENS

Eratosthenes' measurement. Geometry offered Greek cosmologists not only a way to speculate about the structure of the universe but also the means to measure it. South of Alexandria and roughly on the same meridian of longitude is the village of Syene (modern Aswān), where the Sun stands directly overhead at noon on a midsummer day. At the same moment at Alexandria, the Sun's rays make an angle α with the tip of a vertical rod, as shown in Figure 16. Since the Sun's rays fall almost parallel on the Earth, the angle subtended by the arc l (representing the distance between Alexandria and Syene) at the centre of the Earth also equals α; thus the ratio of the Earth's circumference, C, to the distance, l, must equal the ratio of 360° to the angle α—in symbols, $C{:}l = 360°{:}\alpha$. Eratosthenes made the measurements, obtaining a value of about 5,000 stadia for l, which gave a value for the Earth's circumference of about 400,000 stadia. Because the accepted length of the Greek stadium varied locally, we cannot accurately determine Eratosthenes' margin of error. However, if we credit the ancient historian Plutarch's guess at Eratosthenes' unit of length, we obtain a value for the Earth's circumference of about 46,250 kilometres (27,750 miles)—about 15 percent larger than the modern value but remarkably close, considering the difficulty in accurately measuring l and α.

ILLVSTRISS: PRINCIPI AC DÑO DÑO FRIDERICO, DVCI WIR-

Figure 15: Illustration of the cosmos in Johannes Kepler, *Mysterium Cosmographicum* (1596).

Poseidonius's measurement. In addition to the attempts of Eratosthenes to measure the Earth, two other early attempts had a lasting historical impact, since they provided values that Christopher Columbus (1451–1506) exploited in selling his project to reach Asia by traveling west from Europe. One was devised by the Greek philosopher Poseidonius (*c.* 135–*c.* 51 BC), the teacher of the great Roman statesman Marcus Tullius Cicero (106–43 BC). According to Poseidonius, when the star Canopus sets at Rhodes, it appears to be 7.5° above the horizon at Alexandria. (In fact, it is a little over 5°.) The situation appears in Figure 17, where the dark lines represent the horizons at Rhodes (R) and Alexandria (A). Because of the right angles at R and A and the parallel lines of sight to Canopus, $\angle RCA$ equals the angular height of Canopus at Alexandria (the errant 7.5°). To obtain the radius $r = CR = CA$, Poseidonius needed the length of the arc RA. It could not be paced out, as travelers from Aswān to Alexandria had done for Eratosthenes' result, because the journey lay over water. Poseidonius could only guess the distance, and his calculation

Christopher Columbus selling his voyage

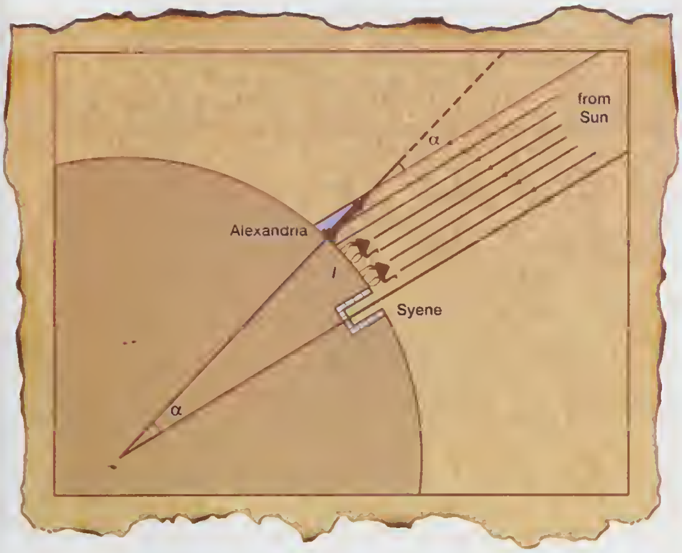

Figure 16: Eratosthenes' measurement of the Earth.

for the size of the Earth was less than three-quarters of what Eratosthenes had found.

Arabic measurement. The second method, devised by the Muslim mathematician Abu al-Bīrūnī (973–1048), required a free-standing mountain of known height AB (see Figure 18). The observer measured $\angle ABH$ between the vertical BA and the line to the horizon BH. Since $\angle BHC$ is a right angle, the Earth's radius $r = CH = AC$ is given by solution of the simple trigonometric equation $\sin(\angle ABH) = r/(r + AB)$. The Arab value for the Earth's circumference agreed with the value calculated by Poseidonius—or so Columbus argued, ignoring or forgetting that the Arabs expressed their results in Arab miles, which were longer than the Roman miles with which Poseidonius worked. By claiming that the "best" measurements agreed that the real Earth was three-fourths the size of Eratosthenes' Earth, Columbus reassured his backers that his small wooden ships could survive the journey—he put it at 30 days—to "Cipangu" (Japan).

Measuring the solar distance. Aristarchus of Samos (*c.* 310–230 BC) has garnered the credit for extending the grip of number as far as the Sun. Using the Moon as a ruler and noting that the apparent sizes of the Sun and the Moon are about equal, he calculated values for his treatise "On the Sizes and Distances of the Sun and Moon." The great difficulty of making the observations resulted in an underestimation of the solar distance about 20-fold—he obtained a solar distance roughly 1,200 times the Earth's radius. Possibly Aristarchus's inquiry into the relative sizes of the Sun, Moon, and Earth led him to propound the first heliocentric ("Sun-centred") model of the universe.

Aristarchus's value for the solar distance, no matter how mistaken, was confirmed by an astonishing coincidence. Ptolemy equated the maximum distance of the Moon in its eccentric orbit with the closest approach of Mercury riding on its epicycle; the farthest distance of Mercury with the closest of Venus; and the farthest of Venus with the closest of the Sun. Thus he could compute the solar distance in terms of the lunar distance and thence the terrestrial radius. His answer agreed with that of Aristarchus. The Ptolemaic conception of the order and machinery of the planets, the most powerful application of Greek geometry to the physical world, thus corroborated the result of direct measurement and established the dimensions of the cosmos for over a thousand years. As the ancient philosophers said, there is no truth in astronomy.

The postclassical period

PASSAGE THROUGH ISLĀM

Two centuries after they broke out of their desert around Mecca, the followers of Muḥammad occupied the lands from Persia to Spain and settled down to master the arts and sciences of the peoples they had conquered. They admired especially the works of the Greek mathematicians and physicians and the philosophy of Aristotle. By the late 9th century they were already able to add to the geometry of Euclid, Archimedes, and Apollonius. In the 10th century they went beyond Ptolemy. Stimulated by the problem of finding the effective orientation for prayer (the *qibla,* or direction from the place of worship to Mecca), Islāmic geometers and astronomers developed the stereographic projection (invented to project the celestial sphere onto a two-dimensional map or instrument), as well as plane and spherical trigonometry. Here they incorporated elements derived from India as well as from Greece. Their achievements in geometry and geometrical astronomy materialized in instruments for drawing conic sections and, above all, in the beautiful brass astrolabes with which they reduced to the turn of a dial the toil of calculating astronomical quantities.

Finding the *qibla*

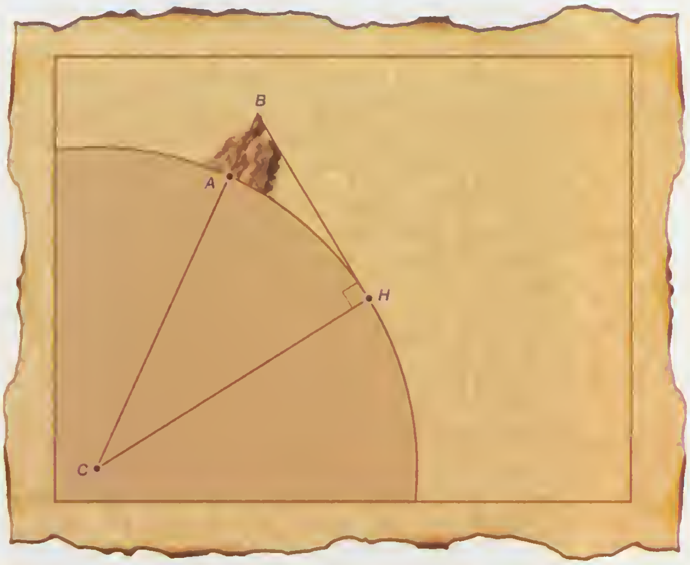

Figure 18: Arabic method of measuring the Earth.

Thābit ibn Qurrah (836–901) had precisely the attributes required to bring the geometry of the Arabs up to the mark set by the Greeks. As a member of a religious sect close but hostile to both Jews and Christians, he knew Syriac and Greek as well as Arabic; as a money changer, he knew how to calculate; as both, he recommended himself to the Banū Mūsā, a set of mathematician brothers descended from a robber who had diversified into astrology. The Banū Mūsā

This map spans more than 600 years of prominent Islāmic mathematicians, from al-Khwārizmī (*c.* AD 600) to al-Kāshī (c. AD 1400).

House of Wisdom

directed a House of Wisdom in Baghdad sponsored by the caliph. There they presided over translations of the Greek classics. Thābit became an ornament of the House of Wisdom. He translated Archimedes and Apollonius, some of whose books now are known only in his versions. In a notable addition to Euclid, he tried valiantly to prove the parallel postulate (see below, *Non-Euclidean geometries*).

Among the pieces of Greek geometrical astronomy that the Arabs made their own was the planispheric astrolabe, which incorporated one of the methods of projecting the celestial sphere onto a two-dimensional surface invented in ancient Greece. One of the desirable mathematical features of this method (the stereographic projection) is that it converts circles into circles or straight lines, a property proved in the first pages of Apollonius's *Conics*. As Ptolemy showed in his *Planisphaerium*, the fact that the stereographic projection maps circles into circles or straight lines makes the astrolabe a very convenient instrument for reckoning time and representing the motions of celestial bodies. The earliest known Arabic astrolabes and manuals for their construction date from the 9th century. The Islāmic world improved the astrolabe as an aid for determining the time for prayers, for finding the direction to Mecca, and for astrological divination.

EUROPE REDISCOVERS THE CLASSICS

Contacts among Christians, Jews, and Arabs in Catalonia brought knowledge of the astrolabe to the West before the year 1000. During the 12th century many manuals for its use and construction were translated into Latin along with geometrical works by the Banū Mūsā, Thābit, and others. Some of the achievements of the Arab geometers were rediscovered in the West after wide and close study of Euclid's *Elements*, which was translated repeatedly from the Arabic and once from the Greek in the 12th and 13th centuries. The *Elements* (Venice, 1482) was one of the first technical books ever printed. Archimedes also came West in the 12th century, in Latin translations from Greek and Arabic sources. Apollonius arrived only by bits and pieces. Ptolemy's *Almagest* appeared in Latin manuscript in 1175. Not until the humanists of the Renaissance turned their classical learning to mathematics, however, did the Greeks come out in standard printed editions in both Latin and Greek.

These texts affected their Latin readers with the strength of revelation. Europeans discovered the notion of proof, the power of generalization, and the superhuman cleverness of the Greeks; they hurried to master techniques that would enable them to improve their calendars and horoscopes, fashion better instruments, and raise Christian mathematicians to the level of the infidels. It took more than two centuries for the Europeans to make their unexpected heritage their own. By the 15th century, however, they were prepared to go beyond their sources. The most novel developments occurred where creativity was strongest, in the art of the Italian Renaissance.

LINEAR PERSPECTIVE

The theory of linear perspective, the brainchild of the Florentine architect-engineers Filippo Brunelleschi (1377–1446) and Leon Battista Alberti (1404–72) and their followers, was to help remake geometry during the 17th century. The scheme of Brunelleschi and Alberti, as given without proofs in Alberti's *De pictura* (1435; *On Painting*), exploits the pyramid of rays that, according to what they had learned from the Westernized versions of the optics of Ibn Al-Haytham (*c.* 965–1040), proceeds from the object to the painter's eye. Imagine, as Alberti directed, that the painter studies a scene through a window, using only one eye and not moving his head; he cannot know whether he looks at an external scene or at a glass painted to present to his eye the same visual pyramid. Supposing this decorated window to be the canvas, Alberti interpreted the painting-to-be as the projection of the scene in life onto a vertical plane cutting the visual pyramid. A distinctive feature of his system was the "point at infinity" at which parallel lines in the painting appear to converge, as shown in Figure 20.

Point of infinity

Alberti's procedure, as developed by Piero della Francesca (*c.* 1410–92) and Albrecht Dürer (1471–1528), was used by many artists who wished to render perspective persuasively. At the same time, cartographers tried various projections of the sphere to accommodate the record of geographical discoveries that began in the mid-15th century with Portuguese exploration of the west coast of Africa. Coincidentally with these explorations, mapmakers recovered Ptolemy's *Geography*, in which he had recorded by latitude (sometimes near enough) and longitude (usually

far off) the principal places known to him and indicated how they could be projected onto a map.

The discoveries that enlarged the known Earth did not fit easily on Ptolemy's projections. Cartographers therefore adopted the stereographic projection that had served astronomers. Several projected the Northern Hemisphere onto the Equator just as in the standard astrolabe, but the most widely used aspect, popularized in the world maps made by Gerardus Mercator's son for later editions of his father's atlas (beginning in 1595), projected points on the Earth onto a cylinder tangent to the Earth at the Equator. After cutting the cylinder along a vertical line and flattening the resulting rectangle, the result was the now-familiar Mercator projection map.

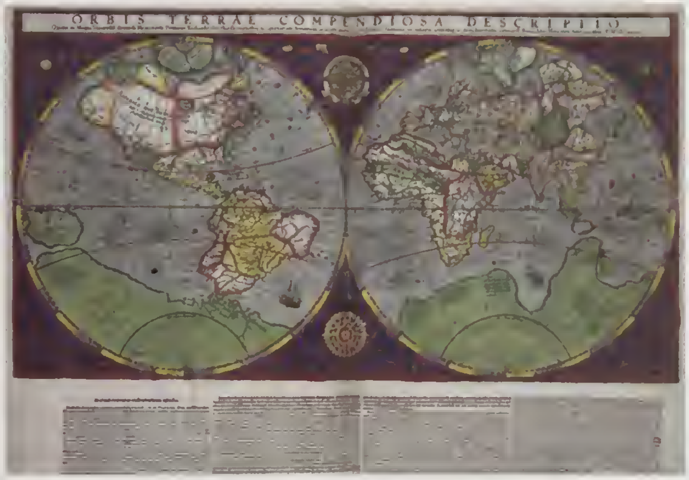

Figure 22: Mercator projection map, *Orbis terrae compendiosa descriptio*, 1587.

The intense cultivation of methods of projection by artists, architects, and cartographers during the Renaissance eventually provoked mathematicians into considering the properties of linear perspective in general. The most profound of these generalists was a sometime architect named Girard Desargues (1591–1661).

Transformation

FRENCH CIRCLES

Desargues was a member of intersecting circles of 17th-century French mathematicians worthy of Plato's Academy of the 4th century BC or Baghdad's House of Wisdom of the 9th century AD. They included René Descartes (1596–1650) and Pierre de Fermat (1601–65), inventors of analytic geometry; Gilles Personne de Roberval (1602–75), a pioneer in the development of the calculus; and Blaise Pascal (1623–62), a contributor to the calculus and an exponent of the principles set forth by Desargues.

Projective geometry. Two main directions can be distinguished in Desargues's work. Like Renaissance artists, Desargues freely admitted the point at infinity into his demonstrations and showed that every set of parallel lines in a scene (apart from those parallel to the sides of the canvas) should project as converging bundles at some point on the "line at infinity" (the horizon). With the addition of points at infinity to the Euclidean plane, Desargues could frame all his propositions about straight lines without excepting parallel ones—which, like the others, now met one another, although not before "infinity." A farther-reaching matter arising from artistic perspective was the relation between projections of the same object from different points of view and different positions of the canvas. Desargues observed that neither size nor shape is generally preserved in projections, but collinearity is, and he provided an example, possibly useful to artists, in images of triangles seen from different points of view. The statement that accompanied this example became known as Desargues's theorem.

Desargues's theorem

Desargues's second direction was to "simplify" Apollonius's work on conic sections. Despite his generality of approach, Apollonius had to prove all his theorems for each type of conic separately. Desargues saw that he could prove them all at once and, moreover, by treating a cylinder as a cone with vertex at infinity, demonstrate useful analogies between cylinders and cones. Following his lead, Pascal made his surprising discovery that the intersections of the three pairs of opposite sides of a hexagon inscribed in a conic lie on a straight line. (See Figure 23.) In 1685, in his *Sectiones Conicæ*, Philippe de la Hire (1640–1718), a Parisian painter turned mathematician, proved several hundred propositions in Apollonius's *Conics* by Desargues's efficient methods.

Cartesian geometry. In 1619, as part of the great illumination that inspired Descartes to assume the modest chore of reforming philosophy as well as mathematics, he devised "compasses" made of sticks sliding in grooved frames to duplicate the cube and trisect angles. Descartes esteemed these implements and the constructions they effected as (to quote from a letter of 1619) "no less certain and geometrical than the ordinary ones with which circles are drawn." By the use of apt instruments, he would bring ancient mathematics to perfection: "scarcely anything will remain to be discovered in geometry."

What Descartes had in mind was the use of compasses with sliding members to generate curves. To classify and

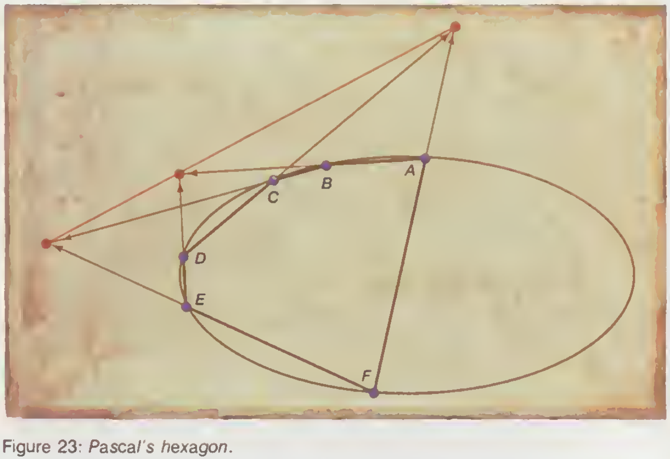

Figure 23: *Pascal's hexagon.*
Blaise Pascal proved that for any hexagon inscribed in any conic section (ellipse, parabola, hyperbola) the three pairs of opposite sides when extended intersect in points that lie on a straight line. In the figure an irregular hexagon is inscribed in an ellipse. Opposite sides *AB* and *DE*, *BC* and *EF*, and *CD* and *AF* intersect at points on a line outside the ellipse.

study such curves, Descartes took his lead from the relations Apollonius had used to classify conic sections, which contain the squares, but no higher powers, of the variables. To describe the more complicated curves produced by his instruments or defined as the loci of points satisfying involved criteria, Descartes had to include cubes and higher powers of the variables. He thus overcame what he called the deceptive character of the terms square, rectangle, and cube as used by the ancients and came to identify geometric curves as depictions of relationships defined algebraically. By reducing relations difficult to state and prove geometrically to algebraic relations between coordinates (usually rectangular) of points on curves, Descartes brought about the union of algebra and geometry that gave birth to the calculus.

GEOMETRICAL CALCULUS

The familiar use of infinity, which underlay much of perspective theory and projective geometry, also leavened the tedious Archimedean method of exhaustion. Not surprisingly, a practical man, the Flemish engineer Simon Stevin (1548–1620), who wrote on perspective and cartography among many other topics of applied mathematics, gave the first effective impulse toward redefining the object of Archimedean analysis. Instead of confining the circle between an inscribed and a circumscribed polygon, the new view regarded the circle as identical to the polygons, and the polygons to one another, when the number of their sides becomes infinitely great.

Cavalieri's indivisibles

Cavalieri's method. This revitalized approach to exhaustion received a preliminary systematization in the *Geometria Indivisibilibus Continuorum Nova Quadam Ratione Promota* (1635; "A Method for the Determination of a New Geometry of Continuous Indivisibles") by the Italian mathematician Bonaventura (Francesco) Cavalieri (1598–1647). Cavalieri, perhaps influenced by Kepler's method of determining volumes in *Nova Steriometria Doliorum* (1615; "New Stereometry of Wine Barrels"), regarded lines as made up of an infinite number of dimensionless points, areas as made up of lines of infinitesimal thickness, and volumes as made up of planes of infinitesimal depth in order to obtain algebraic ways of summing the elements into which he divided his figures. Cavalieri's method may be stated as follows: if two figures (solids) of equal height are cut by parallel lines (planes) such that each pair of lengths (areas) matches, then the two figures (solids) have the same area (volume). (See Figure 24.) Although not up to the rigorous standards of today and criticized by "classicist" contemporaries (who were unaware that Archimedes himself had explored similar techniques), Cavalieri's method of indivisibles became a standard tool for solving volumes until the introduction of integral calculus near the end of the 17th century.

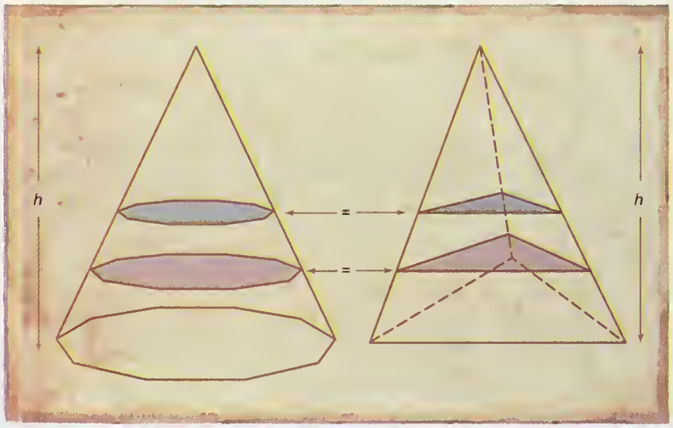

Figure 24: *Cavalieri's principle.*
Take a regular polygon equal in area to an equilateral triangle. Erect a pyramid on the triangle and a cone-like figure of the same height on the polygon. Cross sections of both figures taken at the same height above the bases are equal. Therefore, by Cavalieri's theorem, so are the volumes of the solids.

Fermat's method. A second geometrical inspiration for the calculus derived from efforts to define tangents to curves more complicated than conics. Fermat's method, representative of many, had as its exemplar the problem of finding the rectangle that maximizes the area for a given perimeter. Let the sides sought for the rectangle be denoted by a and b. Increase one side and diminish the other by a small amount ε; the resultant area is then given by $(a + \varepsilon)(b - \varepsilon)$. Fermat observed what Kepler had perceived earlier in investigating the most useful shapes for wine casks, that near its maximum (or minimum) a quantity scarcely changes as the variables on which it depends alter slightly. On this principle, Fermat equated the areas ab and $(a + \varepsilon)(b - \varepsilon)$ to obtain the stationary values: $ab = ab - \varepsilon a + \varepsilon b - \varepsilon^2$. By canceling the common term ab, dividing by ε, and then setting ε at zero, Fermat had his well-known answer, $a = b$. The figure with maximum area is a square.

To obtain the tangent to a curve at a point P (x, y), Fermat began by drawing a secant line to a nearby point P_1 $(x + \varepsilon, y_1)$, as shown in Figure 25. Thus, for small ε, the secant line PP_1 is approximately equal to the true tangent line PT. Finally, Fermat allowed ε to shrink to zero, thus obtaining a mathematical expression for the true tangent line.

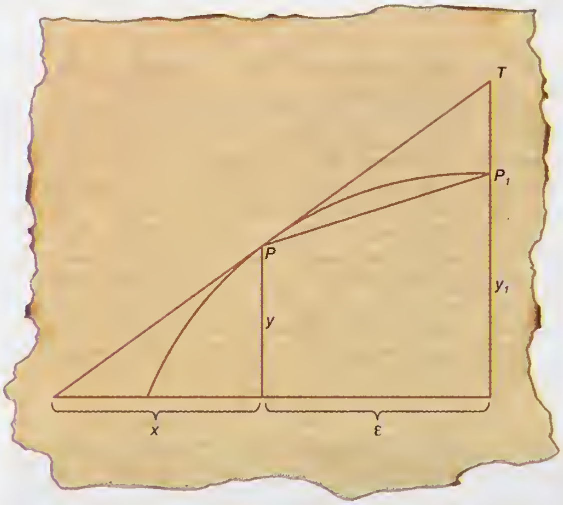

Figure 25: Fermat's tangent method.

THE WORLD SYSTEM

Part of the motivation for the close study of Apollonius during the 17th century was the application of conic sections to astronomy. Kepler not only replaced the many circles of the old planetary system with a few ellipses, he also substituted a complicated rule of motion (his "second law") for the relatively simple Ptolemaic rule that all motions must be compounded of rotations performed at constant velocity. Kepler's second law states that a planet moves in its ellipse so that the line between it and the Sun placed at a focus sweeps out equal areas in equal times. His astronomy thus made pressing and practical the otherwise merely difficult problem of the quadrature of conics and the associated theory of indivisibles.

Newton and planetary dynamics

With the methods of Apollonius and a few infinitesimals, an inspired geometer showed that the laws regarding both area and ellipse can be derived from the suppositions that bodies free from all forces either rest or travel uniformly in straight lines and that each planet constantly falls toward the Sun with an acceleration that depends only on the distance between their centres. The inspired geometer was Isaac Newton (1642 [Old Style]–1727), who made planetary dynamics a matter entirely of geometry by replacing the planetary orbit by a succession of infinitesimal chords, planetary acceleration by a series of centripetal jerks, and, in keeping with Kepler's second law, time by an area.

Besides the problem of planetary motion, questions in optics pushed 17th-century natural philosophers and mathematicians to the study of conic sections. As Archimedes is supposed to have shown (or shone) in his destruction of a Roman fleet by reflected sunlight, a parabolic mirror brings all rays parallel to its axis to a common focus. The story of Archimedes provoked many later geometers, including Newton, to emulation. Eventually they created instruments powerful enough to melt iron.

The fitting of lenses to surveying instruments in the 1660s greatly improved the accuracy of the Greek method of measuring the Earth, and this soon became the preferred technique. In its modern form, the method requires the following elements: two stations on the same meridian of longitude, which play the same parts as Aswān and Alexandria in the method of Eratosthenes; a precise determination of the angular height of a designated star at the same time from the two stations; and two perfectly level and accurately measured baselines a few kilometres long near each station. What was new 2,000 years after Eratosthenes was the accuracy of the stellar positions and the measured distance between the stations, accomplished through the use of the baselines. At each end of one baseline surveyors raise tall posts that can be seen from some nearby vantage point, say a church steeple, and the angle between the posts is measured. From a second viewpoint, say the top of a tree, the angle made between one of the posts and the steeple is taken. Observation from a third station gives an angle between the treetop and the steeple. Proceeding thus from positions on either side of the line to be measured, the surveyors create a series of virtual triangles whose sides they can compute trigonometrically from the observed angles and the measured length of the first baseline. The closeness of agreement between the calculation based on the first baseline and the measurement of the second baseline gives a check on the work.

During the 18th century surveyors and astronomers, practicing their updated Greek geodesy in Lapland and Peru, corroborated the conclusion of Newton, deduced at his desk in Cambridge, England, that the Earth's equatorial axis exceeds its polar axis by a few miles. So precise was the method that subsequent investigation using it revealed that the Earth does not have the shape of an ellipsoid of revolution (an ellipse rotated around one of its axes) but rather has an ineffable shape of its own, now known as the geoid. The method further established the fundamental grids for the mapping of Europe and its colonies. During the French Revolution modernized Greek geodesy was employed to find the equivalent, in the old royal system of measurement, of the new fundamental unit, the standard metre. By definition, the metre was one ten-millionth part of a quarter of the meridian through Paris, making the Earth circumference a nominal 40,000 kilometres.

Relaxation and rigour

The dominance of analysis (algebra and the calculus) during the 18th century produced a reaction in favour of geometry early in the 19th century. Fundamental new branches of the subject resulted that deepened, generalized, and violated principles of ancient geometry. The cultivators of these new fields, such as Jean-Victor Poncelet (1788–1867) and his self-taught disciple Jakob Steiner (1796–1863), vehemently urged the claims of geometry over analysis. The early 19th-century revival of pure geometry produced the discovery that Euclid had devoted his efforts to only one of several comprehensive geometries, the others of which can be created by replacing Euclid's fifth postulate with another about parallels.

PROJECTION AGAIN

Poncelet, who was an officer in the French corps of engineers, learned scraps of Desargues's work from his teacher Gaspard Monge (1746–1818), who developed his own method of projection for drawings of buildings and machines. Poncelet relied on this information to keep himself alive. Taken captive during Napoleon's invasion of Russia in 1812, he passed his time by rehearsing in his head the things he had learned from Monge. The result was projective geometry.

Poncelet employed three basic tools. One he took from Desargues's theorem: the demonstration of difficult theorems about a complicated figure by working out equivalent simpler theorems on an elementary figure interchangeable with the original figure by projection. The second tool, continuity, allows the geometer to claim certain things as true for one figure that are true of another equally general figure provided that the figures can be derived from one another by a certain process of continual change. Poncelet and his defender Michel Chasles (1793–1880) extended the principle of continuity into the domain of the imagination by considering constructs such as the common chord in two circles that do not intersect.

Principle of duality

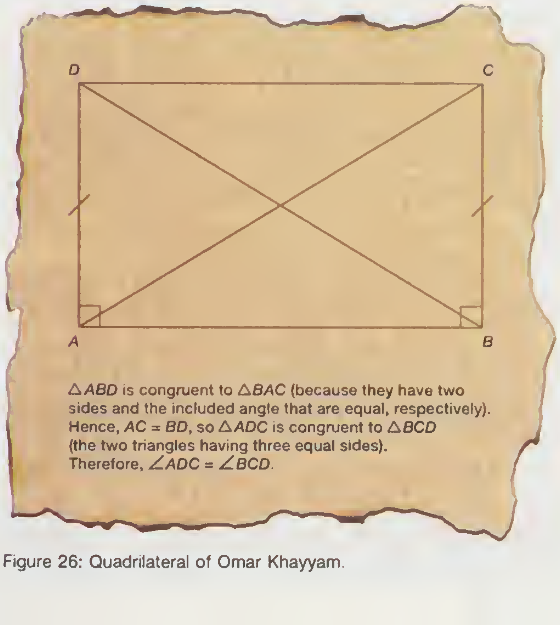
Poncelet's third tool was the "principle of duality," which interchanges various concepts such as points with lines, or lines with planes, so as to generate new theorems from old theorems. Desargues's theorem allows their interchange. So, as Steiner showed, does Pascal's theorem that the three points of intersection of the opposite sides of a hexagon inscribed in a conic lie on a line; thus, the lines joining the opposite vertices of a hexagon circumscribed about a conic meet in a point. (See Figure 23.)

Poncelet's followers realized that they were hampering themselves, and disguising the true fundamentality of projective geometry, by retaining the concept of length and congruence in their formulations, since projections do not usually preserve them. Similarly, parallelism had to go. Efforts were well under way by the middle of the 19th century, by Karl George Christian von Staudt (1798–1867) among others, to purge projective geometry of the last superfluous relics from its Euclidean past.

NON-EUCLIDEAN GEOMETRIES

The Enlightenment was not so preoccupied with analysis as to completely ignore the problem of Euclid's fifth postulate. In 1733 Girolamo Saccheri (1667–1733), a Jesuit professor of mathematics at the University of Pavia, Italy, substantially advanced the age-old discussion by setting forth the alternatives in great clarity and detail before declaring that he had "cleared Euclid of every defect" (*Euclides ab Omni Naevo Vindicatus,* 1733). Euclid's fifth postulate runs: "If a straight line falling on two straight lines makes the interior angles on the same side less than two right angles, the straight lines, if produced indefinitely, will meet on that side on which are the angles less than two right angles." Saccheri took up the quadrilateral of Omar Khayyam (1048–1131), who started with two parallel lines AB and DC, formed the sides by drawing lines AD and BC perpendicular to AB, and then considered three hypotheses for the internal angles at C and D: to be right, obtuse, or acute (see Figure 26). The first possibility gives Euclidean geometry. Saccheri devoted himself to proving that the obtuse and the acute alternatives both end in contradictions, which would thereby eliminate the need for an explicit parallel postulate.

On the way to this spurious demonstration, Saccheri established several theorems of non-Euclidean geometry—for example, that according to whether the right, obtuse, or



$\triangle ABD$ is congruent to $\triangle BAC$ (because they have two sides and the included angle that are equal, respectively). Hence, $AC = BD$, so $\triangle ADC$ is congruent to $\triangle BCD$ (the two triangles having three equal sides). Therefore, $\angle ADC = \angle BCD$.

Figure 26: Quadrilateral of Omar Khayyam.

acute hypothesis is true, the sum of the angles of a triangle respectively equals, exceeds, or falls short of 180°. He then destroyed the obtuse hypothesis by an argument that depended upon allowing lines to increase in length indefinitely. If this is disallowed, the hypothesis of the obtuse angle produces a valid system that is equivalent to standard spherical geometry, the geometry of figures drawn on the surface of a sphere.

As for the acute angle, Saccheri could defeat it only by appealing to an arbitrary hypothesis about the behaviour of lines at infinity. One of his followers, the Swiss-German polymath Johann Heinrich Lambert (1728–77), observed that, based on the acute hypothesis, the area of a triangle is the negative of that of a spherical triangle. Since the latter is proportional to the square of the radius, r, the former appeared to Lambert to be the area of an imaginary sphere with radius ir, where $i = \sqrt{-1}$, which he deemed ridiculous.

Although both Saccheri and Lambert aimed to establish the hypothesis of the right angle, their arguments seemed rather to indicate the unimpeachability of the alternatives. Several mathematicians at the University of Göttingen, notably the great Carl Friedrich Gauss (1777–1855), then took up the problem. Gauss was probably the first to perceive that a consistent geometry could be built up independent of Euclid's fifth postulate, and he derived many relevant propositions, which, however, he promulgated only in his teaching and correspondence. The earliest published non-Euclidean geometric systems were the independent work of two young men from the East who had nothing to lose by their boldness. Both can be considered Gauss's disciples once removed: the Russian Nikolay Ivanovich Lobachevsky (1792–1856), who learned his mathematics from a close friend of Gauss's at the University of Kazan, where Lobachevsky later became a professor; and János Bolyai (1802–60), an officer in the Austro-Hungarian army whose father also was a friend of Gauss's. Both Lobachevsky and Bolyai had worked out their novel geometries by 1826.

Lobachevsky and Bolyai reasoned about the hypothesis of the acute angle in the manner of Saccheri and Lambert and recovered their results about the areas of triangles. They advanced beyond Saccheri and Lambert by deriving an imaginary trigonometry to go with their imaginary geometry. Just as Desargues's projective geometry was neglected for many years, so the work of Bolyai and Lobachevsky made little impression on mathematicians for a generation and more. It was largely the posthumous publication in 1855 of Gauss's ideas about non-Euclidean geometry that gave the new approaches the cachet to attract the attention of later mathematicians.

A GRAND SYNTHESIS

Another of the profound impulses Gauss gave geometry concerned the general description of surfaces. Typically—with the notable exception of the geometry of the sphere—mathematicians had treated surfaces as structures in three-dimensional Euclidean space. However, as these surfaces occupy only two dimensions, only two variables are needed to describe them. This prompted the thought that two-dimensional surfaces could be considered as "spaces" with their own geometries, not just as Euclidean structures in ordinary space. For example, the shortest distance, or path, between two points on the surface of a sphere is the lesser arc of the great circle joining them, whereas, considered as points in three-dimensional space, the shortest distance between them is an ordinary straight line.

The shortest path between two points on a surface lying wholly within that surface is called a geodesic, which reflects the origin of the concept in geodesy, in which Gauss took an active interest. His initiative in the study of surfaces as spaces and geodesics as their "lines" was pursued by his student and, briefly, his successor at Göttingen, Bernhard Riemann (1826–66). Riemann began with an abstract space of n dimensions. That was in the 1850s, when mathematicians and mathematical physicists were beginning to use n-dimensional Euclidean space to describe the motions of systems of particles in the then-new kinetic theory of gases. Riemann worked in a quasi-Euclidean space—"quasi" because he used the calculus to

Abstract n-dimensional Euclidean space

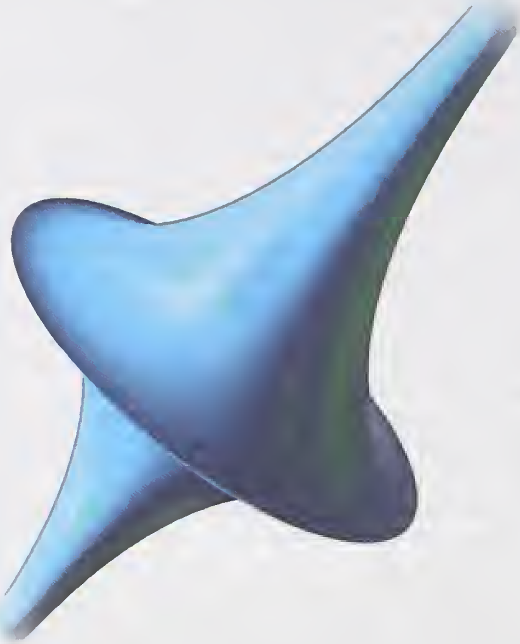


Figure 27: The pseudosphere.

generalize the Pythagorean theorem to supply sufficient flexibility to provide for geodesics on any surface.

When this very general differential geometry came down to two-dimensional surfaces of constant curvature, it revealed excellent models for non-Euclidean geometries. Riemann himself pointed out that, merely by calling the geodesics of a sphere "straight lines," the maligned hypothesis of the obtuse angle produces the geometry appropriate to the sphere's surface. Similarly, as shown by Eugenio Beltrami (1835–1900), who ended his teaching career in Saccheri's old post at Pavia, the geometry defined in the plane by the hypothesis of the acute angle fits perfectly a surface of revolution of constant negative curvature now called a pseudosphere (see Figure 27)—again, provided that its geodesics are accepted as the straight lines of the geometry.

Since the hypothesis of the obtuse angle correctly characterizes Euclidean geometry applied to the surface of a sphere, the non-Euclidean geometry based on it must be exactly as consistent as Euclidean geometry. The case of the acute angle treated by Lobachevsky and Bolyai required a sharper tool. Beltrami found it in a projection into a disc in the Euclidean plane of the points of a non-Euclidean space, in which each geodesic from the non-Euclidean space corresponds to a chord of the disc (see Figure 49 in *Hyperbolic Geometry,* below). Geometry built on the hypothesis of the acute angle has the same consistency as Euclidean geometry.

The key role of Euclidean geometry in proofs of the consistency of non-Euclidean geometries exposed the *Elements* to ever-deeper scrutiny. The old blemishes—particularly appeals to intuition and diagrams for the meaning of concepts like "inside" and "between" and the use of questionable procedures like superposition to prove congruency—became intolerable to mathematicians who laboured to clarify the foundations of arithmetic and the calculus as well as the interrelations of the new geometries. The German mathematician Moritz Pasch (1843–1930), in his *Vorlesungen über neuere Geometrie* (1882; "Lectures on the New Geometry"), identified what was wanting: undefined concepts, axioms about those concepts, and more rigorous logic based on those axioms. The choice of undefined concepts and axioms is free, apart from the constraint of consistency. Mathematicians following Pasch's path introduced various elements and axioms and developed their geometries with greater or lesser elegance and trouble. The most successful of these systematizers was the Göttingen professor David Hilbert (1862–1943), whose

Foundations of Geometry (1899) greatly influenced efforts to axiomatize all of mathematics.

THE REAL WORLD

Euclid's *Elements* had claimed to be a true account of space. Within this interpretation, Euclid's fifth postulate was an empirical finding; non-Euclidean geometries did not apply to the real world. Bolyai apparently could not free himself from the persuasion that Euclidean geometry represented reality. Lobachevsky observed that, if there were a star so distant that its parallax was not observable from the Earth's orbit, his geometry would be indistinguishable from Euclid's at the point where the parallax vanished. By his calculation, based on stellar parallaxes then just detected, his geometry could be physically meaningful only in gargantuan triangles spanning interstellar space.

In fact, non-Euclidean geometries apply to the cosmos more locally than Lobachevsky imagined. In 1916 Albert Einstein (1879–1955) published "The Foundation of the General Theory of Relativity," which replaced Newton's description of gravitation as a force that attracts distant masses to each other through Euclidean space with a principle of least effort, or shortest (temporal) path, for motion along the geodesics of a curved space. Einstein not only explained how gravitating bodies give this surface its properties—that is, mass determines how the differential distances, or curvatures, in Riemann's geometry differ from those in Euclidean space—but also successfully predicted the deflection of light, which has no mass, in the vicinity of a star or other massive body. This was an extravagant piece of geometrizing—the replacement of gravitational force by the curvature of a surface. But it was not all. In relativity theory time is considered to be a dimension along with the three dimensions of space. On the closed four-dimensional world thus formed, the history of the universe stands revealed as describable by motion within a vast congeries of geodesics in a non-Euclidean universe. (J.L.He.)

Einstein's space-time model

BRANCHES OF GEOMETRY

Euclidean geometry

Euclidean geometry is the study of plane and solid figures on the basis of axioms and theorems employed by the Greek mathematician Euclid (*c.* 300 BC). In its rough outline, Euclidean geometry is the plane and solid geometry commonly taught in secondary schools. Indeed, until the second half of the 19th century, when non-Euclidean geometries attracted the attention of mathematicians, geometry meant Euclidean geometry. It is the most typical expression of general mathematical thinking. Rather than the memorization of simple algorithms to solve equations by rote, it demands true insight into the subject, clever ideas for applying theorems in special situations, an ability to generalize from known facts, and an insistence on the importance of proof. In Euclid's great work, the *Elements*, the only tools employed for geometrical constructions were the ruler and compass—a restriction retained in elementary Euclidean geometry to this day.

In its rigorous deductive organization, the *Elements* remained the very model of scientific exposition until the end of the 19th century, when the German mathematician David Hilbert wrote his famous *Foundations of Geometry* (1899). The modern version of Euclidean geometry is the theory of Euclidean (coordinate) spaces of multiple dimensions, where distance is measured by a suitable generalization of the Pythagorean theorem.

FUNDAMENTALS

Euclid realized that a rigorous development of geometry must start with the foundations. Hence, he began the *Elements* with some undefined terms, such as "a point is that which has no part" and "a line is a length without breadth." Proceeding from these terms, he defined further ideas such as angles, circles, triangles, and various other polygons and figures. For example, an angle was defined as the inclination of two straight lines, and a circle was a plane figure consisting of all points that have a fixed distance (radius) from a given centre.

Euclid's five axioms

As a basis for further logical deductions, Euclid proposed five common notions, such as "things equal to the same thing are equal," and five unprovable but intuitive principles known variously as postulates or axioms. Stated in modern terms, the axioms are as follows:

1. Given two points, there is a straight line that joins them.
2. A straight line segment can be prolonged indefinitely.
3. A circle can be constructed when a point for its centre and a distance for its radius are given.
4. All right angles are equal.
5. If a straight line falling on two straight lines makes the interior angles on the same side less than two right angles, the two straight lines, if produced indefinitely, will meet on that side on which the angles are less than the two right angles.

Hilbert refined axioms (1) and (5) as follows:

1. For any two different points, (a) there exists a line containing these two points, and (b) this line is unique.

5. For any line L and point p not on L, (a) there exists a line through p not meeting L, and (b) this line is unique.

The fifth axiom became known as the "parallel postulate," since it provided a basis for the uniqueness of parallel lines. (It also attracted great interest because it seemed less intuitive or self-evident than the others. In the 19th century, Carl Friedrich Gauss, János Bolyai, and Nikolay Lobachevsky all began to experiment with this postulate, eventually arriving at new, non-Euclidean, geometries.) All five axioms provided the basis for numerous provable statements, or theorems, on which Euclid built his geometry. The rest of this section briefly explains the most important theorems of Euclidean plane and solid geometry.

PLANE GEOMETRY

Congruence of triangles. Two triangles are said to be congruent if one can be exactly superimposed on the other by a rigid motion, and the congruence theorems specify the conditions under which this can occur. The first theorem illustrated in Figure 28 is the side-angle-side (SAS) theorem: If two sides and the included angle of one triangle are equal to two sides and the included angle of another triangle, the triangles are congruent. Following this, there are corresponding angle-side-angle (ASA) and side-side-side (SSS) theorems.

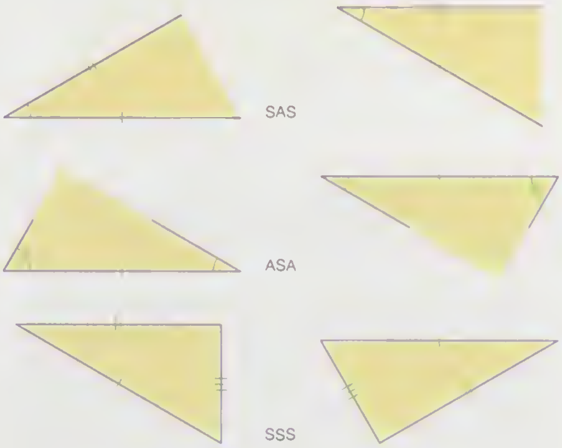

Figure 28: Congruent triangle theorems.

The first very useful theorem derived from the axioms is the basic symmetry property of isosceles triangles, *i.e.*, that two sides of a triangle are equal if and only if the angles opposite them are equal. Euclid's proof of this theorem was once called *Pons Asinorum* ("Bridge of Asses"), supposedly because mediocre students could not proceed across it to the farther reaches of geometry (see Figure 10 in *History of geometry: Idealization and proof,* above). The Bridge of Asses opens the way to various theorems on the congruence of triangles.

The parallel postulate is fundamental for the proof of the theorem that the sum of the angles of a triangle is always 180 degrees. A simple proof of this theorem, attributed to the Pythagoreans, is shown in Figure 29.

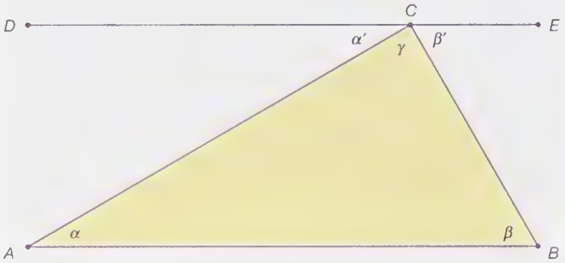

Figure 29: *The sum of the angles in a triangle is 180 degrees.* According to an ancient theorem, a transversal through two parallel lines (*DE* and *AB* in the figure) forms several equal angles, such as the alternating angles α/α' and β/β', labeled in the figure. By definition, the three angles α', γ, and β' on the line *DE* must sum to 180 degrees. Since $\alpha = \alpha'$ and $\beta = \beta'$, the sum of the angles in the triangle (α, β, and γ) is also 180 degrees.

Similarity of triangles. As indicated above, congruent figures have the same shape and size. Similar figures, on the other hand, have the same shape but may differ in size. Shape is intimately related to the notion of proportion, as ancient Egyptian artisans observed long ago. Segments of lengths a, b, c, and d are said to be proportional if $a{:}b = c{:}d$ (read, a is to b as c is to d; in older notation $a{:}b{::}c{:}d$). The fundamental theorem of similarity states that a line segment splits two sides of a triangle into proportional segments if and only if the segment is parallel to the triangle's third side (see Figure 30).

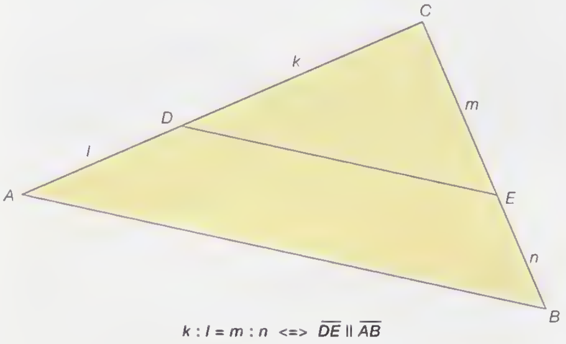

Figure 30: *The fundamental theorem of similarity.* The formula in the figure reads *k* is to *l* as *m* is to *n* if and only if line *DE* is parallel to the line *AB*. This theorem then enables one to show that the small and large triangles are similar.

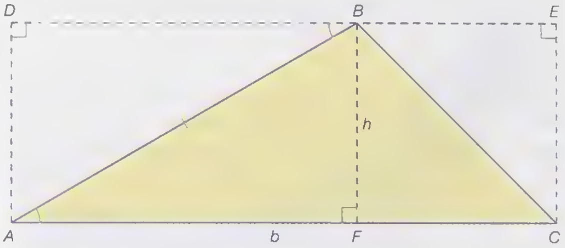
The similarity theorem may be reformulated as the AAA (angle-angle-angle) similarity theorem: two triangles have their corresponding angles equal if and only if their corresponding sides are proportional. Two similar triangles are related by a scaling (or similarity) factor s: if the first triangle has sides a, b, and c, then the second one will have sides sa, sb, and sc. In addition to the ubiquitous use of scaling factors on construction plans and geographic maps, similarity is fundamental to trigonometry.

Areas. Just as a segment can be measured by comparing it with a unit segment, the area of a polygon or other plane figure can be measured by comparing it with a unit square. The common formulas for calculating areas reduce this kind of measurement to the measurement of certain suitable lengths. The simplcst case is a rectangle with sides a and b, which has area ab. By putting a triangle into an appropriate rectangle (see Figure 31), one can show that the area of the triangle is half the product of the length of one of its bases and its corresponding height—$bh/2$. One can then compute the area of a general polygon by dissecting it into triangular regions. If a triangle (or more general figure) has area A, a similar triangle (or figure) with a scaling factor of s will have an area of s^2A.



The right triangle $\triangle AFB$ is $\frac{1}{2}$ of the rectangle □$ADBF$.
Similarly, $\triangle BFC$ is $\frac{1}{2}$ of □$BECF$.
Thus, the area of $\triangle ABC = \frac{1}{2}$ area of □$ADEC = \frac{1}{2}\ AC \cdot BF = \frac{1}{2}$ base · height. ■

Figure 31: Area of a triangle.

Pythagorean theorem. For a triangle ΔABC the Pythagorean theorem has two parts: (1) if $\angle ACB$ is a right angle, then $a^2 + b^2 = c^2$; (2) if $a^2 + b^2 = c^2$, then $\angle ACB$ is a right angle. For an arbitrary triangle, the Pythagorean theorem is generalized to the law of cosines: $a^2 + b^2 = c^2 - 2ab$ cos ($\angle ACB$). When $\angle ACB$ is 90 degrees, this reduces to the Pythagorean theorem because cos (90°) = 0.

Law of cosines

Since Euclid, a host of professional and amateur mathematicians have found more than 300 distinct proofs of the Pythagorean theorem. Despite its antiquity, it remains one of the most important theorems in mathematics. It enables one to calculate distances or, more importantly, to define distances in situations far more general than elementary geometry. For example, it has been generalized to multidimensional vector spaces.

Circles. A chord AB is a segment in the interior of a circle connecting two points (A and B) on the circumference. When a chord passes through the circle's centre, it is a diameter, d. The circumference of a circle is given by πd, or $2\pi r$ where r is the radius of the circle; the area of a circle is πr^2. In each case, π is the same constant (3.14159 . . .). The Greek mathematician Archimedes (*c.* 285–212/211 BC) used the method of exhaustion to obtain upper and lower bounds for π by circumscribing and inscribing regular polygons about a circle (see Figure 9).

A semicircle has its end points on a diameter of a circle. Thales (fl. 6th century BC) is generally credited with proving that any angle inscribed in a semicircle is a right angle; that is, for any point C on the semicircle with diameter AB, $\angle ACB$ will always be 90 degrees. Another important theorem states that for any chord AB in a circle, the angle subtended by any point on the same semiarc of the circle will be invariant (see Figure 32). Slightly modified, this means that in a circle, equal chords determine equal angles, and vice versa.

Summarizing the above material, the five most important theorems of plane Euclidean geometry are: the sum of the angles in a triangle is 180 degrees, the Bridge of Asses, the fundamental theorem of similarity, the Pythagorean theorem, and the invariance of angles subtended by a chord in

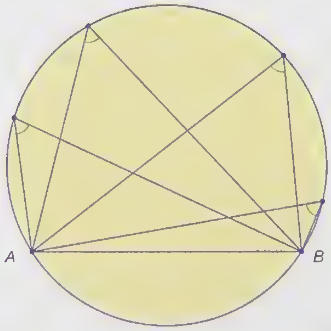


Figure 32: Invariance of subtended angles on a chord.

a circle. Most of the more advanced theorems of plane Euclidean geometry are proved with the help of these theorems.

Regular polygons. A polygon is called regular if it has equal sides and angles. Thus, a regular triangle is an equilateral triangle, and a regular quadrilateral is a square. A general problem since antiquity has been the problem of constructing a regular n-gon, for different n, with only ruler and compass. For example, Euclid constructed a regular pentagon by applying the above-mentioned five important theorems in an ingenious combination.

Techniques, such as bisecting the angles of known constructions, exist for constructing regular n-gons for many values, but none is known for the general case. In 1797, following centuries without any progress, Gauss surprised the mathematical community by discovering a construction for the 17-gon. More generally, Gauss was able to show that for a prime number p, the regular p-gon is constructible if and only if p is a "Fermat prime": $p = F(k) = 2^{2^k} + 1$. Because it is not known in general which $F(k)$ are prime, the construction problem for regular n-gons is still open.

Fermat primes

Three other unsolved construction problems from antiquity were finally settled in the 19th century by applying tools not available to the Greeks. Comparatively simple algebraic methods showed that it is not possible to trisect an angle with ruler and compass, or to construct a cube with a volume double that of a given cube. To show that it is not possible to square a circle, *i.e.*, to construct a square equal in area to a given circle by the same means, however, demanded deeper insights into the nature of the number π.

Conic sections and geometric art. The most advanced part of plane Euclidean geometry is the theory of the conic sections (the ellipse, parabola, and hyperbola; see Figure 12). Much as the *Elements* displaced all other introductions to geometry, the *Conics* of Apollonius of Perga (*c.* 240–190 BC), known by his contemporaries as "The Great Geometer," was for many centuries the definitive treatise on the subject.

Islāmic artists explored ways of using geometric figures for decoration. For example, the decorations of the Alhambra of Granada, Spain, demonstrate an understanding of all 17 of the different "Wallpaper groups" that can be used to tile the plane. In the 20th century, internationally renowned artists such as Josef Albers, Max Bill, and Sol Le Witt were inspired by motifs from Euclidean geometry.

SOLID GEOMETRY

The most important difference between plane and solid Euclidean geometry is that human beings can look at the plane "from above," whereas three-dimensional space cannot be looked at "from outside." Consequently, intuitive insights are more difficult to obtain for solid geometry than for plane geometry.

Some concepts, such as proportions and angles, remain unchanged from plane to solid geometry. For other familiar concepts, there exist analogies—most noticeably, volume for area and three-dimensional shapes for two-dimensional shapes (sphere for circle, tetrahedron for triangle, box for rectangle). However, the theory of tetrahedra is not nearly as rich as it is for triangles. Active research in higher-dimensional Euclidean geometry includes convexity and sphere packings and their applications in cryptology and crystallography.

Volume. As is explained above, in plane geometry the area of any polygon can be calculated by dissecting it into triangles. A similar procedure is not possible for solids. In 1901 the German mathematician Max Dehn showed that there exist a cube and a tetrahedron of equal volume that cannot be dissected and rearranged into each other. This means that calculus must be used to calculate volumes for even many simple solids like pyramids.

Regular solids. Regular polyhedra are the solid analogies to regular polygons in the plane. Regular polygons are defined as having equal (congruent) sides and angles. In analogy, a solid is called regular if its faces are congruent regular polygons and its polyhedral angles (angles at which the faces meet) are congruent. This concept has been generalized to higher-dimensional (coordinate) Euclidean spaces.

Whereas in the plane there exist (in theory) infinitely many regular polygons, in three-dimensional space there exist exactly five regular polyhedra. These are known as the Platonic solids: the tetrahedron, or pyramid, with 4 triangular faces; the cube, with 6 square faces; the octahedron, with 8 equilateral triangular faces; the dodecahedron, with 12 pentagonal faces; and the icosahedron, with 20 equilateral triangular faces. (See Figure 14.)

Platonic solids

In four-dimensional space there exist exactly six regular polytopes, five of them generalizations from three-dimensional space. In any space of more than four dimensions there exist exactly three regular polytopes, the generalizations of the tetrahedron, the cube, and the octahedron.

(B.Ar.)

Projective geometry

Projective geometry is the branch of mathematics that deals with the relationships between geometric figures and the images, or mappings, that result from projecting them onto another surface. Common examples of projections are the shadows cast by opaque objects and motion pictures displayed on a screen.

Projective geometry has its origins in the early Italian Renaissance, particularly in the architectural drawings of Filippo Brunelleschi (1377–1446) and Leon Battista Alberti (1404–1472), who invented the method of perspective drawing. By this method, as shown in Figure 33, the eye of the painter is connected to points on the landscape (the horizontal reality plane, *RP*) by so-called sight lines. The intersection of these sight lines with the vertical picture plane (*PP*) generates the drawing. Thus, the reality plane is projected onto the picture plane, hence the name projective geometry.

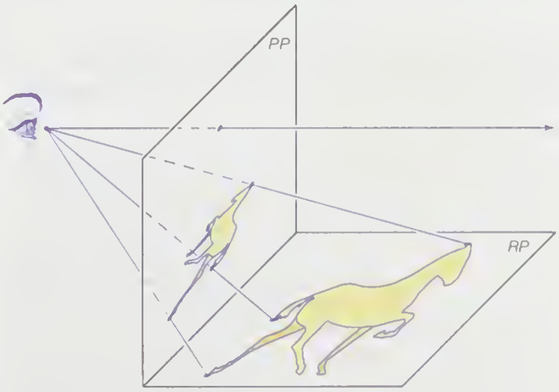

Figure 33: Projective drawing.

Although some isolated properties concerning projections were known in antiquity, particularly in the study of optics, it was not until the 17th century that mathematicians returned to the subject. The French mathematicians Girard Desargues (1591–1661) and Blaise Pascal (1623–62) took the first significant steps by examining what properties of figures were preserved (or invariant) under perspective mappings. The subject's real importance, however, became clear only after 1800 in the works of several other French mathematicians, notably Jean-Victor Poncelet (1788–1867). In general, by ignoring geometric measurements such as distances and angles, projective geometry enables a clearer understanding of some more generic properties of geometric objects. Such insights have since been incorporated in many more advanced areas of mathematics.

PARALLEL LINES AND THE PROJECTION OF INFINITY

A theorem from Euclid's *Elements* (*c.* 300 BC) states that if a line is drawn through a triangle such that it is parallel to one side (see Figure 30), then the line will divide the other two sides proportionately—that is, the ratio of segments on each side will be equal. This is known as the proportional segments theorem, or the fundamental theorem of similar-

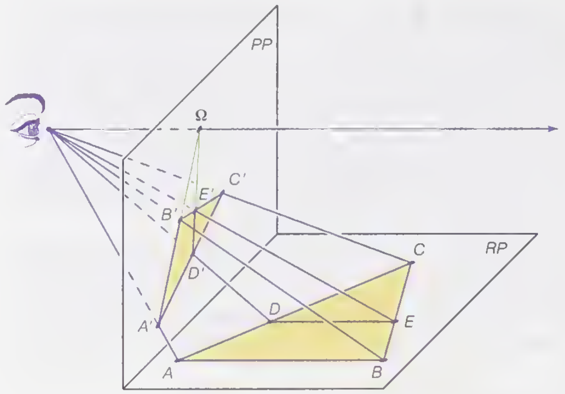

Figure 34: Similarity under projection.

ity, and for triangle ABC, shown in Figure 34, with line segment DE parallel to side AB, the theorem corresponds to the mathematical expression $CD/DA = CE/EB$.

Single point at infinity

Now consider the effect produced by projecting these line segments onto another plane. The first thing to note is that the projected line segments $A'B'$ and $D'E'$ are not parallel—*i.e.*, angles are not preserved. From the point of view of the projection, the parallel lines AB and DE appear to converge at the horizon, or at infinity, whose projection in the picture plane is labeled Ω. (It was Desargues who first introduced a single point at infinity to represent the projected intersection of parallel lines. Furthermore, he collected all the points along the horizon in one line at infinity.) With the introduction of Ω, the projected figure corresponds to a theorem discovered by Menelaus of Alexandria in the 1st century AD:

$$\frac{C'D'}{D'A'} = \frac{C'E'}{E'B'} \cdot \frac{\Omega B'}{\Omega A'}$$

Since the factor $\Omega B'/\Omega A'$ corrects for the projective distortion in lengths, Menelaus's theorem can be seen as a projective variant of the proportional segments theorem.

PROJECTIVE INVARIANTS

With Desargues's provision of infinitely distant points for parallels, the reality plane and the projective plane are essentially interchangeable—that is, ignoring distances and directions (angles), which are not preserved in the projection. Other properties are preserved, however. For instance, two different points have a unique connecting line, and two different lines have a unique point of intersection. Although almost nothing else seems to be invariant under projective mappings, one should note that lines are mapped onto lines. This means that if three points are collinear (share a common line), then the same will be true for their projections. Thus, collinearity is another invariant property. Similarly, if three lines meet in a common point, so will their projections.

The following theorem is of fundamental importance for projective geometry. In its first variant, by Pappus of Alexandria (*c.* AD 320) as shown in Figure 35, it only uses collinearity:

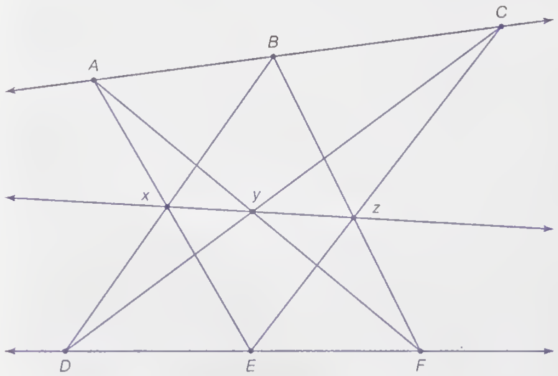

Figure 35: Pappus's theorem.

Let the distinct points A, B, C and D, E, F be on two different lines. Then the three intersection points—x of AE and BD, y of AF and CD, and z of BF and CE—are collinear.

The second variant, by Pascal, as shown in Figure 36, uses certain properties of circles:

If the distinct points A, B, C, D, E, and F are on one circle, then the three intersection points x, y, and z (defined as above) are collinear.

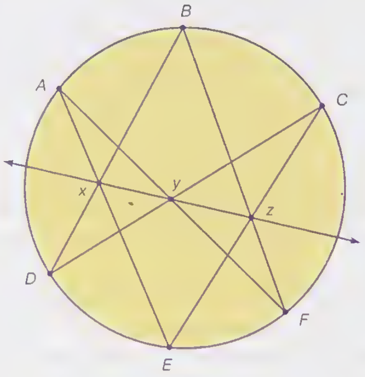

Figure 36: Pascal's projective theorem.

There is one more important invariant under projective mappings, known as the cross ratio (see Figure 37). Given four distinct collinear points A, B, C, and D, the cross ratio is defined as $\mathrm{CRat}(A, B, C, D) = AC/BC \cdot BD/AD$. It may also be written as the quotient of two ratios:

$$\mathrm{CRat}(A, B, C, D) = AC/BC : AD/BD$$

The latter formulation reveals the cross ratio as a ratio of ratios of distances. And while neither distance nor the ratio of distance is preserved under projection, Pappus proved the startling fact that the cross ratio was invariant—that is, $\mathrm{CRat}(A, B, C, D) = \mathrm{CRat}(A', B', C', D')$. However, this result remained a mere curiosity until its real significance became gradually clear in the 19th century as mappings became more and more important for transforming problems from one mathematical domain to another.

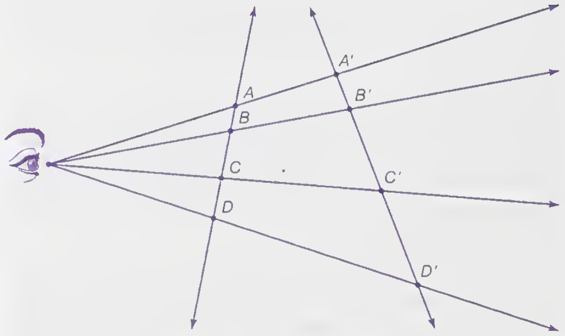

Figure 37: Cross ratio.

PROJECTIVE CONIC SECTIONS

Conic sections can be regarded as plane sections of a right circular cone. By regarding a plane perpendicular to the cone's axis as the reality plane (RP), a "cutting" plane as the picture plane (PP), and the cone's apex as the projective "eye," each conic section can be seen to correspond to a projective image of a circle (see Figure 38). Depending on the orientation of the cutting plane, the image of the circle will be a circle, an ellipse, a parabola, or a hyperbola.

A plane Ω passing through the apex and parallel to PP defines the line at infinity in the projective plane PP. The situation of Ω relative to RP determines the conic section in PP: If Ω intersects RP outside the base circle (the circle formed by the intersection of the cone and RP), the image of the circle will be an ellipse (as shown in Figure 38). If Ω is tangent to the base circle (in effect, tangent to the cone), the image will be a parabola. If Ω intersects the base circle (thus, cutting the circle in two), a hyperbola will result.

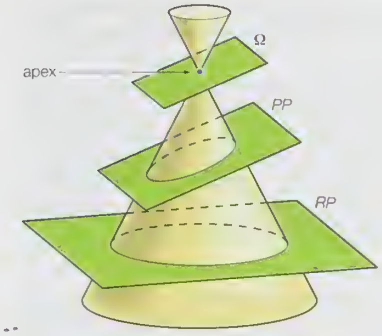

Figure 38: Conic sections as projections.

Pascal's theorem, quoted above, also follows easily for any conic section from its special case for the circle. Start by selecting six points on a conic section and project them back onto the base circle. As given earlier, the three relevant intersection points for six points on the circle will be collinear. Now project all nine points back to the conic section. Since collinear points (the three intersection points from the circle) are mapped onto collinear points, the theorem holds for any conic section. In this way the projective point of view unites the three different types of conics.

Similarly, more complicated curves and surfaces in higher-dimensional spaces can be unified through projections. For example, Isaac Newton (1643–1727) showed that all plane curves defined by polynomials in x and y of degree 3 (the highest power of the variables is 3) can be obtained as projective images of just five types of polynomials.

(B.Ar.)

Differential geometry

Differential geometry is the branch of mathematics that studies the geometry of curves, surfaces, and manifolds (the higher-dimensional analogs of surfaces). The discipline owes its name to its use of ideas and techniques from differential calculus, though the modern subject often uses algebraic and purely geometric techniques instead. Although basic definitions, notations, and analytic descriptions vary widely, the following geometric questions prevail: How does one measure the curvature of a curve within a surface (intrinsic) versus within the encompassing space (extrinsic)? How can the curvature of a surface be measured? What is the shortest path within a surface between two points on the surface? How is the shortest path on a surface related to the concept of a straight line?

While curves had been studied since antiquity, the discovery of calculus in the 17th century opened up the study of more complicated plane curves—such as those produced by the French mathematician René Descartes (1596–1650) with his "compass." In particular, integral calculus led to general solutions of the ancient problems of finding the arc length of plane curves and the area of plane figures. This in turn opened the stage to the investigation of curves and surfaces in space—an investigation that was the start of differential geometry.

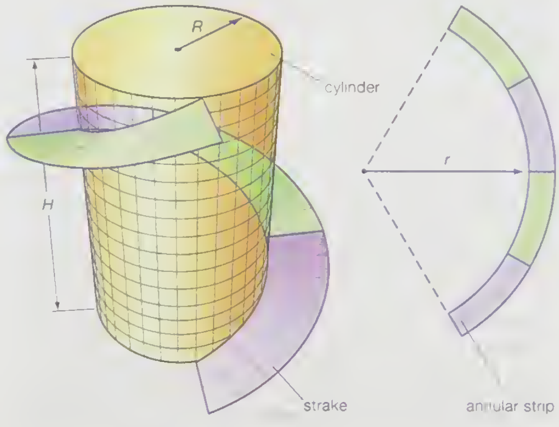

Figure 39: Forming a strake.

Some of the fundamental ideas of differential geometry can be illustrated by the strake, a spiraling strip often designed by engineers to give structural support to large metal cylinders such as smokestacks. A strake can be formed by cutting an annular strip (the region between two concentric circles) from a flat sheet of steel and then bending it into a helix that spirals around the cylinder, as illustrated in Figure 39. What should the radius r of the annulus be to produce the best fit? Differential geometry supplies the solution to this problem by defining a precise measurement for the curvature of a curve; then r can be adjusted until the curvature of the inside edge of the annulus matches the curvature of the helix.

An important question remains: Can the annular strip be bent, without stretching, so that it forms a strake around the cylinder? In particular, this means that distances measured along the surface (intrinsic) are unchanged. Two surfaces are said to be isometric if one can be bent (or transformed) into the other without changing intrinsic distances. (For example, because a sheet of paper can be rolled into a tube without stretching, the sheet and tube are "locally" isometric—only locally because new, and possibly shorter, routes are created by connecting the two edges of the paper.) Thus, the second question becomes: Are the annular strip and the strake isometric? To answer this and similar questions, differential geometry developed the notion of the curvature of a surface.

Isometric surfaces

CURVATURE OF CURVES

Although mathematicians from antiquity had described some curves as curving more than others and straight lines as not curving at all, it was the German mathematician Gottfried Leibniz who, in 1686, first defined the curvature of a curve at each point in terms of the circle that best approximates the curve at that point. As shown in Figure 40, Leibniz named his approximating circle the osculating circle, from the Latin *osculare* ("to kiss"). He then defined the curvature of the curve (and the circle) as $1/r$, where r is the radius of the osculating circle. As a curve becomes straighter, a circle with a larger radius must be used to approximate it, and so the resulting curvature decreases. In the limit, a straight line is said to be equivalent to a circle of infinite radius and its curvature defined as zero everywhere. The only curves in ordinary Euclidean space with constant curvature are straight lines, circles, and helices. In practice, curvature is found with a formula that gives the rate of change, or derivative, of the tangent to the curve as one moves along the curve. This formula was discovered by Isaac Newton and Leibniz for plane curves in the 17th century and by the Swiss mathematician Leonhard Euler for curves in space in the 18th century. (Note that the derivative of the tangent to the curve is not the same as the second derivative studied in calculus, which is the rate of change of the tangent to the curve as one moves along the x-axis.)

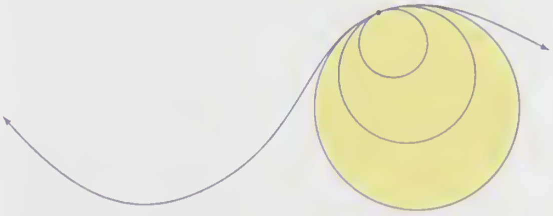

Figure 40: *Osculating circles.*
Note that while all of the circles in the figure are tangent to the curve at the same point, only the largest circle is a true osculating circle.

With these definitions in place, it is now possible to compute the ideal inner radius r of the annular strip that goes into making the strake shown in Figure 39. The annular strip's inner curvature $1/r$ must equal the curvature of the helix on the cylinder. If R is the radius of the cylinder and H is the height of one turn of the helix, then the curvature of the helix is $4\pi^2R/[H^2 + (2\pi R)^2]$. For example, if $R = 1$ metre and $H = 10$ metres, then $r = 3.533$ metres.

CURVATURE OF SURFACES

To measure the curvature of a surface at a point, Euler, in 1760, looked at cross sections of the surface made by planes that contain the line perpendicular (or "normal") to the surface at the point (see Figure 41). Euler called the curvatures of these cross sections the normal curvatures of the surface at the point. For example, on a right cylinder of radius r, the vertical cross sections are straight lines and thus have zero curvature; the horizontal cross sections are circles, which have curvature $1/r$. The normal curvatures at a point on a surface are generally different in different directions. The maximum and minimum normal curvatures at a point on a surface are called the principal (normal) curvatures, and the directions in which these normal curvatures occur are called the principal directions. Euler proved that for most surfaces where the normal curvatures are not constant (for example, the cylinder), these principal directions are perpendicular to each other. (Note that on a sphere all the normal curvatures are the same and thus all are principal curvatures.) These principal normal curvatures are a measure of how "curvy" the surface is.

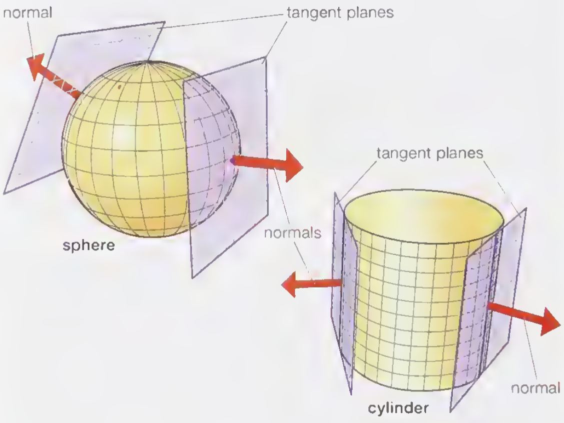

Figure 41: Normals to a surface.

Gaussian curvature

The theory of surfaces and principal normal curvatures was extensively developed by French geometers led by Gaspard Monge (1746–1818). It was in an 1827 paper, however, that the German mathematician Carl Freidrich Gauss made the big breakthrough that allowed differential geometry to answer the question raised above of whether the annular strip is isometric to the strake. The Gaussian curvature of a surface at a point is defined as the product of the two principal normal curvatures; it is said to be positive if the principal normal curvatures curve in the same direction and negative if they curve in opposite directions. Normal curvatures for a plane surface are all zero, and thus the Gaussian curvature of a plane is zero. For a cylinder of radius r, the minimum normal curvature is zero (along the vertical straight lines), and the maximum is $1/r$ (along the horizontal circles). Thus, the Gaussian curvature of a cylinder is also zero.

If the cylinder is cut along one of the vertical straight lines, the resulting surface can be flattened (without stretching) onto a rectangle. In differential geometry, it is said that the plane and cylinder are locally isometric. These are special cases of two important theorems: Gauss's "Remarkable Theorem" (1827) states that if two smooth surfaces are isometric, then the two surfaces have the same Gaussian curvature at corresponding points. (Although defined extrinsically, Gaussian curvature is an intrinsic notion.)

Minding's theorem (1839) states that two smooth surfaces ("cornerless") with the same constant Gaussian curvature are locally isometric.

As corollaries to these theorems:

> A surface with constant positive Gaussian curvature c has locally the same intrinsic geometry as a sphere of radius $\sqrt{1/c}$. (This is because a sphere of radius r has Gaussian curvature $1/r^2$.)
>
> A surface with constant zero Gaussian curvature has locally the same intrinsic geometry as a plane. (Such surfaces are called developable.)
>
> A surface with constant negative Gaussian curvature c has locally the same intrinsic geometry as a hyperbolic plane.

The Gaussian curvature of an annular strip (being in the plane) is constantly zero. So to answer whether or not the annular strip is isometric to the strake, one needs only to check whether a strake has constant zero Gaussian curvature. The Gaussian curvature of a strake is actually negative, hence the annular strip must be stretched—although this can be minimized by narrowing the shapes.

SHORTEST PATHS ON A SURFACE

From an outside, or extrinsic, perspective, no curve on a sphere is straight. Nevertheless, the great circles are intrinsically straight—an ant crawling along a great circle does not turn or curve with respect to the surface. In about 1830 the Estonian mathematician Ferdinand Minding defined a curve on a surface to be a geodesic if it is intrinsically straight; that is, if there is no identifiable curvature from within the surface. A major task of differential geometry is to determine the geodesics on a surface. The great circles are the geodesics on a sphere.

A great circle arc that is longer than a half circle is intrinsically straight on the sphere, but it is not the shortest distance between its endpoints. On the other hand, the shortest path in a surface is not always straight, as shown in Figure 42. An important theorem is:

> On a surface which is complete (every geodesic can be extended indefinitely) and smooth, every shortest curve is intrinsically straight and every intrinsically straight curve is the shortest curve between nearby points.

(D.W.H.)

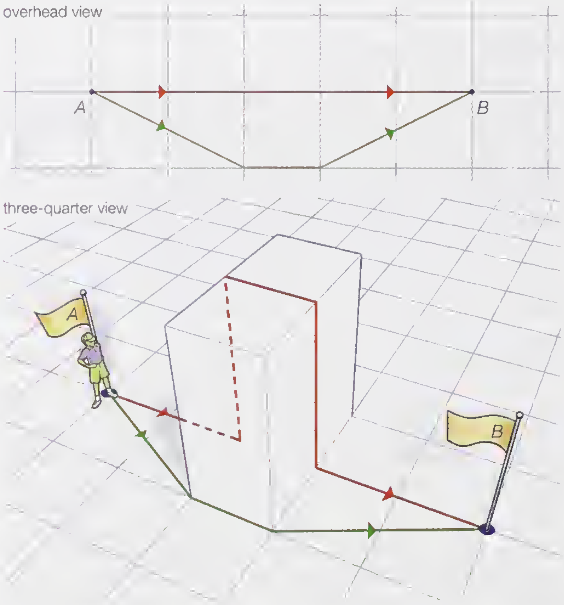

Figure 42: *Shortest paths are not always straight.* Although the red path (which appears straight from overhead) is intrinsically straight, the green path (around the elevation) is a shorter path.

Analytic geometry

Analytic geometry, also called coordinate geometry, is the mathematical subject in which algebraic symbolism and methods are used to represent and solve problems in geometry. The importance of analytic geometry is that it establishes a correspondence between geometric curves and algebraic equations. This correspondence makes it possible to reformulate problems in geometry as equivalent problems in algebra, and vice versa; the methods of either subject can then be used to solve problems in the other. For example, computers create animations for display in games and films by manipulating algebraic equations.

Analytic geometry was once called Cartesian geometry, after René Descartes, who described the basic approach in an appendix to his *Discourse on Method* (1937).

ELEMENTARY ANALYTIC GEOMETRY

Coordinate systems and algebraic symbolism. Apollonius of Perga (*c.* 262–190 BC), known by his contemporaries as "The Great Geometer," foreshadowed the development of analytic geometry by more than 1,800 years with his book *Conics*. He defined a conic as the intersection of a cone and a plane (see Figure 12). Using Euclid's results on similar triangles and on secants of circles, he found a relation satisfied by the distances from any point P of a conic to two perpendicular lines, the major axis of the conic and the tangent at an endpoint of the axis. These distances correspond to coordinates of P, and the relation between these coordinates corresponds to a quadratic equation of the conic. Apollonius used this relation to deduce fundamental properties of conics.

Viète and algebraic symbolism

Further development of coordinate systems (see Figure 43) in mathematics emerged only after algebra had matured under Islāmic and Indian mathematicians. At the end of the 16th century, the French mathematician François Viète introduced the first systematic algebraic notation, using letters to represent known and unknown numerical quantities, and he developed powerful general methods for working with algebraic expressions and solving algebraic equations. With the power of algebraic notation, mathematicians were no longer completely dependent upon geometric figures and geometric intuition to solve problems. The more daring began to leave behind the standard geometric way of thinking in which linear (1st power) variables corresponded to lengths, squares (2nd power) to areas, and cubics (3rd power) to volumes, with higher powers lacking "physical" interpretation. Two Frenchmen, the mathematician-philosopher René Descartes and the lawyer-mathematician Pierre de Fermat, were among the first to take this daring step.

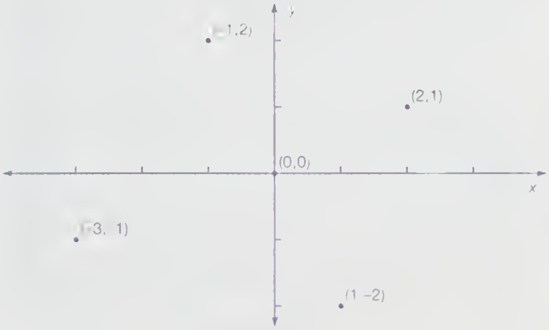

Figure 43: *Cartesian coordinates.*
Several points are labeled in a two-dimensional graph, known as the Cartesian plane. Note that each point has two coordinates, the first number (x value) indicates its distance from the y-axis—positive values to the right and negative values to the left—and the second number (y value) gives its distance from the x-axis—positive values upward and negative values downward.

Descartes and Fermat independently founded analytic geometry in the 1630s by adapting Viète's algebra to the study of geometric loci. They moved decisively beyond Viète by using letters to represent distances that are variable instead of fixed. Descartes used equations to study curves defined geometrically, and he stressed the need to consider general algebraic curves—graphs of polynomial equations in x and y of all degrees. He demonstrated his method on a classical problem: finding all points P such that the product of the distances from P to certain lines equals the product of the distances to other lines.

Fermat emphasized that any relation between x and y coordinates determines a curve (see Figure 44). Using this idea, he recast Apollonius's arguments in algebraic terms and restored lost work. Fermat indicated that any quadratic equation in x and y can be put into the standard form of one of the conic sections.

Fermat did not publish his work, and Descartes deliberately made his hard to read in order to discourage "dabblers." Their ideas gained general acceptance only through the efforts of other mathematicians in the latter half of the 17th century. In particular, the Dutch mathematician Frans van Schooten translated Descartes's writings from French to Latin. He added vital explanatory material, as did the French lawyer Florimond de Beaune and the Dutch mathematician Johan de Witt. In England, the mathematician John Wallis popularized analytic geometry, using equations to define conics and derive their properties. He used negative coordinates freely, although it was Isaac Newton who unequivocally used two (oblique) axes to divide the plane into four quadrants, as shown in Figure 43.

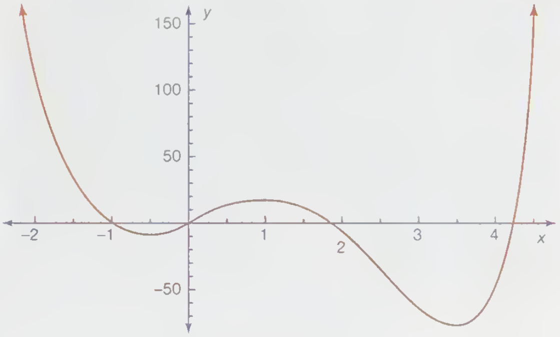

Figure 44: *Polynomial graph.*
The figure shows part of the graph of the polynomial equation $y = 3x^4 - 16x^3 + 6x^2 + 24x + 1$. Note that the same scale need not be used for the x- and y-axis.

Analytic geometry and the development of calculus. Analytic geometry had its greatest impact on mathematics via calculus. Without access to the power of analytic geometry, classical Greek mathematicians such as Archimedes (*c.* 285–212/211 BC) solved special cases of the basic problems of calculus: finding tangents and extreme points (differential calculus) and arc lengths, areas, and volumes (integral calculus). Renaissance mathematicians were led back to these problems by the needs of astronomy, optics, navigation, warfare, and commerce. They naturally sought to use the power of algebra to define and analyze a growing range of curves.

Descartes and differential calculus

Fermat developed an algebraic algorithm for finding the tangent to an algebraic curve at a point by finding a line that has a double intersection with the curve at the point—in essence, inventing differential calculus. Descartes introduced a similar but more complicated algorithm using a circle. Fermat computed areas under the curves $y = ax^k$ for all rational numbers $k \neq -1$ by summing areas of inscribed and circumscribed rectangles. For the rest of the 17th century, the groundwork for calculus was continued by many mathematicians, including the Frenchman Gilles Personne de Roberval, the Italian Bonaventura Cavalieri, and the Britons James Gregory, John Wallis, and Isaac Barrow.

Newton and the German Gottfried Leibniz revolutionized mathematics at the end of the 17th century by independently demonstrating the power of calculus. Both men used coordinates to develop notations that expressed the ideas of calculus in full generality and led naturally to differentiation rules and the fundamental theorem of calculus (connecting differential and integral calculus).

Newton demonstrated the importance of analytic methods in geometry, apart from their role in calculus, when he asserted that any cubic—algebraic curve of degree three—has one of four standard equations

$$\begin{aligned} xy^2 + ey &= ax^3 + bx^2 + cx + d, \\ xy &= ax^3 + bx^2 + cx + d, \\ y^2 &= ax^3 + bx^2 + cx + d, \\ y &= ax^3 + bx^2 + cx + d \end{aligned}$$

for suitable coordinate axes. The Scottish mathematician James Stirling proved this assertion in 1717, possibly with Newton's aid. Newton divided cubics into 72 species, a total later corrected to 78.

Newton also showed how to express an algebraic curve near the origin in terms of fractional power series $y = a_1x^{1/k} + a_2x^{2/k} + \dots$ for a positive integer k. Mathematicians have since used this technique to study algebraic curves of all degrees.

ANALYTIC GEOMETRY OF THREE OR MORE DIMENSIONS

Although both Descartes and Fermat suggested using three coordinates to study curves and surfaces in space, three-dimensional analytic geometry developed slowly until about 1730, when the Swiss mathematicians Leonhard Euler and Jakob Hermann and the French mathematician Alexis Clairaut produced general equations for cylinders, cones, and surfaces of revolution. For example, Euler and Hermann showed that the equation $f(z) = x^2 + y^2$ gives the surface that is produced by revolving the curve $f(z) = x^2$ about the z-axis (see Figure 45, which gives the elliptic paraboloid $z = x^2 + y^2$).

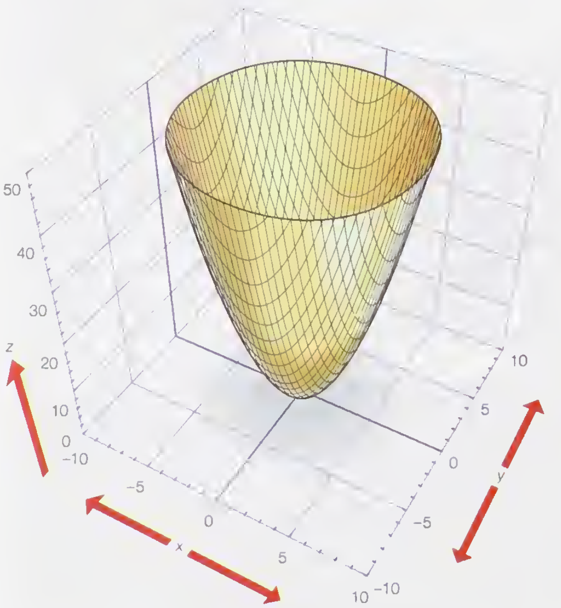

Figure 45: *Elliptic paraboloid.*
The figure shows part of the elliptic paraboloid $z = x^2 + y^2$, which can be generated by rotating the parabola $z = x^2$ (or $z = y^2$) about the z-axis. Note that cross sections of the surface parallel to the xy plane, as shown by the cutoff at the top of the figure, are ellipses.

Newton made the remarkable claim that all plane cubics arise from those in his third standard form by projection between planes. This was proved independently in 1731 by Clairaut and the French mathematician François Nicole. Clairaut obtained all the cubics in Newton's four standard forms as sections of the cubical cone

$$zy^2 = ax^3 + bx^2z + cxz^2 + dz^3$$

consisting of the lines in space that join the origin (0, 0, 0) to the points on the third standard cubic in the plane $z = 1$.

In 1748 Euler used equations for rotations and translations in space to transform the general quadric surface

$$ax^2 + by^2 + cz^2 + dxy + exz + fyz + gx + hy + iz + j = 0$$

so that its principal axes coincide with the coordinate axes. Euler and the French mathematicians Joseph-Louis Lagrange and Gaspard Monge made analytic geometry independent of synthetic (nonanalytic) geometry.

Vector analysis. In Euclidean space of any dimension, vectors—directed line segments—can be specified by coordinates. An n-tuple $(a_1, \ldots, a_n)$ represents the vector in n-dimensional space that projects onto the real numbers $a_1, \ldots, a_n$ on the coordinate axes.

Quaternions

In 1843 the Irish mathematician-astronomer William Rowan Hamilton represented four-dimensional vectors algebraically and invented the quaternions, the first noncommutative algebra to be extensively studied. Multiplying quaternions with one coordinate zero led Hamilton to discover fundamental operations on vectors. Nevertheless, mathematical physicists found the notation used in vector analysis more flexible—in particular, it is readily extendable to infinite-dimensional spaces. The quaternions remained of interest algebraically and were incorporated in the 1960s into certain new particle physics models.

Projections. As readily available computing power grew exponentially in the last decades of the 20th century, computer animation and computer-aided design became ubiquitous. These applications are based on three-dimensional analytic geometry. Coordinates are used to determine the edges or parametric curves that form boundaries of the surfaces of virtual objects. Vector analysis is used to model lighting and determine realistic shadings of surfaces.

As early as 1850, Julius Plücker had united analytic and projective geometry by introducing homogeneous coordinates that represent points in the Euclidean plane and at infinity in a uniform way as triples. Projective transformations, which are invertible linear changes of homogeneous coordinates, are given by matrix multiplication. This lets computer graphics programs efficiently change the shape or the view of pictured objects and project them from three-dimensional virtual space to the two-dimensional viewing screen.

ALGEBRAIC GEOMETRY

Algebraic geometry is the study of the geometric properties of solutions to polynomial equations, including solutions in dimensions beyond three. (Solutions in two and three dimensions are first covered in plane and solid analytic geometry, respectively.)

Classification of curves by their genus

Algebraic geometry emerged from analytic geometry after 1850 when topology, complex analysis, and algebra were used to study algebraic curves. An algebraic curve C is the graph of an equation $f(x, y) = 0$, with points at infinity added, where $f(x, y)$ is a polynomial in two complex variables that cannot be factored. Curves are classified by a nonnegative integer—known as their genus g—that can be calculated from their polynomial.

The equation $f(x, y) = 0$ determines y as a function of x at all but a finite number of points of C. Since x takes values in the complex numbers, which are two dimensional over the real numbers, the curve C is two dimensional over the real numbers near most of its points. C looks like a hollow sphere with g hollow handles attached and finitely many points pinched together—a sphere has genus 0, a torus has genus 1, and so forth. The Riemann-Roch theorem uses integrals along paths on C to characterize g analytically.

A birational transformation matches up the points on two curves via maps given in both directions by rational functions of the coordinates. Birational transformations preserve intrinsic properties of curves, such as their genus, but provide leeway for geometers to simplify and classify curves by eliminating singularities (problematic points).

An algebraic curve generalizes to a variety, which is the solution set of r polynomial equations in n complex variables. In general, the difference $n - r$ is the dimension of the variety—*i.e.*, the number of independent complex parameters near most points. For example, curves have (complex) dimension one and surfaces have (complex) dimension two. The French mathematician Alexandre Grothendieck revolutionized algebraic geometry in the 1950s by generalizing varieties to schemes and extending the Riemann-Roch theorem.

Arithmetic geometry combines algebraic geometry and number theory to study integer solutions of polynomial equations. It lies at the heart of the British mathematician Andrew Wiles's 1995 proof of Fermat's last theorem.

(R.A.B./H.J.D'S.)

Non-Euclidean geometry

Non-Euclidean geometry is literally any geometry that is not the same as Euclidean geometry. Although the term is frequently used to refer only to hyperbolic geometry, common usage also includes those few geometries (hyperbolic and spherical) that differ from but are very close to Euclidean geometry (see Table 1).

The non-Euclidean geometries developed along two different historical threads. The first thread started with the search to understand the movement of stars and planets in the apparently hemispherical sky. For example, Euclid (*c.* 300 BC) wrote about spherical geometry in his astronomical work *Phaenomena*. In addition to looking to the heav-

Table 1: Comparison of Euclidean, Spherical, and Hyperbolic Geometries

Given a line and a point not on the line, there exists ___________ through the given point and parallel to the given line.	
(a) exactly one line	(Euclidean)
(b) no line	(spherical)
(c) infinitely many lines	(hyperbolic)
Euclid's fifth postulate is ______.	
(a) true	(Euclidean)
(b) true	(spherical)
(c) false	(hyperbolic)
The sum of the interior angles of a triangle ___ 180 degrees.	
(a) =	(Euclidean)
(b) >	(spherical)
(c) <	(hyperbolic)

ens, the ancients attempted to understand the shape of the Earth and to use this understanding to solve problems in navigation over long distances (and later for large-scale surveying). These activities are aspects of spherical geometry.

Euclid's parallel postulate

The second thread started with the fifth ("parallel") postulate in Euclid's *Elements*:

> If a straight line falling on two straight lines makes the interior angles on the same side less than two right angles, the two straight lines, if produced indefinitely, will meet on that side on which the angles are less than the two right angles.

For 2,000 years following Euclid, mathematicians attempted either to prove the postulate as a theorem (based on the other postulates) or to modify it in various ways. These attempts culminated when the Russian Nikolay Lobachevsky (1827) and the Hungarian János Bolyai (1831) independently published a description of a geometry that, except for the parallel postulate, satisfied all of Euclid's postulates and common notions. It is this geometry that is called hyperbolic geometry.

SPHERICAL GEOMETRY

From early times, people noticed that the shortest distance between two points on Earth were great circle routes. For example, the Greek astronomer Ptolemy wrote in his *Geography* (*c.* AD 150) "it has been demonstrated by mathematics that the surface of the land and water is in its entirety a sphere . . . and that any plane which passes through the centre makes at its surface, that is, at the surface of the Earth and of the sky, great circles."

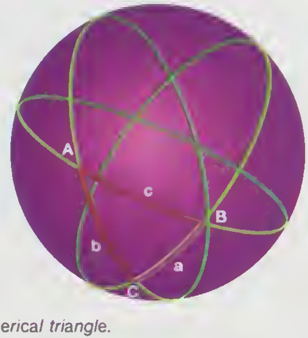

Figure 46: *Spherical triangle.*
The intersection of the three great circles, *AB*, *AC*, and *BC*, form the spherical triangle with sides a, *b*, and c on the sphere's surface.

Great circles are the "straight lines" of spherical geometry. This is a consequence of the properties of a sphere, in which the shortest distances on the surface are great circle routes. Such curves are said to be "intrinsically" straight. (Note, however, that intrinsically straight and shortest are not identical, as shown in Figure 42.) Three intersecting great circle arcs form a spherical triangle (see Figure 46); while a spherical triangle must be distorted to fit on another sphere with a different radius, the difference is only one of scale. In differential geometry (discussed above), spherical geometry is described as the geometry of a surface with constant positive curvature.

There are many ways of projecting a portion of a sphere, such as the surface of the Earth, onto a plane. These are known as maps or charts, and they must necessarily distort distances and either area or angles. Cartographers' need for various qualities in map projections gave an early impetus to the study of spherical geometry.

Elliptic geometry

Elliptic geometry is the term used to indicate an axiomatic formalization of spherical geometry in which each pair of antipodal points is treated as a single point. An intrinsic analytic view of spherical geometry was developed in the 19th century by the German mathematician Bernhard Riemann. It is usually called the Riemann sphere (see Figure 47) and is studied in university courses on complex analysis. Some texts call this study Riemannian geometry (as well as spherical geometry), but this term more correctly applies to a part of differential geometry that gives a way of intrinsically describing any surface.

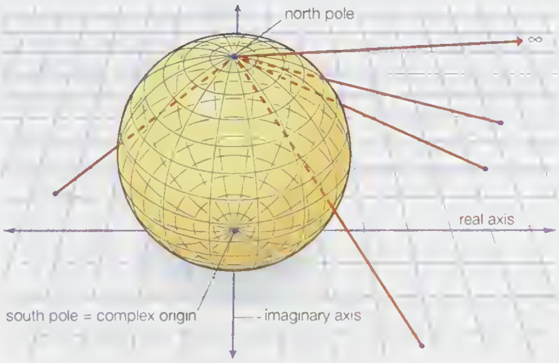

Figure 47: *Riemann sphere.*
With the south pole of the Riemann sphere placed on the origin of the complex plane (the intersection of the real and the imaginary axis), each line segment connecting points in the plane and the sphere's north pole intersects the sphere in a unique point. "Mapping" the points in the complex plane to the corresponding points on the sphere—and infinity to the sphere's north pole—transforms problems involving complex numbers into problems that reside in a portion of ordinary Euclidean space.

HYPERBOLIC GEOMETRY

The first description of hyperbolic geometry was given in the context of Euclid's postulates, and it was soon proved that all hyperbolic geometries differ only in scale (in the same sense that spheres differ only in size). In the mid-19th century it was shown that hyperbolic surfaces must have constant negative curvature. However, this still left open the question of whether any surface with hyperbolic geometry actually exists.

In 1868 the Italian mathematician Eugenio Beltrami described a surface, called the pseudosphere (shown in Figure 27), that has constant negative curvature. However, the pseudosphere is not a complete model for hyperbolic geometry because intrinsically straight lines on the pseudosphere may intersect themselves and cannot be continued past the bounding circle (neither of which is true in hyperbolic geometry). In 1901 the German mathematician David Hilbert proved that it is impossible to define a complete hyperbolic surface using real analytic functions (essentially, functions that can be expressed in terms of ordinary formulas). In those days, a surface always meant one defined by real analytic functions, and so the search was abandoned. However, in 1955 the Dutch mathematician Nicolaas Kuiper proved the existence of a complete hyperbolic surface; and in the 1970s the American mathematician William Thurston described the construction of a hyperbolic surface. Such a surface, as shown in Figure 48, can also be "crocheted."

In the 19th century, mathematicians developed three models of hyperbolic geometry that can now be interpreted as projections (or maps) of the hyperbolic surface. Although these models all suffer from some distortion—similar to the way that flat maps distort the spherical Earth—they are useful individually and in combination as aides to understand hyperbolic geometry. In 1869–71 Beltrami and the German mathematician Felix Klein devel-

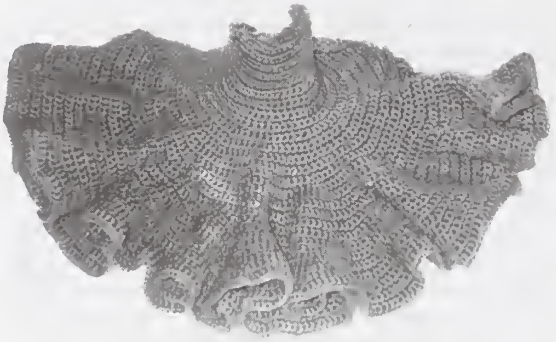

Figure 48: Hyperbolic plane, designed and crocheted by Daina Taimina.

By courtesy of Daina Taimina, Cornell University, Ithaca, New York

oped the first complete model of hyperbolic geometry (and first called the geometry "hyperbolic"). In the Klein-Beltrami model (see Figure 49, left), the hyperbolic surface is mapped to the interior of a circle, with geodesics in the hyperbolic surface corresponding to chords in the circle. Thus, the Klein-Beltrami model preserves "straightness" but at the cost of distorting angles. Around 1880 the French mathematician Henri Poincaré developed two more models. In the Poincaré disk model (Figure 49, right), the hyperbolic surface is mapped to the interior of a circular disk, with hyperbolic geodesics mapping to circular arcs (or diameters) in the disk that meet the bounding circle at right angles. In the Poincaré upper half-plane model (Figure 49, bottom), the hyperbolic surface is mapped onto the half-plane above the x-axis, with hyperbolic geodesics mapped to semicircles (or vertical rays) that meet the x-axis at right angles. Both Poincaré models distort distances while preserving angles as measured by tangent lines. (D.W.H./D.Ta.)

BIBLIOGRAPHY

General history. The best overview in English of the history of geometry and its applications consists of the relevant chapters of MORRIS KLINE, *Mathematical Thought from Ancient to Modern Times* (1972, reissued in 3 vol., 1990), which can be supplemented, for further applications, by *Mathematics in Western Culture* (1953, reissued 1987). Three other useful books of large scope are PETR BECKMANN, *A History of π*, 4th ed. (1977, reissued 1993); JULIAN LOWELL COOLIDGE, *A History of Geometrical Methods* (1940, reissued 1963); and DAVID WELLS, *The Penguin Dictionary of Curious and Interesting Geometry* (1991). A fine recent survey at a college level of the various branches of geometry, with much historical material, is DAVID A. BRANNAN, MATTHEW F. ESPLEN, and JEREMY J. GRAY, *Geometry* (1999).

Ancient Greek geometry. The standard English editions of the Greek geometers are those prepared by THOMAS LITTLE HEATH beginning in the 1890s. They contain important historical and critical notes. Most exist in inexpensive reprints: *Apollonius of Perga: Treatise on Conic Sections* (1896, reissued 1961); *The Works of Archimedes* (1897, reissued 1953); *Aristarchus of Samos, The Ancient Copernicus* (1913, reprinted 1981); and *The Thirteen Books of Euclid's Elements*, 2nd ed., rev. with additions, 3 vol. (1926, reissued 1956). The historical material has been shortened and simplified, and its coverage extended, in *A History of Greek Mathematics*, 2 vol. (1921, reprinted 1993). Further information about technical-historical points—for example, the lunules of Hippocrates—may be found in WILBUR RICHARD KNORR, *The Ancient Tradition of Geometric Problems* (1986, reissued 1993). The epistemology of Greek geometry can be approached via the editor's introduction to and the text of Proclus, *A Commentary on the First Book of Euclid's Elements*, trans. and ed. by GLENN R. MORROW (1970, reprinted 1992).

Ancient non-Greek geometry. Other ancient geometrical traditions are covered in A.K. BAG, *Mathematics in Ancient and Medieval India* (1979); RICHARD J. GILLINGS, *Mathematics in the Time of the Pharaohs* (1972, reprinted 1982); JOSEPH NEEDHAM, *Mathematics and the Sciences of the Heavens and the Earth* (1959), vol. 3 of *Science and Civilization in China*; and B.L. VAN DER WAERDEN, *Science Awakening*, 4th ed., 2 vol. (1975).

Geometry in Islām. Aspects of the extensive development of geometry by Islāmic mathematicians can be studied in J.L. BERGGREN, *Episodes in the Mathematics of Medieval Islam* (1986). Otherwise, the best route to a survey is through the relevant chapters in vol. 2 of ROSHDI ROSHED (RUSHDI RASHID) (ed.), *Histoire des Sciences Arabes*, 3 vol. (1997), and the articles on Arab mathematicians and astronomers in CHARLES COULSTON GILLISPIE (ed.), *Dictionary of Scientific Biography*, 18 vol. (1970–90).

Renaissance geometry and applications. J.L. HEILBRON, *Geometry Civilized: History, Culture, and Technique* (1998, reissued 2000), considers examples of geometry from some modern cultures as well as from the ancient Mediterranean and gives examples of the development of Greek geometry in the Middle Ages and Renaissance. A more advanced book along similar lines, but with more restricted coverage, is ALISTAIR MACINTOSH WILSON, *The Infinite in the Finite* (1995). James Evans, *The History and Practice of Ancient Astronomy* (1998), is by far the best introduction to the theoretical and instrumental methods of the old astronomers. ALBERT VAN HELDEN, *Measuring the Universe* (1985), describes the methods of the Greeks and their development to the time of Halley. JOHN P. SNYDER, *Flattening the Earth: Two Thousand Years of Map Projections* (1993, reissued 1997), gives the neophyte cartographer a start. J.V. FIELD, *The Invention of Infinity: Mathematics and Art in the Renaissance* (1997), contains an elegant account, in both words and pictures, of the theory of projection of Brunelleschi, Alberti, and their followers. (J.L.He.)

Euclidean geometry. BENNO ARTMANN, *Euclid: The Creation of Mathematics* (1999), presents the contents of the *Elements* in modern terms accessible to a general reader and shows how many aspects of modern mathematics are prefigured by Euclid. H.S.M. COXETER, *Introduction to Geometry*, 2nd ed. (1969, reissued 1989), is a very readable scientific work starting from elementary Euclidean geometry and going on to more advanced topics. ROBIN HARTSHORNE, *Geometry: Euclid and Beyond* (2000), is an exhaustive modern presentation for mathematics students; it includes an extensive bibliography. EUCLID, *The Thirteen Books of Euclid's Elements*, trans. by THOMAS L. HEATH, 2nd ed., rev., 3 vol. (1926, reprinted 1956), is the standard English translation, with extensive commentary by Heath. DAVID HILBERT, *Foundations of Geometry*, 2nd ed. (1971, reissued 1992; trans. from German 10th ed., rev. and enlarged, 1968), gives a rigorous and logical account of the foundations of the subject. (B.Ar.)

Projective geometry. All of the following books contain some discussion of projective geometry by one of the greatest expositors of geometry, H.S.M. COXETER: with S.L. GREITZER, *Geometry Revisited* (1967), suitable for high school students; *Introduction to Geometry*, 2nd ed. (1969), suitable for advanced high school students and general undergraduates; and *Projective Geometry*, 2nd ed. (1974, reprinted with corrections, 1994); *The Real Projective Plane*, 3rd ed. (1993); and *Non-Euclidean Geometry*, 6th ed. (1998), all suitable for undergraduate mathematics students. (B.Ar.)

Differential geometry. JAMES CASEY, *Exploring Curvature* (1996), is a truly delightful book full of "experiments" to explore the curvature of curves and surfaces. JEFFREY R. WEEKS, *The Shape of Space: How to Visualize Surfaces and Three-Dimensional Manifolds* (1985), contains an elementary but deep discussion of different two- and three-dimensional spaces that may be models for the shape of our physical universe. ALFRED GRAY, *Modern Differential Geometry of Curves and Surfaces*

with Mathematica, 2nd ed. (1998), allows exploration of the subject through computer-generated figures. VLADIMIR ROVENSKI, *Geometry of Curves and Surfaces with MAPLE* (2000), is another textbook-software package for exploring differential geometry. DAVID W. HENDERSON, *Differential Geometry: A Geometric Introduction* (1998), emphasizes the underlying geometric intuitions, rather than analytic formalisms. JOHN MCCLEARY, *Geometry from a Differentiable Viewpoint* (1994), emphasizes the history of the subject from Euclid's fifth (parallel) postulate and the development of the hyperbolic plane through the genesis of differential geometry. RICHARD S. MILLMAN and GEORGE D. PARKER, *Elements of Differential Geometry* (1977), uses linear algebra extensively to treat the formalisms of extrinsic differential geometry. SAUL STAHL, *The Poincaré Half-Plane: A Gateway to Modern Geometry* (1993), is an analytic introduction to some of the ideas of intrinsic differential geometry starting from calculus. ETHAN D. BLOCH, *A First Course in Geometric Topology and Differential Geometry* (1997), explores the notion of curvature on polyhedra and contains the topological classification and differential geometry of surfaces.
(D.W.H.)

Analytic and algebraic geometry. CARL B. BOYER, *History of Analytic Geometry* (1956, reissued 1988), traces the early development of analytic geometry. JULIAN LOWELL COOLIDGE, *A History of Geometrical Methods* (1940, reissued 1963), provides proofs of important results in the history of analytic geometry. GORDON FULLER and DALTON TARWATER, *Analytic Geometry*, 7th ed. (1992, reissued 1994), is a classic introduction to the subject. ROBERT BIX, *Conics and Cubics: A Concrete Introduction to Algebraic Curves* (1998), provides a transition from analytic to algebraic geometry. PHILLIP A. GRIFFITHS, *Introduction to Algebraic Curves*, trans. from Chinese (1989), develops the topological and analytical properties of complex curves. Vol. 1 of IGOR R. SHAFAREVICH, *Basic Algebraic Geometry*, 2nd rev. and expanded ed., 2 vol. (1994; originally published in Russian, 1988), elegantly demonstrates the power of modern approaches to higher-dimensional algebraic geometry. ROBIN HARTSHORNE, *Algebraic Geometry* (1977, reprinted with corrections, 1997), is the best précis of Grothendieck's work in the foundations of algebraic geometry. SIMON SINGH, *Fermat's Enigma* (also published as *Fermat's Last Theorem*, 1997), gives a historical introduction to Fermat's last theorem and its proof.
(R.A.B./H.J.D'S.)

Non-Euclidean geometry. DAVID W. HENDERSON and DAINA TAIMINA, *Experiencing Geometry in Euclidean, Spherical, and Hyperbolic Spaces*, 2nd ed. (2001), compares non-Euclidean geometries and includes directions for constructing hyperbolic surfaces.
(D.W.H./D.Ta.)
